the transients in these circuits inherently can be but moderately fast. Experience has shown that in this important field a recording speed of 10 inches per microsecond (250 kilometers per second) is sufficient for most practical purposes.

Having recognized this fact, the development of a new cathode-ray oscillograph was undertaken with the object of producing an instrument with sufficient recording speed to meet the practical requirements stated above. It was believed that by omitting the ultrahigh-speed feature and by employing a sealed cathode-ray tube requiring no vacuum pumps, and external camera photography, the apparatus would become simpler and less costly.

## The New Cathode-Ray Tube

The development of a cathode-ray tube to meet the above specifications had its origin in the high-vacuum hot-cathode glass type of cathode-ray tubes described by Zworykin[44] and Metcalf.[54] In recording-speed tests made with the General Electric type *FP*-53 cathode-ray tube, single sweep traces of 100,000-cycle oscillator waves were successfully photographed at an anode voltage of 10,000 volts, the maximum tube rating. The more than linear growth of the recording speed, with increasing

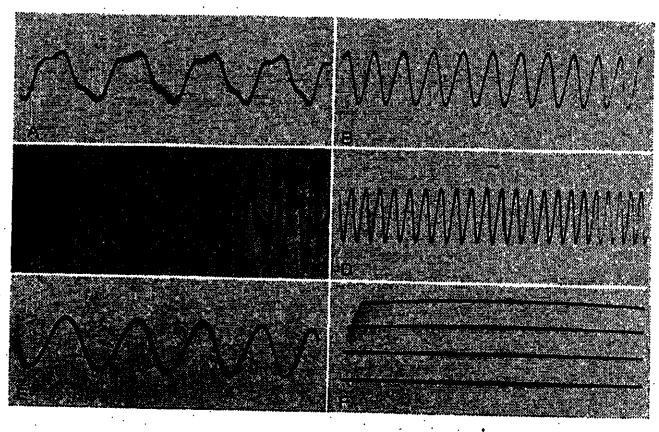

**Figure 4. Oscillator oscillograph records**

*A*—100,000 cycles per second
*B*—500,000 cycles per second
*C*—500,000 cycles per second
*D*—2,000,000 cycles per second
*E*—2,000,000 cycles per second
*F*—D-c calibration record showing 250-volt steps

anode voltage, observed in the tests, suggested further tests at anode voltages higher than 10,000 volts. Therefore, additional tests at higher voltages were made and the boosted to as high as 18,000 volts. that beginning at around 15,000 waves like the 1 x 5- and the 1½ x could satisfactorily be recorded. itely established that a tube of this the field intended for it.

the cathode-ray tube used stood up quite successfully under the added voltage stresses in these early tests, considerable difficulties were first encountered in attempting to reproduce this tube commercially for continuous operation at 15,000 volts. The most annoying and stubborn obstacles were internal discharges, flashovers, and field currents. These tended to render the tubes sometimes completely inoperative. Most often, however, the local field currents distorted the electrostatic focusing field, so that a sharp focus was not obtainable, and other times they caused a flickering, disturbing screen glow. After many disappointments

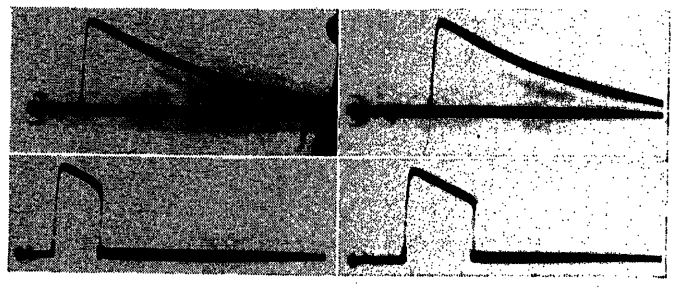

**Figure 5. Impulse oscillograph records**

1½x40-microsecond impulse waves and rod gap flashovers

these difficulties were finally traced to residual gases liberated by the high-speed electrons from the internal tube parts. This discovery led to the adoption of added refinements of the manufacturing processes, mainly during the evacuation stages, and in conjunction with the R. C. A. Manufacturing Company, Radiotron Division, a completely reliable practical 15,000-volt tube known as type RCA-912 was ultimately produced.

## Description of the Oscillograph

The new oscillograph, described in the following, was built around the cathode-ray tube, the successful development of which was discussed above. On account of the relatively low cathode-tube operating voltage used, a very compact arrangement of the complete oscillograph equipment was made possible. Thus there were installed in a single cabinet shown in figure 1 the following component parts: the cathode-ray tube and recording camera; auxiliary circuit units for the cathode excitation and focus of the tube, for the automatic initiation of the cathode-ray beam, for producing the sweep and for the proper time co-ordination of the oscillograph with impulse generator or other external circuits; an oscillator for the time axis calibration; and a d-c supply unit for the oscillograph deflection calibration.

The physical arrangement of the various circuits shown in figure 2 presented many interesting problems. Inasmuch as sharp voltage impulses are used in the oscillograph to perform certain precise timing functions with fairly large currents involved the circuits had to be critically arranged for minimum mutual interference. Also undesirable magnetic fields resulting in a disturbed cathode-

ray beam deflection were carefully eliminated by partial field compensation and shielding. A considerable study was also devoted to the proper arrangement of the deflection-plate-circuit leads and all other leads to prevent pickup through magnetically or electrostatically induced voltages from auxiliary timing circuits operating at as high as 7,500 volts. The cathode-ray tube at 15,000 volts tube voltage was measured to have a deflection sensitivity of approximately 500 volts per inch.

In order to obtain a clear understanding of the purpose and function of each oscillograph circuit, these circuits will now briefly be described.

### The Oscillograph Circuits

In figure 3 is shown a simplified schematic diagram of the oscillograph circuits. For the production of the cathode-ray beam, the tube requires proper d-c potentials for the several elements. These voltages are derived from the cathode-excitation circuit shown at the right of figure 3. For this purpose a simple voltage-doubling circuit was used with bleeder resistance *A*—*E*. The control-grid rheostat was proportioned so that the potential *G* may be varied from complete shut-off of the beam to full intensity. It was also found desirable to provide a separate rectifier circuit for independently adjusting the focusing potential *F*. For the prevention of d-c voltage fluctuations all essential d-c potentials were carefully stabilized with capacitors.

When the oscillograph tube is to be operated at maximum intensity as required for high-speed recording, the time during which the cathode-ray beam is on must be limited. This is necessary because a prolonged high-intensity beam may not only damage the tube screen, but may even soften the glass locally. For the proper time duration of the cathode-ray beam the automatic beam-initiating circuit unit shown in the center of figure 3 was developed. It is seen to consist essentially of a thyratron capacitor resistance discharge circuit *HIK*. For the discharge resistor *K*, thyrite was used which transmits approximately one ampere at 1,000 volts and 0.001 ampere at 100 volts. The circuit operates as follows: By applying a positive voltage impulse to the thyratron grid *L* the capacitor discharge is precipitated. When the discharge current has dropped to a critical value of approximately one milliampere the negative thyratron grid bias shuts off the current and the capacitor charges again slowly through the high charging resistor shown. During the discharge period the voltage drop across the thyratron tube *H* remains approximately constant at around 20 volts. By the use of the thyrite resistor mentioned, instead of an ordinary resistor, it was intended never to let the capacitor voltage drop to less than approximately 100 volts. This special circuit feature was developed to give a sharp cathode-ray beam shut-off as discussed below. After the application of the positive initiating impulse on the thyratron grid *L* the tube voltage quickly drops to a low value and remains essentially at that value until the tube current has reached the critical shut-off point. When the tube shuts off, the voltage instantly rises to about 100 volts and then increases slowly again to the initial value as the capacitor recharges. Referring to the diagram the thyratron anode is connected to the cathode-ray tube cathode through a resistor and the thyratron cathode is connected to *B*. Before the initiation of the thyratron discharge circuit the cathode of the cathode-ray tube is seen to have a positive potential bias with respect to the beam intensity control grid. This is, of course, equivalent to a negative control-grid bias. During the transmission of current through the thyratron, this bias is removed and the cathode-ray beam is on. Owing to the use of the thyrite resistor described above the beam shuts off instantly when the current through the thyratron tube ceases to flow because of the quick rise of the thyratron anode voltage. The resistor shown between the thyratron anode and the oscillograph tube cathode was added to prevent local oscillations. The initiation and timing of the cathode-ray beam could, of course, have been accomplished by swinging the cathode tube control grid rather than the cathode. However, the solution described was found to be more convenient.

The positive initiating impulse for the thyratron grid *L* is obtained from a group of circuits which were designed to provide suitable voltages for the sweep deflection, and the proper time correlation of the oscillograph with the impulse generator or other external circuits. These circuit units are shown schematically in the diagram of figure 3 on the left.

By pressing pushbutton *P* the 3-electrode gap of the primary initiating circuit breaks down near the negative crest of the initiating transformer voltage. The capacitor discharges into the resistor shown and a very steep positive polarity voltage impulse of 7,500 volts appears at *M*. This impulse is transmitted to the thyratron grid *L* through the coupling capacitor shown and the cathode-ray beam comes on and stays on for a predetermined short time. The voltage impulse at *M* is also transmitted through a delay resistance to the midsphere of the 3-electrode gap of the sweep-initiating unit, causing these gaps to break down. The time delay of the gap breakdown was designed to be approximately 20 microseconds. The 2 capacitors of this circuit discharge through the resistors *NO*. A negative polarity voltage of 7,500 volts instantly appears at *N* and a voltage of equal magnitude but of positive polarity appears at *O*. The time constant of this circuit was designed to be 50,000 microseconds so as to give essentially a square voltage wave (d-c voltage) for

Wave-front sphere-gap spark-overs and 2,000,000-cycle oscillator waves with harmonics

**Figure 6. High-speed impulse records**

the excitation of the sweep circuit whose time constant is very much less.

The square voltage wave at *NO* is applied to the sweep capacitor *S* through charging resistors by breaking down a pair of small gaps. This causes the sweep voltage on capacitor *S* gradually to rise, moving the cathode-ray beam sideways along the time axis. When the voltage on *S* has reached approximately 3,000 volts the small protective gap across *S* breaks down. The resistors in series with this gap were so designed in proportion to the charging resistors of *S* that the voltage on *S* remains essentially constant after the protective gap breakdown. The sweep voltage of 3,000 volts is sufficient to deflect the cathode-ray beam off the tube screen where it will remain until the thyratron tube of the beam initiating unit shuts it off.

As may be recognized in the circuit diagram, the sweep initiating unit and the sweep itself are balanced with respect to ground. A carefully balanced design was developed to eliminate pattern distortions on the oscillograph-tube screen. When an unbalanced sweep was used, the deflection amplitude obtained with a given voltage was found to be larger at one end of the time axis than at the other end.

In order that the cathode-ray spot may start from the edge of the tube screen instead of from the center, the sweep capacitor *S* and the sweep deflection plates connected to it must have an initial bias voltage of polarity opposite to that of the sweep voltage. This bias voltage was conveniently tapped off at *D* and *E* of the cathode excitation circuit as shown. This necessitated the use of the small gaps in the sweep circuit to isolate the sweep deflection plate circuit until the initiation of the sweep.

A selector switch was installed to connect to the vertical oscillograph deflection plates either the oscillograph terminals *X*, the d-c calibrating unit, or the time axis calibrating oscillator. The selector switch, the d-c calibrating unit and the oscillator are shown on the right of the cathode-ray tube in the diagram of figure 3.

## The Recording Camera

Considerable developmental work was done to produce a fast lens system giving a one-to-one magnification ratio. Such a lens was produced by the Bausch and Lomb Optical Company and it is used in the photographic camera shown in figures 1 and 2. It gives a full-size reproduction of the cathode-tube screen image. This feature was obtained by the use of 2 lens systems of equal focal lengths connected in series and mounted in one lens barrel. The cathode tube screen was placed at the focal point of one lens and the image appeared at the focal point of the other. Two separate corrective negative lenses were added to compensate for some field curvature and also to partly compensate for the spherical curvature of the cathode tube screen. The lens assembly was designed to have a nominal lens speed of *f*3.

## Oscillograph Records

In designing the oscillograph, consideration was given to a practical photographic equipment which can be operated by anybody with average experience; thus the handling of the films does not require special refinements inasmuch as commercial films and developers may be used. Supersensitive panchromatic film was found to give the best practical results, but for moderately fast work excellent results were also obtained with Kodak Verichrome film.

In. figure 4 are shown reproductions of oscillator oscillograms obtained with the camera described above. Attention is called to the uniform deflection along the entire sweep. This result is due to the use of the balanced sweep circuit described above. Typical records of $1^1/_2$x40 microsecond impulse waves are shown in figure 5.

A set of interesting high-speed records obtained with a sweep of 2 microseconds and a small commercial *f*2 camera are shown in figure 6.

This type of oscillograph may also readily be adapted to rotating film drum recording. In this case only one pair of deflection plates is used and the luminous spot on the tube screen is projected on the moving film by means of a photographic lens. For this application the cathode-ray tube used contains a fluorescent substance having a very short persistence of fluorescence. With film speeds of 500 feet per second oscillatory waves of as high as 100,000 cycles per second were successfully recorded.

By the use of more than one cathode-ray tube multi-

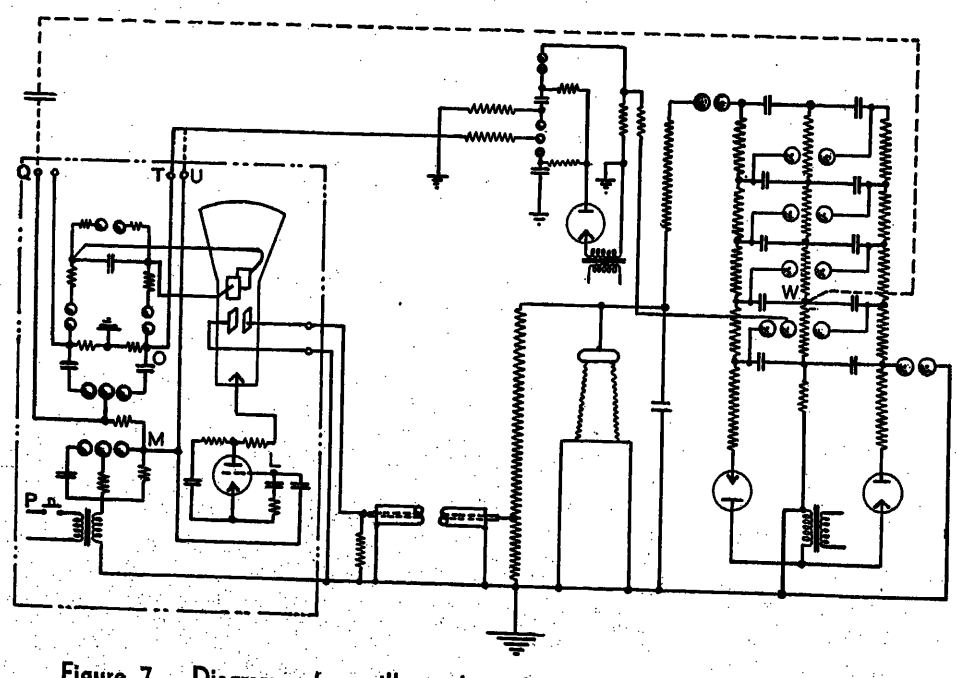

Figure 7. Diagram of oscillograph and impulse-generator co-ordination

circuit recording instruments may be built. Several 3-tube cathode-ray oscillographs are now in use in the General Electric Company.

In one of these instruments the persistence of fluorescence is made use of. The cathode-ray beam is made to sweep across the tube screens recurrently by means of a saw-tooth wave time axis oscillator. Upon occurrence of the fault to be recorded, a relay quickly operates the triggered camera shutter and a snapshot of the tube screens is thus taken. In spite of the time delay introduced by the relay and shutter, the camera successfully photographs the "memory" (persistence of fluorescence) of the fault on the tube screens.

In the development and design of this oscillograph the adoption of 15,000 volts for the cathode tube was quite arbitrary and does, therefore, not represent a final limit for this type of tube. It is believed to be entirely feasible to produce still higher voltage tubes if the range of this type of instrument is to be extended into fields requiring higher recording speeds.

## Application of the Oscillograph to Impulse Testing

There are many ways of co-ordinating a cathode-ray oscillograph with impulse generator equipment and it would be impossible here to describe them all. The engineers concerned with this work have always liked to resort to their own ingenuity for accomplishing desired results and the competition between the various groups has made for remarkable refinements in the art. In order to illustrate the performance of the new oscillograph a method is given of co-ordinating the oscillograph with a Marx-type impulse generator. This method was successfully used in the Schenectady high-voltage laboratory of the General Electric Company.

The simplified circuits are shown schematically in figure 7. As shown, a small 2-stage Marx circuit is used to act as an intermediate initiating circuit between the oscillograph and the impulse generator. The intermediate circuit receives its initiating impulse from the cathode-ray oscillograph and its output in turn is used to trip the impulse generator 3-electrode gap.

In taking an impulse wave record the sequence of events is briefly as follows: With the face held against the viewing window on the front panel of the oscillograph and with the eyes focused on the cathode-tube screen, the camera shutter is first opened. Shortly after pushbutton $P$ is pressed. This causes the 3-electrode gap of the primary oscillograph initiating unit to break down and the impulse from $M$ fires the thyratron tube of the beam-initiating unit. The cathode-ray beam appears on the left edge of the tube screen where it remains stationary. However, within about 20 microseconds the impulse from $M$ also trips the 3-electrode gap of the sweep-initiating circuit and the sweep begins. Simultaneously a voltage impulse of 7,500 volts from $O$ through terminal $T$ travels out through some delay resistance to the trip gap of the intermediate initiating circuit whose output in turn precipitates the impulse generator discharge. The voltage divider leads from the impulse-generator discharge circuit bring the desired voltage impulse to the oscillograph deflection plates. The luminous cathode-ray spot now traces the wave shape which can be seen at the same time the photographic record is taken and the spot finally disappears at the right edge of the cathode tube screen where it is automatically shut off. The camera shutter is now closed and the record is taken.

When very fast sweeps are employed requiring ultra-precision timing, the sequence of the various circuit initiating events is slightly altered. The first impulse from $M$ which establishes the cathode-ray beam is now used to initiate through terminal $U$ the intermediate circuit and impulse generator before the sweep begins. As shown in dotted lines in figure 7 a portion of the impulse generator voltage from $W$ is used to trip the gaps of the sweep-initiating unit through the oscillograph terminal $Q$. This takes place before the arrival of the impulse from $M$ on the same sphere. This modification was found to provide very sharp timing between the start of the sweep and the precipitation of the impulse generator discharge as illustrated by the fast records shown in figure 6.

In conclusion a practical high-speed cathode-ray oscillograph was successfully constructed with external camera photography, incorporating a sealed glass cathode-ray tube, capable of recording transients at a recording speed of 250 kilometers per second (10 inches per microsecond). It was shown that higher recording speeds are not needed in most practical fields of application.

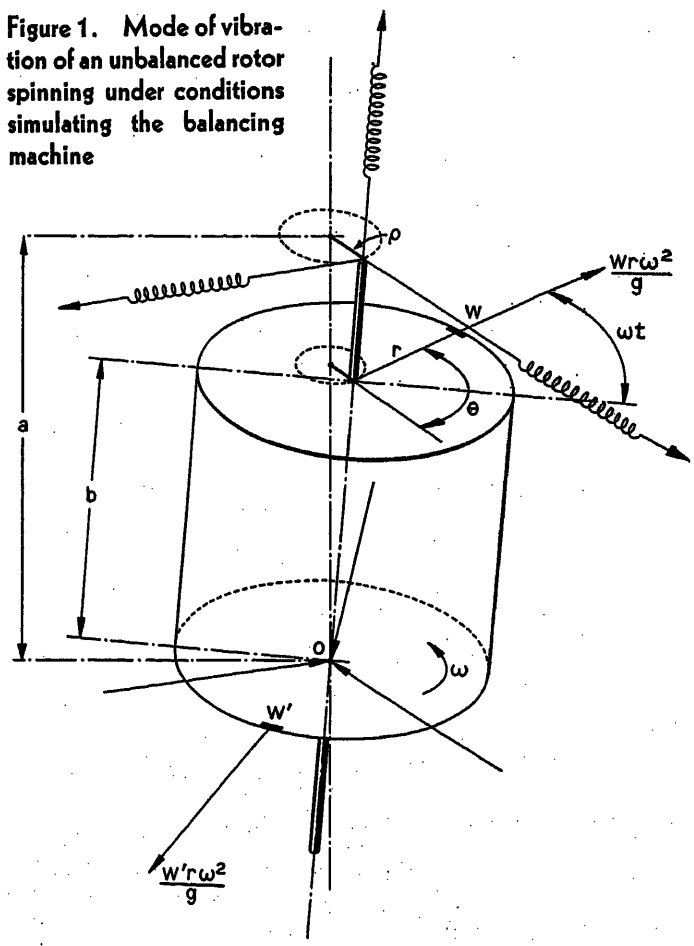
# Dynamic Balancing of Small Gyroscope Rotors

By O. E. ESVAL
ASSOCIATE AIEE

C. A. FRISCHE
Member Amer. Phys. Soc.

A DIRECT METHOD[1] of balancing is generally possible for any type of rotor provided it can be run in a special fixture for the measurements. However, some rotors due to large size or other restrictions can be run only on their permanent mountings and balancing usually requires more or less "trial and error" testing. On the other hand, certain rotors of the first group that are small in size and may be run in special fixtures, impose unusual obstacles which make it difficult to apply the well-known principles to produce a rational method of dynamic balancing. This paper is devoted to a description of the solution of such a balancing problem.

The present method was originally developed to balance a wheel capable of spinning 30,000 to 40,000 rpm. At that time the production method of balancing small gyro rotors in the Sperry Company consisted of placing small amounts of putty or Vulcatex on the rotor periphery and shifting the position and amount until the rotor felt smooth. The rotor was then drilled in accordance with the position and the amount of putty present. This required skilled operators but at the time seemed to be the only method which produced a satisfactory balance. However, this method broke down when applied to very high-speed rotors, since the operators no longer have a proper sense of "feel" at high frequencies. After the application had been made to the high-speed wheel, it was decided that the method would be very useful for production balancing of air-driven gyroscope rotors such as are shown in figure 4. These rotors are used in the standard airplane flight instruments shown in figure 5. Several factors in this balancing problem are unique. The most important of these is the unusually high degree of balance required. This requirement is peculiar to gyroscopic instruments since very sensitive antifriction bearings must be used for rotor and gimbal bearings. Also it is frequently found that dynamic unbalance, even in small amounts, will excite destructive gyroscopic nutations. This is particularly true of gyros with very free gimbal bearings. Quantitatively, the maximum allowable vibration is of the order of $10^{-5}$ inch at the bearing housing. This is not remote from the threshold of "feeling" on these instruments at 200 revolutions per second. It is understood, of course, that very high-grade, smooth running bearings must be used, otherwise one may mistake the "feel" of bearing "noise" for rotor unbalance. This requires an excellence of running balance that is far beyond the range tolerated in any other type of rotating apparatus.



A paper recommended for publication by the AIEE committee on electrical machinery. Manuscript submitted March 13, 1937; released for publication April 21, 1937.

O. E. ESVAL and C. A. FRISCHE are employed in the research laboratory of the Sperry Gyroscope Company, Inc., Brooklyn, N. Y.

1. A list of references relating to many of the most important rotor balancing methods is given at the end of this paper.

Pivot-type cone bearings are used on these rotors. These are shown on the central shafts in figure 4. The pivots run on ball bearings in the case of the instrument. Due to this type of construction, it is impracticable to connect mechanically to any type of speed indicator, voltage generator, commutator, or interruptor. Furthermore, any mechanical connections would, when removed after balancing, in all probability cause an unbalance. Therefore, any signal which is to be generated for indication of rotor speed and position must be derived by other than mechanical means.

**Figure 1. Mode of vibration of an unbalanced rotor spinning under conditions simulating the balancing machine**

Due to the nature of the product, extreme care must be exercised in handling the rotors to prevent damage. The sensitive bearings used are affected very badly by any foreign material. The slightest abrasion of the pivot means scrapping. There is also another hazard, namely, the danger of striking the unprotected rotor pivot against some object while it is being removed or assembled in the balancing fixture. Therefore, the machine must be constructed in such a manner that unskilled operators

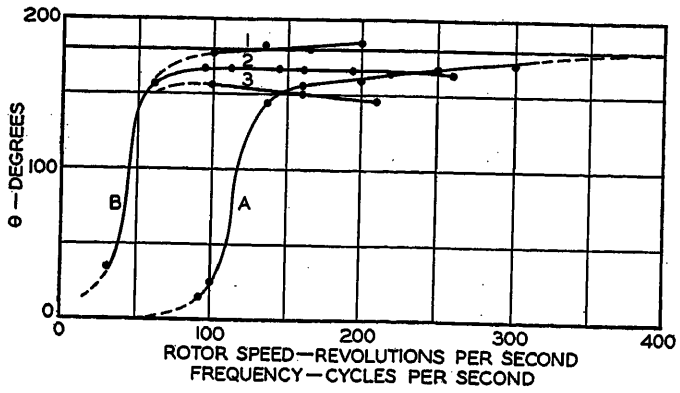


**Figure 2. Phase shift curves**

*A*—Phonograph pickup *B*—Ring pickup

can manipulate it rapidly with the minimum hazard to the finished rotor.

Another condition to contend with is high speed. It must be possible to measure rotor unbalance at a comparatively high speed. This speed may be anywhere from 5,000 to 40,000 rpm. Thus, to obtain high sensitivity, the rotor casing and vibration pickup must be as light as possible and the critical frequency of the mount should be very low with respect to the lowest speed at which we wish to balance.

## Choice of Method

In choosing a method of balancing these gyroscope rotors, we were forewarned that our problem was so different that an unusual machine was necessary. Attempts by various companies interested in up-to-date balancing methods to balance these rotors failed to produce results. The reason, obviously, was that their standard apparatus while excellent for their own product, was not adapted to the small gyro rotors.

## Rotor Mounting

The first attempt at a balancing machine is shown in figure 6. The rotor is mounted in a rigid 3-legged frame. At each end of the frame, in the correction planes, (planes normal to the spin axis which include the balancing weights) are mountings for flat leaf springs 120 degrees apart as shown at the bottom of the frame. The springs can be attached at either end of the frame and their outside ends are secured to a heavy base. The frame is then virtually pivoted at the rotor axis in the plane of the springs. The springs maintain equal rigidity in all planes which include the axis. Therefore, the rotor axis will oscillate in a conical path (this will be found demonstrated in figure 1), the apex of which lies in the plane of the springs. For small vibrations, the damping of such a spring mount is exceedingly low. It is easy to adjust the resonant speed by varying length and thickness of springs and maintain at the same time sufficient rigidity in the plane of the springs to substantially block out the vibration of the end not being measured.

## Reference Signal

Since it is impossible to attach any kind of a signa generator mechanically to the rotor, the obvious way o of obtaining a signal which depends for its phase on a reference mark on the rotor, is the application of the photoelectric cell. A beam of light is reflected from the surface of the rotor to a photocell. A certain part of the rotor surface is highly polished, the rest is not. The rotation, therefore, varies the reflected light and pulsates the photocell current at rotor frequency. This means of voltage generation obviously does not impede motion of the rotor or the frame.

## Vibration Instruments

The first requirement of the vibration instrument is that it must permit adjustment of the phase of the output voltage. In practically all other balancing methods, the phase of the reference voltage is adjusted to be in or out of phase with the vibration voltage. But it is inconvenient to adjust the phase of the reference voltage in this device because in moving the optical system around the axis of rotation, the light beam would be intercepted by the frame work. The vibration instrument shown in figure 6 is an ordinary electromagnetic phonograph pickup. It is mounted to rotate on the axis of the needle which rests on the top of the rotor frame. Vibration of the frame is transmitted to the pickup through the needle, thus generating a voltage. The frame vibration is circular around the spin axis but the pickup generates a voltage by only that component of the vibration that lies in one axial plane. Now, to advance or retard the phase of the voltage, it is necessary only to advance or retard the axial plane in which the pickup is sensitive.

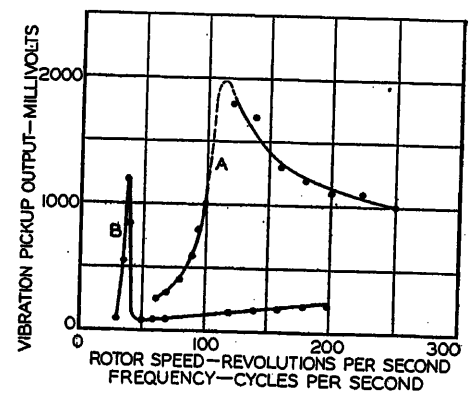

**Figure 3. Resonance curves**

*A*—Phonograph pickup

*B*—Ring pickup

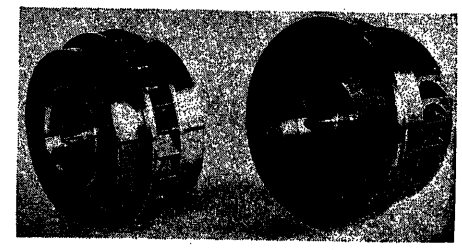

**Figure 4. Gyroscope rotors**

This means that rotation of the pickup about the needle axis, adjusts the phase of the output. The dial indicates pickup position. It is apparent that the voltage magnitude is not affected by angular position of the pickup as long as the rotor axis describes a circular path under the influence of an unbalanced rotor.

The voltage output of the pickup is proportional to frequency ($\omega$) and amplitude of the vibration ($\rho$) and is, therefore, a measure of unbalance ($Wr/g$) at any given speed, where $W$ is the unbalanced weight, $r$ is its radial distance from the spin axis, and $g$ is acceleration of gravity. The position of the unbalance is determined by adding to the vibration voltage the reference voltage. The magnitudes are first made equal by attenuation. The pickup is then rotated to the point where the sum of the 2 voltages is zero. The dial reading indicates the position of the unbalance as measured in degrees from some arbitrary reference mark on the rotor. The phonograph pickup was tried first because of its availability and simplicity but it was not entirely satisfactory, as will be discussed later. First, another necessary feature of the system will be discussed.

## Filtering

Figure 7 is what might be called a vibration spectrum of a rotor with bearings and frame. It indicates the relative magnitude (not taking into account the fact that the voltage induced in the pickup is proportional to frequency), of all the harmonics that are present in the vibrations of a fairly well-balanced rotor. The rotor speed is 200 revolutions per second and the amplitude at that frequency is considerably less than some near-by frequencies. Naturally, these other frequencies tend to give an erroneous voltage reading in measuring magnitude and make it impossible to phase against the reference voltage for position. Obviously, filtering is necessary. If the precision of balance required were not so high, the vibration component at rotor speed would still be large and filtering would not be necessary. Under existing conditions, it is, however, a prime requisite. The reference signal also has a high harmonic content so it must be filtered too. The combined output is filtered after the 2 voltages are added together. This precludes the possibility of uncompensated phase shifts in filtering. The schematic wiring diagram, figure 8, shows the method of adding voltages, filtering, and amplifying. A very sharp bandpass filter is used.

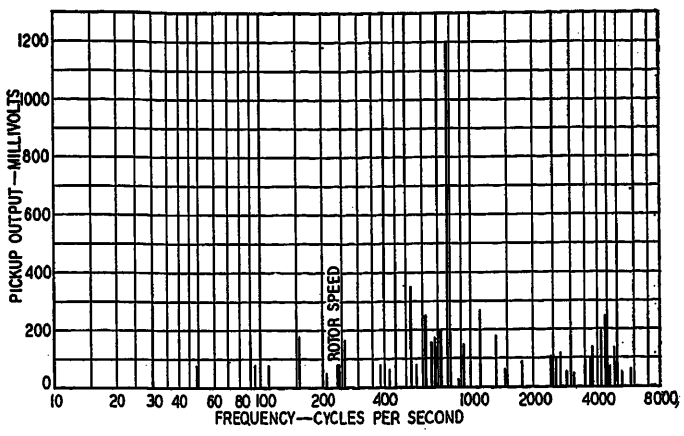

**Figure 7. Gyroscope vibration spectrum**

Pickup response is not a measure of amplitude of vibration at various frequencies because output is proportional to frequency

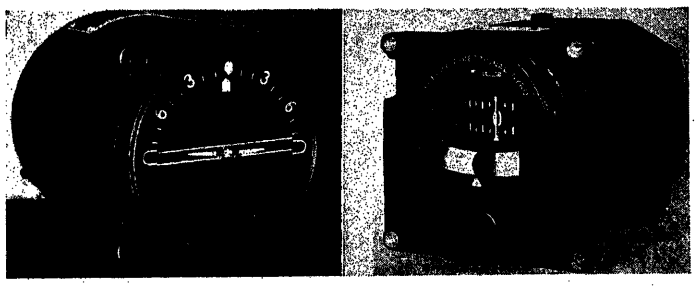

**Figure 5. Flight instruments**

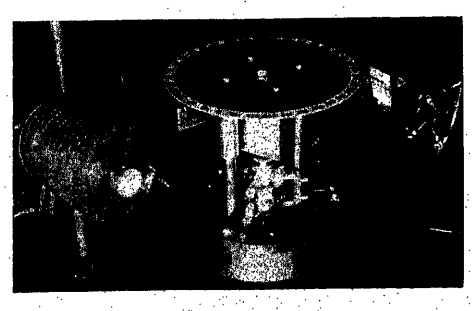

**Figure 6. Experimental machine with phonograph pickup**

## Voltage Balance

In practice, it is found that in order to obtain an accurate indication of unbalance position, the 2 voltages must be very nearly equal. At least one of them must therefore be adjustable. The reference signal is the one adjusted. The effect of imperfectly balanced voltages is shown in figure 9. The slope of the curves is a measure of sensitivity in locating the correct position. The abscissas of this family of curves is the angle ($\alpha$) between minus $e_v$ and plus $e_r$, and the ordinates are their sum ($e$) in per cent of the vibration voltage ($e_v$). Plots at several ratios ($P$) between $e_v$ and $e_r$ are given to show the effect of inequality of the signal voltages. It should be noted that $\alpha$ is the angular error in locating the unbalanced weight.

Let

$$e_v = E_v \cos(\omega t + \alpha - 180°)$$
$$e_r = E_r \cos \omega t$$

When $E_v = E_r$ by adjustment and $\alpha = 0$. Then

$$e_v + e_r = E_v \cos(\omega t - 180°) + E_v \cos \omega t = 0$$

It can then be shown that

$$e/e_v = \sqrt{1 - 2P \cos \alpha + P^2}$$

For small angles this relation can be simplified to

$$e/e_v = \sqrt{(P-1)^2 + P\alpha^2}$$

The curves of figure 9 are a plot of this equation.

Since the slope of the curves is proportional to sensitivity in setting $\alpha$ equal to zero, it is apparent that the voltages must not be unequal by more than approximately one per cent to measure position with an accuracy of one-half a degree. Furthermore, to obtain the same sensitivity of position for small magnitudes, as for large magnitudes, a tapered attenuator on the reference voltage must be used.

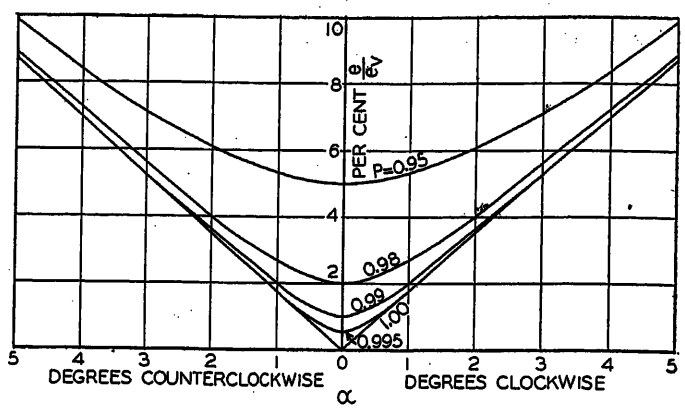

**Figure 9. Positioning error curves**

In order to determine accurately the position of unbalance $\alpha$ must be made zero. To obtain high accuracy in setting $\alpha$ to zero, $P$ must be close to unity

## Phonograph-Type Pickup

The resonance curves of figure 2, curve $A$, and figure 3, curve $A$, indicate that damping is considerable because the angular position is never independent of speed in the operation range. In fact, at 200 revolutions per second a change of 20 revolutions per second results in position change of $2^1/_2$ degrees. Of course, the band-pass filter limits the possible variation in speed, but with air driven rotors, speed changes of less than 10 revolutions per second are difficult to control. Such changes in frequency will not appreciably change the attenuation of the desired signal. A more serious difficulty was the unsuitable critical speed. The curves, figure 2, curve $A$, and figure 3, curve $A$, show resonance at about 115 cycles. Experience indicated that 150 revolutions per second (9,000 rpm) is a good compromise speed at which to balance the rotor. It is undesirable to balance at full speed, 12,000 rpm, because initial unbalance forces are a hazard to rotor pivots. Balancing at 2 speeds was found unnecessary, hence the compromise. Since 150 revolutions per second was found to be the best balancing speed, resonance at 115 revolutions per second put the knee of the curve right at running speed. Such a condition would produce bad errors in position with imperceptible changes in speed. In attempting to lower the resonance speed, several modifications of the mounting and vibration pickup were tried. The pivoting springs were made longer to lower the free resonance of the frame. But, in doing so, the loading effect of the pickup on the system was accentuated to such an extent that all gain in reduced frame resonance speed was lost. This was caused partly by the phenomenon of 2 resonances in series, one of which is the spring mounted frame and the other the natural frequency of the magnetic pickup. They are mechanically connected together by the needle. Various attempts to reduce damping and lower the resonance of the pickup were made but decrease of one effect tended to increase the other. This was an indication that the pickup was the wrong type of instrument. It became necessary to investigate the use of other types of vibration measuring devices. A piezoelectric microphone was given a trial but with little success.

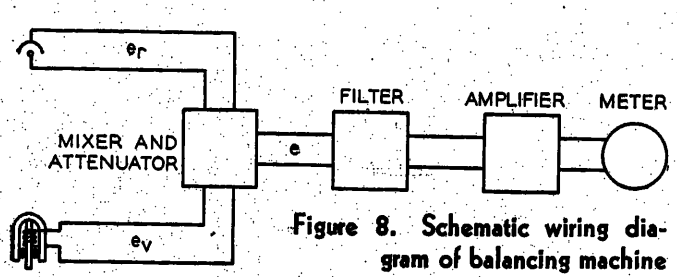

**Figure 8. Schematic wiring diagram of balancing machine**

In the course of experiments, it became apparent that the important requirement of the system is a very loose coupling between the oscillating frame and the pickup. The next section describes such a vibration instrument.

## Ring-Type Pickup

Figures 10 and 11 illustrate the type of instrument that was finally evolved. This pickup has the desirable feature of having a very loose coupling with the rotor frame. It is noted that there is no mechanical coupling between these parts.

The instrument comprises a permanent horseshoe magnet with a center pole of soft iron on which is wound a coil and a soft iron ring attached to the moving element (rotor frame). The iron ring oscillates with the rotor axis under influence of rotor unbalance. This oscillation is such that the ring moves in an eccentric path around the central pole of the pickup. This motion varies the flux through the center pole periodically and generates a voltage in the coil the frequency of which is rotor frequency. Examination will show that the phase of the voltage can be changed by turning the permanent magnet on the axis of the center pole. The voltage ($e_v$) is proportional to the amplitude ($\rho$) of the circular oscillation and, therefore, is also proportional to unbalance ($Wr/g$) at fixed speed.

With this device, it was possible to obtain the resonance curves as shown on figure 2, curve $B$, and figure 3, curve $B$. The resonance, it is noted, occurs at 40 revolutions per second as compared to 115 revolutions per second with the phonograph type of pickup. This critical speed is sufficiently low to allow very satisfactory operation at 150 revolutions per second. It will be noted that there are several slopes to the $\theta$ curves. $\theta$ is the angle between the displacement vector ($\rho$) and disturbing force ($Wr\omega^2/g$). Number 1 is the first result. It has a

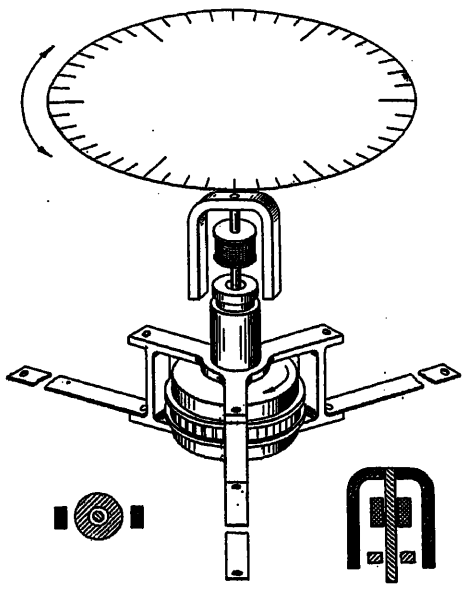

**Figure 10. Ring-type pickup**

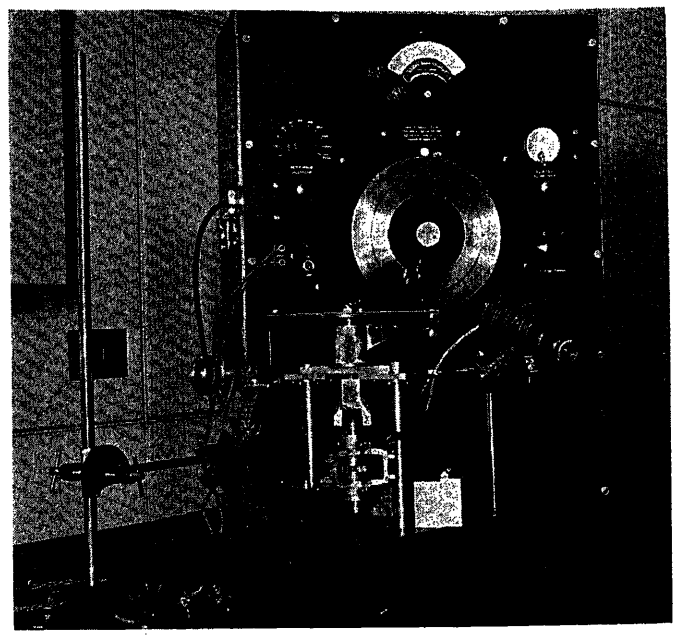

**Figure 11. Experimental machine with ring-type pickup**

slight change of $\theta$ with speed. This condition is not entirely satisfactory and experiments were made to remedy it. This condition, it was possible to correct in the circuit. Capacity across the photoelectric cell coupling transformer was found to provide means of compensating this relative phase shift. Several values of capacity were inserted across the transformer and the results are shown. One value of capacity, it will be noted, produced practically constant $\theta$ with speed variation in the 150-revolution-per-second region. This is the final arrangement.

The critical speed of the system and phase shifts were now reduced to a very satisfactory value. The basic features of the system were now developed. However, some doubt was raised concerning the practicability, owing to the difficulty in mechanically keeping the axis of the ring concentric with the pole of the pickup. Since the frame on which the ring is mounted is supported on 3 springs, it is apparent that close mechanical alignment is not easy to maintain. The air gaps when the ring is centered are 0.040 inch from pole to ring and 0.40 inch from ring to magnet. It is quite possible that a misalignment of less than 0.005 inch would be difficult to maintain on a production machine. In this system it is essential that the phase of $e_v$ can be changed the whole 360 degrees with respect to $e_r$ at constant magnitude. Also, voltage $e_v$ should be constant with given unbalance and its phase with respect to $e_r$ should always indicate true position of unbalance. The curve on figure 12 shows, experimentally, the effect of misalignment on sensitivity. It is noted that the misalignment may be as great as 15 per cent before the calibration is affected more than 1 per cent.

## Sensitivity

Earlier in this paper some indication of required accuracy in balancing was given. Measurements show that it is desirable to detect and correct an unbalance of the order of 0.00001 ounce inch. This unbalance produces a very slight vibration in the frame. The initial unbalance is of the order of 0.001 ounce inch. The maximum unbalance produces about 2 millivolts which reduces to roughly 20 microvolts for the minimum reading. The internal impedance of the pickup is about 1,400 ohms, so the power output is very low. A high-gain amplifier is necessary to produce the power necessary for even a sensitive meter. A fairly simple, 3-stage full a-c operated amplifier can be made to give satisfactory results.

An attenuator to serve as a meter multiplier is necessary to allow the use of the meter on full scale on minimum signal for phasing purposes. The signal may change in the ratio of 100 to 1 or more, so changing of meter scale is mandatory.

Figure 13 shows the very linear relation that exists between magnitude of unbalance and voltage output. In balancing the rotor, the magnitude and position of unbalance is observed and recorded for both ends of the rotor. Then the 2 ends of the rotor are drilled the indicated depth at their proper respective positions. All weight correction is accomplished by drilling. Figure 14 is a calibration curve of drill depth against voltage. The nonlinear characteristic is due to the conical shape of the drill point.

It would be very advantageous to balance the rotor perfectly in one reading. Consideration shows the impossibility of this. First, the unbalance indication must

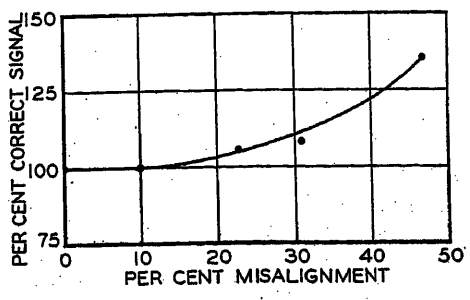

**Figure 12. Effect of misalignment on calibration**

be reduced from 2 millivolts down to less than 10 microvolts, a ratio of 200 to 1. Secondly measuring instruments have inherent errors that in practice cannot be eliminated. A voltmeter is never accurate to better than 1 per cent. Taking the combined inaccuracies of amplifier attenuators, etc., the errors will be not less than 5 per cent. If the error is 5 per cent, the initial unbalance indication can be reduced by a ratio of 100 to 5 or from 2 millivolts to 100 microvolts. Experience shows that 3 "shots" usually are required at each end. It can be shown that a balance in 3 readings can be obtained with over-all calibration errors of as much as 10 per cent.

## Production Balancing

Figure 15 shows the form of the machine that is replacing older methods in production balancing. It is designed especially for speedy manipulation in the factory. The main features of this device are (1) duplicate pickups, one at the top and one underneath and (2) one set of supporting springs for each correction plane. The springs are controlled by cams operated simultaneously by a handwheel for the purpose of changing the support from one correction plane to the other. When the support is shifted to the top springs, a switch operates automatically to connect the bottom pickup to the circuit and vice versa. The 3-sided rotor frame is designed to permit quick insertion or removal of the rotor without damage to the pivots.

This system is the only one to our knowledge which provides the extreme sensitivity required in balancing airplane instrument gyroscope rotors without depending on superkeen perceptions in the operator. Also, the speed of balancing is several times faster than the most skilled operator could make with former methods. Rejections due to defective rotor balancing are reduced from nearly 50 per cent to zero because the machine, in largely removing the human element in the measurements, can obtain exactly the same degree of balance on every unit.

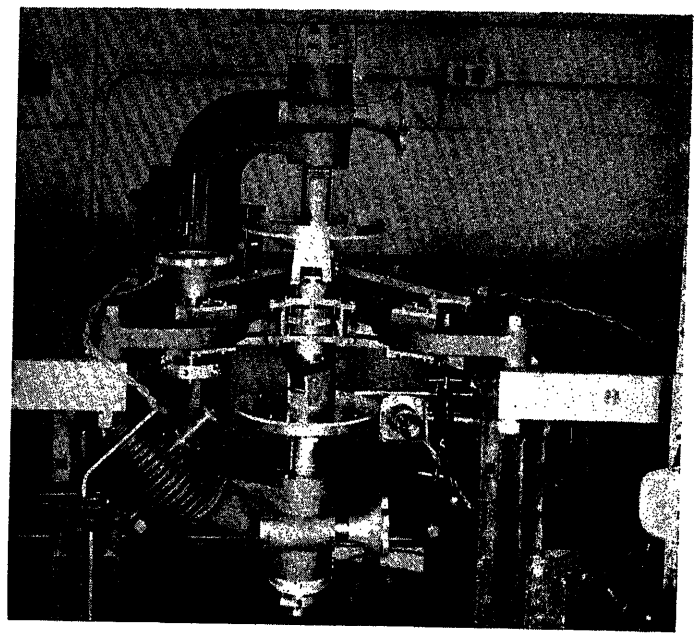

**Figure 15. Production rotor balancing machine**

Another valuable feature of the machine, which has not yet been thoroughly investigated, is its use as a "stethoscope" for checking vibrations caused by sources other than unbalance. In this use, the fixed band-pass filter is taken out and replaced by a "wave analyzer." Such an instrument is shown in figure 11. Frequency spectrums similar to the one shown in figure 7 can then be taken. This information is important in the study of ball bearings, case resonances, high-speed gyroscopic nutations, etc. It has enabled us to measure effect of looseness and out of balance in ball-bearing retainers. All of the possible uses for such a machine have obviously not been explored. However, they appear to be numerous and, no doubt, several other interesting applications will follow.

# The Vibration Isolation of Machinery

By L. H. HANSEL

THE GENERAL purpose of isolating machinery is to reduce the amount of noise and vibration transmitted to the structure in which the machine is housed, or to adjoining structures. The general subject of isolation and isolation materials is receiving increasing attention with the tendency to speed up machinery. Machine designers recognize the fact that increased speed has resulted in troublesome vibration problems that previously had not reached "nuisance" or "damage" levels. The great majority of manufacturing tools are inherently unbalanced. To design a ba'anced drop hammer, loom, punch press or automatic machine is not feasible. In such cases the use of isolation material becomes a necessity.

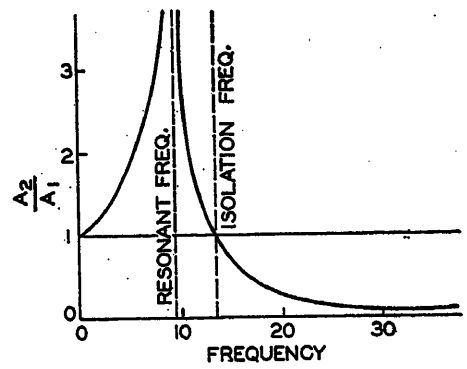
Unfortunately, in many instances, isolation has been tried and the desired results have not been attained. These failures have been generally caused by a lack of understanding as to the principle of isolation and the absence of practical knowledge as to how and where the material should be installed.

The first principle of isolation is that the natural frequency of the machine on its isolation must be considerably less than the operating vibration frequency of the machine. As an example, let us assume that we have a machine which gives rise to vertical vibrations of frequency 30 per second. The machine weighs 1,600 pounds and is to be supported upon 4 equal springs. Furthermore, we desire to reduce the vibrations transmitted to the surroundings to $^1/_9$ of the value when springs are not used. If $k$ is the "stiffness coefficient" of the 4 springs, $n$ the frequency, $A_1$ the amplitude of transmitted vibration without the springs, and $A_2$ is the transmitted vibration with the springs, then

$$\frac{A_2}{A_1} = \frac{k}{4\pi^2 n^2 \frac{w}{g} - k} \qquad (1)$$

substituting

$$\frac{1}{9} = \frac{k}{4\pi^2 \times 900 \frac{1600}{32.2} - k}$$



and $k = 176{,}000$ pounds per foot.

For one spring the stiffness coefficient is 44,000 pounds per foot or 3,660 pounds per inch. Four springs each giving a deflection of one inch for a 3,660-pound load solve the requirements.

It is noted, that the stiffness coefficient is an important property of an isolator. From equation (1) we can calculate what isolation will be obtained at frequencies other than the operating frequency of 30 vibrations per second. When $k = 4\pi^2 n^2 w/g$, $A_2/A_1$ becomes theoretically infinite. The transmitted vibrations at this frequency are very much higher with the springs than without them. This occurs at a frequency of 9.5 vibrations per second. At a frequency of 12.4 vibrations per second $A_2 = A_1$, and the transmitted vibrations are the same with the springs as without them. This frequency is called the "isolating frequency." A plot of the calculated values of $A_2/A_1$ for various frequencies is shown in figure 1.

Examination of this curve shows that below the isolating frequency (where $A_2/A = 1.0$) the transmitted vibrations are larger with the spring isolators than without them. The system only becomes effective at frequencies higher than 12.4 vibrations per second.

Figure 1

If the springs are stiffened the natural and isolating frequencies become higher, and consequently their effectiveness at the operating frequency of 30 per second is lessened. If the springs are reduced in stiffness the situation is improved. Questions of stability will determine what minumum stiffness coefficient is permissible.

The resonance peak is undesirable in the majority of cases. During the starting and stopping of the machine the transmitted vibrations are large and, in addition, the machine on the springs oscillates through a very large amplitude, both of which are objectionable. To remedy these difficulties it is desirable that the isolation material possess "damping" qualities.

Damping has 2 principle effects. It greatly reduces the height of the resonance peak, but the installation is less effective than isolation with no damping at frequencies higher than the isolation frequency. The curves of figure 2 show a material with little damping and one with considerable damping.

Experience has shown that the improvement obtained at frequencies lower than the isolation frequency with the

A paper recommended for publication by the AIEE committee on electrical machinery. Manuscript submitted April 8, 1937; released for publication April 29, 1937.

L. H. HANSEL is vice-president and treasurer of The Felters Company, Inc., Boston, Mass.

material with appreciable damping properties is of great practical importance.

If the material has appreciable damping qualities the $A_2/A_1$ equation 1 becomes:

$$\frac{A_2}{A_1} = \sqrt{\frac{r^2 + \frac{k^2}{4\pi^2 n^2}}{r^2 + \left(2\pi n \frac{w}{g} - \frac{k}{2\pi n}\right)^2}} \qquad (2)$$

Where $r$ is the damping constant.

This constant is measured by taking a record of the damping curve. One method of doing this is illustrated in figure 3.

The test piece is loaded with 2 suitably sized weights. A small stylus bears on the top bearing plate. Any motion of the isolation material causes the mirror to move about its axis and a beam of light to move across the slit of a constant film speed moving picture camera. The lower weight is suddenly moved and a record of the oscillations is made on the film. From measurements on the damping record the value of $r$ can be evaluated.

Control of materials and manufacturing processes makes it possible to make felts covering a very wide range

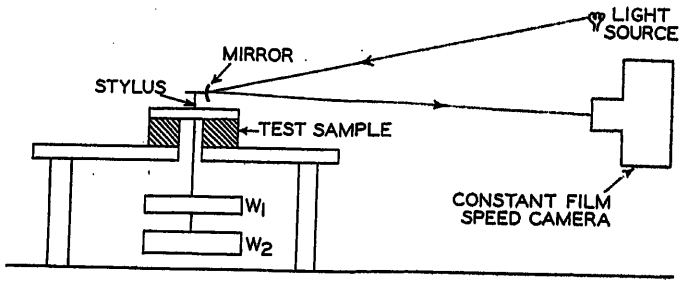


Figure 3

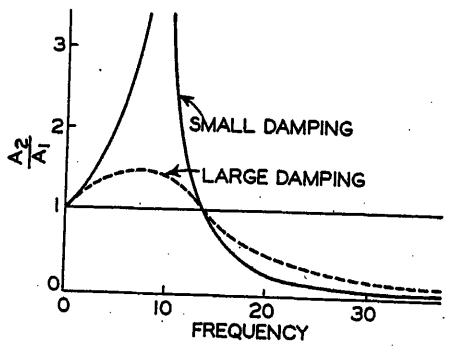

Figure 2

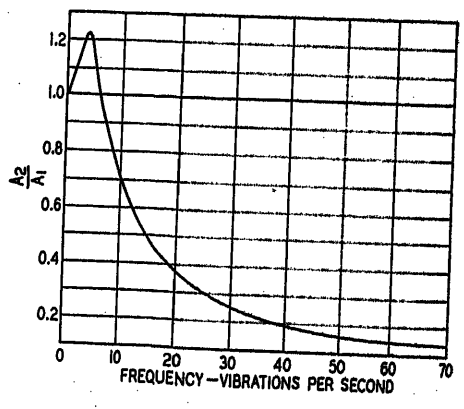
of stiffness coefficients. For example, felts can be made which are suitable for loadings from 2 to 500 pounds per square inch. In determining the properties of these load-deflection curves were measured together with the damping or "resistance" coefficients. Curves similar to that shown in figure 4 were then calculated.



These curves have been checked at numerous points by measuring transmitted vibrations in the following manner.

The vibrations of an eccentrically loaded motor were measured with no isolation, thus giving the value of $A_1$. The test material was installed at the desired loading and the vibrations transmitted to the surroundings were again measured, thus giving the value of $A_2$. The readings so made served as a direct check upon the determination of $A_2/A_1$ by means of equation 2.

For purely rotative devices such as electric motors, the frequency to be isolated is the speed in revolutions per second. The frequency to be isolated for more complex machines is not so easily determined. The satisfactory method is to obtain a photographic record of the vibrations. There are 3 general types of instruments used: displacement recorders, velocity recorders, and accelerographs. Each gives a different recorder, and what is measured as the predominate frequency of the frequency giving the biggest displacement on the record is not necessarly the same for the 3 instruments. As an illustration of this, let us assume that a record similar to figure 6*a* is obtained with some type of velocity recorder. If a record is now made with an accelerograph it appears as in figure 6*b*. An examination of the 2 records discloses that the frequency to be isolated as determined by the accelerograph is 4 times as high as is determined by the velocity recorder. A record of the same vibrations taken on a displacement recorder would give a much smoother curve than 6*a*, and the slight irregularities of 6*a* would be much smaller on the displacement record.

The only case where records from the 3 instruments would be similar is when the vibratory motion is simple harmonic, such as an unbalanced rotor. The question then arises as to which of the 3 should be used in a determination of the frequency to be isolated, where the machine is more complex. Since we are interested in damage to the structure or annoyance to persons, the measurement which best measures damage or annoyance is the proper one to use. Since acceleration is proportional to unbalanced force it seems reasonable to accept acceleration as the best measure of damage. Through evidence collected by seismologists and engineers acceleration is a better measure of structural damage than velocity or displacement.

Figure 4

Experiments have been made in order to establish a unit of "nuisance level" of vibrations, that level at which people term a vibration an annoyance. Neither acceleration, velocity nor displacement are satisfactory as a unit. When the vibrations are accompanied by noise, it very often happens that eliminating the noise results in the opinion that the vibration difficulty has been overcome. What one person calls an objectionable vibration, another does not, so that the establishment of a satisfactory

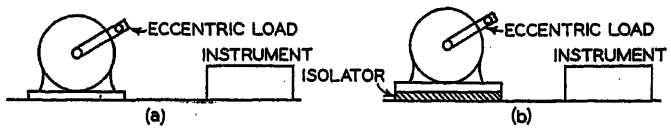


**Figure 5**

nuisance level does not seem possible. Such being the case and accepting the fact that acceleration is the best measure of damage, the accelerograph is preferable to the velocity or displacement recording instruments.

It is well to examine the more practical aspects of vibration isolation with the idea of pointing out the more common errors made in installation. The most common of these is "bridging." Many installations are found in the field where the use of holding-down bolts makes the application useless.

A "bridged" isolator is shown in figure 7*a*. Here the holding-down bolt or lag screw is rigidly connected to the

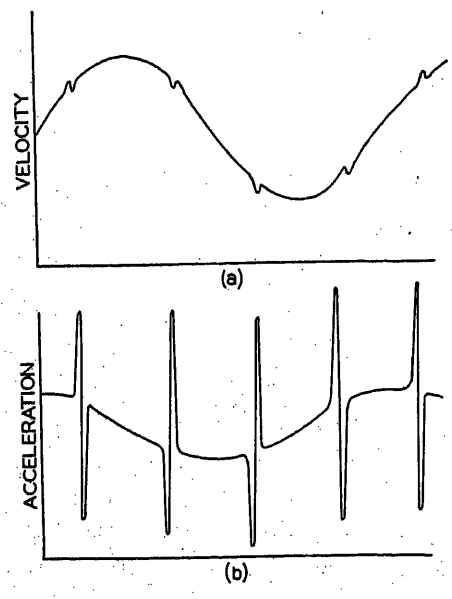

**Figure 6**

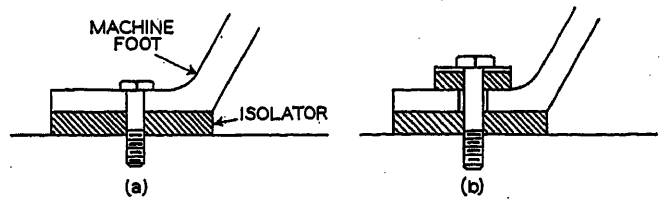
machine foot and to the floor, and offers a direct path for the transmission of vibration. Where holding-down bolts are necessary the installation can be made as in figure 7*b*, where no direct path for the transmission of vibrations is available, except through the isolating material. In such arrangements clearance must be provided between the bolt and the machine footing. The lower pad takes the sum of bolt load plus machine load, and the upper pad, the bolt load. Generally the bolt load is in excess of the mass load of the machine. The efficiency of the isolation is determined by the mass load and not by the bolt load. Consequently, it is necessary to use a material which is capable of taking the bolt plus machine load without deterioration. This is necessarily a stiffer material than one which would have to withstand the machine load alone, and isolation efficiency is sacrificed. Many machines have to be bolted down.

It has been found that a great many others which are ordinarily bolted do not require bolts provided the pad can be cemented to the foot of the machine and to the floor. It has been found, for example, that a satisfactory



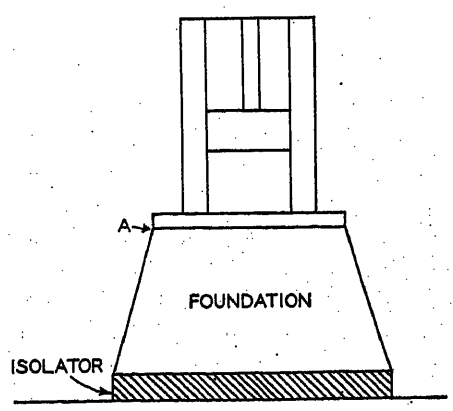


**Figure 7**

and preferable method of mounting looms is by eliminating the bolts or lag screws, and cementing the pad. The loom stays fixed in its location, the mass loading on the pad is correct, and the cost of the pads themselves is largely offset by the saving in the cost of installing the lag screws or bolts.

In connection with the loom problem, it is interesting to note that many loom sheds have very large horizontal

**Figure 8**

vibrations. This occurs when a number of looms get in phase and the disturbing force is high. The natural frequency of the structure in which the looms are housed is often in the neighborhood of the loom speed so that a condition approaching the resonance peak exists. With the advent of increased loom speeds it is probable that in many cases the loom speed will more nearly agree with the natural frequency of the structure and the vibration situation will be very much worse.

One of the most troublesome of vibration transmitting

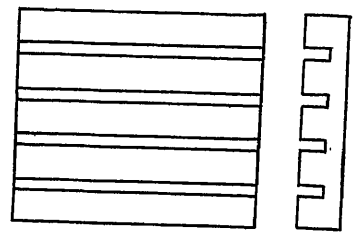
machines is the drop hammer. Unisolated drop hammers give rise to vibration which are transmitted long distances and seriously affect adjoining property owners. To isolate a hammer already installed is an expensive job to do properly. The machine must be taken down and the isolation material installed underneath the foundation as in figure 8.

Placing the isolation material directly under the hammer (at *A*) will result in a loss of hammer efficiency. The material must withstand the mass loads of machine and foundation, and be capable of long life under the effect of the hammer blows. The magnitude of the blow is difficult to determine since it depends upon the size of the hammer, the drop and the temperature and nature of the work. However, on large hammers the impact blow is of the order of 2,000,000 pounds.

Punch presses are serious offenders. The record shown in figure 9*a* is of an unisolated punch press. The film speed of this record was 3.5 inches per second. The calibration of the instrument showed that a displacement of the light source of 0.23 inches from its median position indicated an acceleration of 10 per cent of gravity. The blows occur about every 1.3 seconds. This, however, is not the frequency which has to be isolated. The frequency of vibration at the impact is of the order of 100 vibrations per second. Figure 9*b* shows the effect of installing isolation material.

Machine footings are of all sizes and shapes. The loading on the footings cover a wide range. In the use of pad materials we can vary the thickness and area of the

Figure 9a (top) Figure 9b (bottom)



pad to get the desired load-deflection conditions. Furthermore if the material itself can be manufactured to get various load-deflection properties for a given thickness, all conditions of loading met within practice can be properly treated.

We have previously talked almost entirely of vertical vibrations. These are greater sources of disturbance ordinarily than horizontal vibrations. Where horizontal vibrations are large, then the isolator must be installed with the viewpoint of simultaneously correcting for both vertical and horizontal vibration. This may be accomplished by grooving or slotting the pad in the proper direction, as shown in figure 10.

The pad is placed under the machine so that the direction of maximum horizontal vibrations is perpendicular to the slots. Various other arrangements of grooving or slotting are possible.

Ship vibrations are exceedingly troublesome. These are caused by machinery within the ship and by disturbances originating at the propeller. Very little has been done in isolating the machinery of a ship. Proper alignment of shafting and the demand for stability during the rolling and tossing of the ship are additional demands which must be met by the isolation installation. Recent work on smaller pleasure cruisers has shown, however, that annoying vibrations can be greatly reduced by isolation of the main motor and a suitable flexible coupling in the propeller shaft.

Figure 10

Any isolation material to be effective allows the machine more freedom of motion than an installation with no isolation. In advertising one frequently sees charts of the vibrations of an isolated machine, compared with the vibrations of the surroundings. Such a comparison is unfair. The only fair comparison is a record of the vibrations of the surroundings due to an unisolated machine, as compared to an isolated one operating under the same conditions.

Structurally borne noises are a source of disturbance frequently found in factories particularly where offices are located adjacent to manufacturing operations. Correction can be made by isolating the disturbing machines. Quite frequently attempt has been made to quiet the office by the installation of sound absorbing material on the walls or ceilings. These applications do not give the desired results. The sound absorbing material is effective in correcting air borne disturbances. Those noises which are structurally borne are best handled by attacking the problem as near the source of disturbance as possible and installing proper machine isolation.

# New Oil-Filled Cable Lines in Chicago

By HERMAN HALPERIN
MEMBER AIEE

G. B. SHANKLIN
MEMBER AIEE

Several recent developments in cable, joints, reservoir layout, and installation are incorporated in the 4 66-kv single-conductor oil-filled underground lines being installed in Chicago in 1936–37. The main results are economies and simplification. The emergency ratings of the lines are 115,000 kva in summer and 135,000 kva in winter.

DURING 1936 and 1937 the Commonwealth Edison Company is installing in Chicago 4 66-kv underground lines consisting of about 100 miles of single-conductor oil-filled cable. A summary of developments made in connection with these lines, which have a nominal rating of 100,000 kva, is given in this paper. The main objectives were to simplify oil-filled cable systems and make them adaptable for installation in standard underground conduits and manholes, and to reduce costs.

The principal results obtained as compared with previous oil-filled cable installations were as follows:

1. Ten or 12 per cent reduction in insulation thicknesses.
2. Substitution of copper-bearing lead sheath for more expensive 2 per cent tin sheath.
3. Smaller, simpler, and more economical stop and feeder joints.
4. Use of simpler and more economical reservoirs, and development of staggered system of oil feed.
5. Simplified layout, and development of joints and reservoirs that could all be installed in standard manholes, instead of requiring special manholes or towers.

The changes made during this development work in insulation thicknesses, kind of lead sheath, joint design, reservoir layout, etc., have been adopted in principle for oil-filled cable work in the United States. Employing these and other new ideas developed during the past 10 years, including sheath loss elimination, the cost of an oil-filled 132-kv line to have the same carrying capacity as the 1926–27 Chicago line[1] would be only 55 per cent of the cost of the actual installation.

## Economics

These 4 oil-filled lines are additions to a 66-kv system which connects 5 generating stations and 2 distribution stations, power through transformers being fed in at some stations and being taken out at other stations. See figure 1. The system is divided into 2 parts throughout the city with bus tie switches available at the terminal for special use.

The original 66-kv lines installed in 1926 to 1931 consist of 280 miles of 750,000-circular-mil cable of the ordinary solid type with 1,000,000-circular-mil cable in the warmer conduits, and the carrying capacities in the summer for normal and emergency conditions are, respectively, 52,500 and 56,000 kva. System growth warranted the installation of lines having an emergency rating in the middle of the summer of 115,000 kva. As compared to the former standard lines, these new lines result in a saving of about 25 per cent in cost per kva of carrying capacity and in a substantial saving in cost and space for the terminal facilities.

Satisfactory cables of both the ordinary and oil-filled type were available. Early in 1933, 2,100,000-circular-mil segmental-conductor cable of the ordinary type was used for a 9,000-foot line between Calumet and State Line stations because of a 10 per cent advantage in costs over an oil-filled cable installation for the same copper temperature. For the 1936–37 lines, oil-filled cable was used mainly because of the larger emergency carrying capacity and lower annual charges per kilovolt-ampere. Figure 2 illustrates the 3 main types of 66-kv cable that have been used in Chicago.

From the standpoint of over-all economy as well as from the need to avoid overcrowding principal routes for conduits between stations, it was desirable to use existing conduits for the new lines as much as possible; this has been done for 60 per cent of the oil-filled 66-kv cable installed. It was necessary to limit the average losses of the new lines in order to avoid overheating the existing cables in the conduits. This limitation required the use of 2,100,000-circular-mil conductors for either the oil-filled or the ordinary type of cable in most of the conduits, and 2,800,000- or 2,600,000-circular-mil conductors, respectively, in the congested conduits near stations. Studies and experience with the first line, however, showed that with 2,100,000-circular-mil oil-filled cable it was possible to allow its temperature to be a few degrees above the maximum permissible for cable of the ordinary type. As a result, only 4 per cent of the length of 4 lines will consist of 2,800,000-circular-mil cable, whereas 15 per cent of the length would have had 2,600,000-circular-mil conductor if ordinary cable were used. The oil-filled cable had a hollow core 0.69 inch in diameter, while the ordinary cable considered had a conductor consisting of 3 segments to obtain reduced copper losses. For the emergency ratings of the oil-filled cable, this meant copper temperatures in the warmer conduits about 10 degrees centigrade below the guaranteed maximum value of 75 degrees centigrade.

When the peak loading necessitated by emergency system conditions begins to approach the maximum rating of

A paper recommended for publication by the AIEE committee on power transmission and distribution. Manuscript submitted March 29, 1937; released for publication April 24, 1937.

a line, then an additional line must be installed, in spite of the fact that the carrying capacity of the existing line under normal conditions may be adequate. The emergency ratings for the solid type cable were limited not only by the maximum allowable specification temperature of 60 degrees centigrade, but also by operating experience which indicated that the use of large temperature ranges would create undue internal pressures and sheath expansion. Based on operating experience and measurements of internal pressures on 750,000- and 2,100,000-circular-mil cables in service, and taking the expected normal loading into account, the maximum allowable daily range in copper temperature during emergency loading of the 2,100,000-circular-mil solid-type cable lines considered (656 mils of insulation and 156 mils of sheath) appeared to be about 15 degrees centigrade in summer and 17 in winter. With such daily temperature changes, it was expected that the internal cable pressures might be 50 or 75 pounds per square inch, even after a line had been in service and had experienced some sheath stretching.

The emergency rating for the oil-filled cable in the summertime was limited by the temperature requirements for other cables in the same conduit, while for winter conditions it was determined by what was considered the limit of possible future requirements. The winter rating could have been made larger by the installation of a few more reservoirs.

The relative costs for the 2 types of 2,100,000-circular-mil cable, shown in table I, were determined on the basis (1) of bid prices obtained in the fall of 1935 for cable and accessories and (2) of the experience of the Commonwealth Edison Company in installing, maintaining, and loading somewhat similar lines. Incidentally, the estimated cost of the first line installed differed from the actual cost by only 1 per cent. The costs shown include indirect or overhead costs such as engineering, storeroom, superintendence, and interest during construction.

The total annual charges for the 2 types of cable were almost the same. Due to the higher emergency carrying capacities of the oil-filled cable, however, the annual charges per kilovolt-ampere of carrying capacity were about 9 per cent less for the oil-filled system in summer, and 18 per cent less in winter. Oil-filled cable was, therefore, selected for the new lines. Later experience showed that the saving with oil-filled cable was slightly greater than originally expected.

To figure the fixed charges on the investment, the authors used the same rate of depreciation for both types of cable, although the use of a lower rate for oil-filled cable would have been defensible. The annual charge for "maintenance" includes the cost of (*a*) repairing oil leaks, (*b*) routine inspection of cable in manholes for sheath cracks and checking of reservoirs, and (*c*) the cost of repairing failures. The assumed rate of failures for oil-filled

cable was one cable or joint burnout per 100 miles of cable per year, with no anticipated failures.

One factor that was hard to evaluate for solid type cable was the effect of its maximum diameters being about 3.4 and 3.6 inches, respectively, for its 2 sizes. A slight amount of conduit used had $3^1/_2$-inch ducts, which would not have been usable. Experience showed also that some of the standard 4-inch ducts would have had to be rebuilt for the 2,100,000-circular-mil cable and probably the 2,600,000-circular-mil cable could not have been installed in most of these ducts.

## Insulation

The 1934 edition of the AEIC cable specifications gives an insulation thickness of 350 mils for oil-filled cable having a rating of 69 kv, except that above 2,000,000 circular mils the cable was to have 25 mils more of insulation. The manufacturers first thought that it would be satisfactory to use a thickness of 350 mils for the 2,100,000-circular-mil cable, but that for the 2,800,000-circular-mil cable the extra thickness would be necessary. The thickness used on the only oil-filled 69-kv cable previously

made in this country (in 1930 for Cincinnati) was 406 mils. After some discussion of American and European experience, the thicknesses agreed upon were 315 mils and 330 mils, respectively, for the 2 Chicago sizes.

The Commonwealth Edison Company has been making periodic measurements of the power factors of 2 short oil-filled 132-kv lines put in service early in 1930. The insulation thickness is 719 mils. Figure 3 shows that the power factors at 15 degrees centigrade and operating voltage have remained practically constant, which indicates that the insulation has been quite stable.

About 8 years ago, this utility installed 4 1,000-foot lengths of experimental cable which were tapped to an overhead 132-kv line and were subjected also to heating by means of current transformers. The insulation thicknesses ranged from 386 to 526 mils. For 2 years these cables were

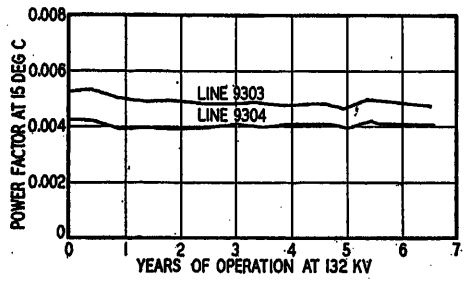

**Figure 3. Power factor of the insulation of 2 commercial oil-filled 132-kv lines**

subjected to daily load cycles with temperatures as high as 75 degrees centigrade. Subsequently, the heating has been continuous to temperatures as high as 85 degrees centigrade, except that occasionally the cables were allowed to cool for power factor measurements. The results of these tests have shown the following:

(*a*) The voltage did not appear to cause any deterioration of the insulation. The maximum stresses ranged from 188 to 250 volts per mil.

(*b*) Temperatures up to about 80 degrees centigrade did not appear to cause any deterioration of the insulation.

(*c*) The changes which have been observed in some of these cables have been of a type that accompanies chemical reactions. If the insulating oil becomes oxidized, chemical action with the metals may result, causing the oil in the cable to darken in color and to increase in power factor, although its dielectric strength remains practically unchanged.

In 1932 it was necessary to remove from a commercial line in Chicago 3,000 feet of 132-kv oil-filled cable that had been installed in 1930, because of deterioration of this kind resulting from oxidation of the oil. The dielectric losses of the cable insulation had increased so much that the cable was fully heated when carrying almost no load. Although extensive investigations were conducted over a period of several years, the origin of this oxidation was not discovered other than that it was due either to overheating of the oil or to contamination of the cable, or both.

This experience indicated again the necessity of preventing overheating of the oil and preventing entrance of air into the cable. Now extensive tests of core oil from the completed cable at the factory, including a power factor or resistance test at 100 degrees centigrade of a sample of oil from each length, and tests of oil used in the field, are made as a routine procedure. Also, as discussed later, special precautions are taken in the field.

The experience with the experimental cables indicates that within limits the thickness of insulation was of little or no importance in connection with the chemical action. Results of tests of power factor, acidity, etc., obtained on samples of core oil removed periodically from the 4 commercial oil-filled 132-kv lines in Chicago have indicated that an initial period of deterioration occurred as a result of minute impurities in the installed line; but this core oil deterioration has caused no perceptible increase in dielectric losses of the cable as a whole. The initial reaction of impurities appears to have taken about 2 years.

In view of all these considerations and of the successful operation of large amounts of oil-filled cable in Chicago and elsewhere, reductions in insulation thicknesses were obviously warranted. The recommended thicknesses are now 315 and 560 mils of insulation for

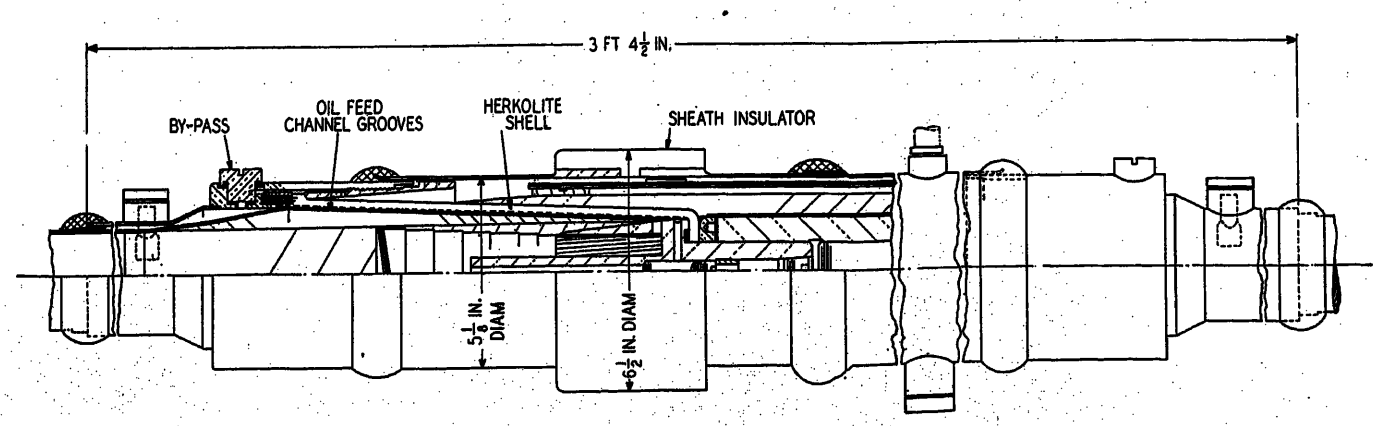

**Figure 4. Herkolite shell stop and feeder joint for 69-kv hollow-core 2,100,000-circular-mil single-conductor oil-filled cable**

cable rated at 69 and 138 kv, respectively, except that slight increases are made for extra-large conductors.

The indications are that, perhaps, even smaller thicknesses may be used from the standpoint of steady voltages, but that further reductions will be retarded by the limitation of impulse strength of the insulation to withstand surges incidental to failures, switching, or lightning.

## Lead Sheath

Until recently, oil-filled cables in the United States were furnished with 2 per cent tin in the lead sheath in order that the cable would present a hard surface during pulling to minimize abrasion. Improvements in the installation of conduit and in the mandreling of ducts to remove small pebbles and other obstructions have made a special hard surface sheathing unnecessary.

Research done at the University of Illinois for the Utilities Research Commission showed that the rate of creep of copper-bearing sheath under tension was usually considerably less than the rate of creep of other sheaths in normal use including 2 per cent tin-lead sheath. The rate of creep is important because oil-filled cables operate continuously with positive internal pressures. Copper-bearing lead may be obtained without any extra expense at present as ASTM grade II lead, or as a mixture of highly refined grade I or III lead and about 0.055 per cent copper having a pure lead content of at least 99.85 per cent.

It was, therefore, decided to use copper-bearing sheath at a saving of almost 5 per cent in the cost of the cable.

In order to prevent excessive expansion of the sheath during the normal life of oil-filled cable, the tensile stress on the sheath has been usually limited to 120 or 150 pounds per square inch, based on the nominal sheath thickness. This corresponds to an internal pressure of 12 or 15 pounds per square inch for the Chicago cables. Important improvements have been made in the manufacture of cable sheaths during the past few years. Better uniformity in sheath thickness and in exclusion of nonmetallic impurities has resulted. It seemed, therefore, especially with copper-bearing lead, that it was feasible to increase the maximum allowable internal pressure with variable pressure reservoirs to 17 pounds per square inch. This was particularly safe for the new lines, since the maximum operating pressures will usually be 8 or 10 pounds. The sheath thicknesses used were $^{9}/_{64}$ and $^{10}/_{64}$ inch, respectively, for the 2,100,000- and 2,800,000-circular-mil cables.

Where differences in elevation give a considerable hydrostatic head of oil within the cable, a double sheath is used, having 2 parallel copper ribbons wound between the 2 sheaths to reinforce it. Such lengths are being installed in Chicago in tunnels under the rivers and where the cable rises to upper levels in a distributing station. The maximum internal pressure in these lengths is 30 pounds.

## Design and Manufacture of Cable

The design and manufacture of oil-filled cable were rather fully developed by the time the first of these 66-kv lines was planned. Consequently, the general process of manufacture did not differ materially from past practice. New features introduced were for purposes of further reducing cost or giving additional assurance of uniformity and freedom from impurities. The cable was furnished by 4 American manufacturers.

The conductor design was of the conventional hollow-core type with a supporting spiral of steel strip. The reduction in insulation thickness has already been discussed. The inner third (approximate) of the insulation consisted of high-density paper tape. The rest was of paper of more conventional density. Previous study had shown these proportions to give a good balance, from both a technical and a cost standpoint. The dielectric power factor, ionization factor, and time of impregnation treatment are not appreciably affected, as they would be with too much high-density paper; and, in return, there is gain in the way of mechanically stronger foundation tapes and increased impulse strength (10 to 15 per cent).

Thoroughly washed wood-pulp paper was used, and a system of testing all paper to assure uniformity and freedom from impurities was followed. Likewise, a system of handling and checking the impregnating oil for uniformity before and after treatment was closely followed. Such oil was used only once, and any oil exposed to the atmosphere or to excessive heat in sealing the cable ends was flushed out and discarded.

The final electrical and physical tests to which every reel length is subjected leave little possibility of nonuniformity. These tests consist chiefly of dielectric power factor and ionization measurements on finished lengths, chemical, electrical, and physical tests on withdrawn samples of core oil, a continuous oil pressure leakage test, and an expulsion test for detection of trapped air.

The change to copper-bearing lead sheath and the

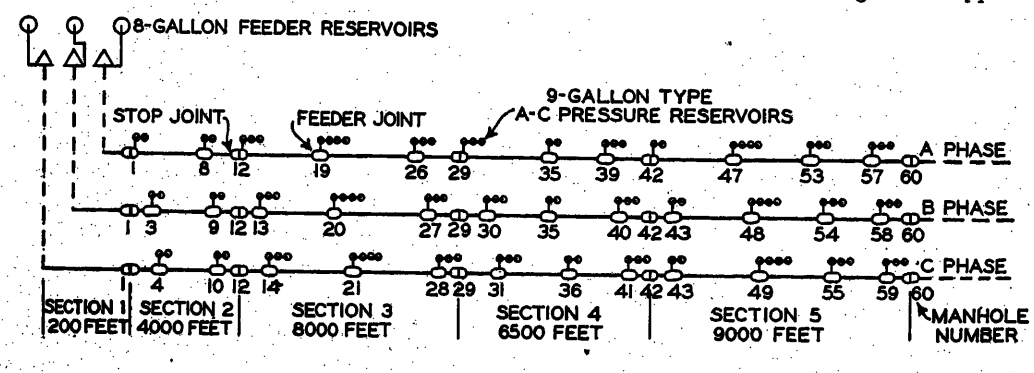

**Figure 5. Typical layout of oil feed system**

Distance between manholes is assumed to average about 500 feet, except adjacent to terminals

factory improvements leading toward a more uniform sheath have already been mentioned. Trouble with single-wall lead sheath, limited to low working pressure (15 pounds per square inch), has been almost negligible in the past. This, of course, is due to the exact control of pressure in oil-filled cable. With sheath of improved quality, practically entire absence of sheath trouble due to working pressure strains may be reasonably expected.

## Design and Manufacture of Accessories

Some general comments on accessories will be given before describing some of them in detail. These high-voltage accessories consist of a surprisingly large number of parts; and, since most of them must be assembled directly in the field, rather than in the factory, it is much more difficult than generally supposed to assure that these parts will always fit together exactly, in the simplest possible way and in minimum time. Perfection of these details requires constant close co-operation between the manufacturer and user. All of the accessories were furnished by one American manufacturer, except that some of the joints for the later lines were furnished by another American manufacturer.

Normal joints and stop joints, and, in most cases, terminals require application of reinforcement insulation wrappings in the field. In Europe these wrappings usually consist of pretreated paper sheet or tape. In this country bias-cut varnished cloth tape has usually been used because it is easier to apply, is more economical, and there is less chance of absorbing impurities during exposure. In the past a vacuum-treated tape made with black asphaltic varnish has been used. This type of varnish is slightly soluble in oil and increases the power factor of oil exposed to it. While this property is not desirable, it has caused no failures in service.

To overcome this, a new and oil-resistant yellow varnished cloth tape was developed and used for the first time in the Chicago 66-kv accessories. (All accessories were rated at 69 kv.) This new tape also has lower dielectric power factor and is mechanically superior.

One primary requirement was that all joints and reservoirs be sufficiently compact to fit in standard-sized manholes and avoid the inconvenience and expense of manhole enlargement. Normal joints of conventional design easily met this requirement as the internal diameters were 5 or $5^1/_2$ inches and the lengths were 32 to $34^1/_2$ inches. A molded or porcelain sheath insulator was incorporated directly in the copper casing, with a resultant material saving in cost and compactness when compared with separate sheath insulators.

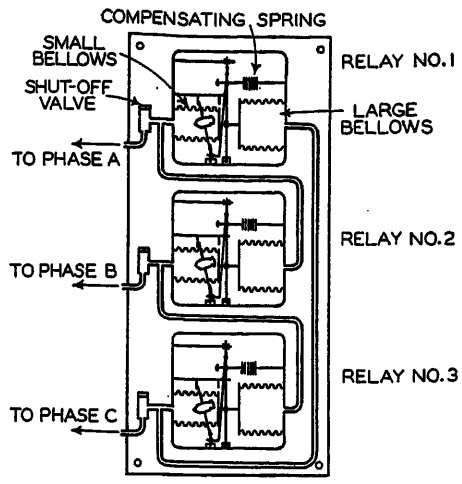

**Figure 7. Diagram of phase differential alarm relays arranged for connection to 3 phases**

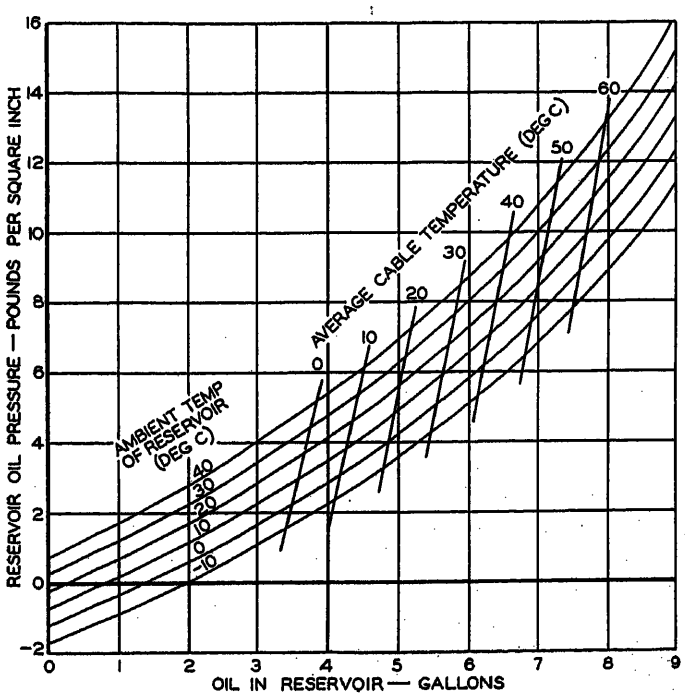

**Figure 6. Operating characteristics of AC reservoirs at one feed point**

At this feed point the oil pressure would be 8 pounds per square inch when the average cable temperature is 40 degrees centigrade and the ambient reservoir temperature is 20 degrees centigrade. At adjacent feed points the pressure on the same phase-section would be higher or lower, in accordance with the intervening hydrostatic head pressure

## Stop and Feed Joints

### Herkolite Shell Joint

The ground contour in Chicago is practically flat. It played no part in determining the best location for stop joints with which a line is segregated into sections, except for a few special cases. Other factors, to be described later, determined this. The length of section in Chicago is of the order of 8,000 feet. Because of pressure drop along the cable core and the requirement of keeping maximum allowable pressure within the limits of single lead sheath, it is necessary to have reservoir feed points at intervals of 2,500 to 3,500 feet along the cable. This requires feed joints at these points, intermediate to stop joints, for purposes of connecting the reservoir to the cable core. As this same requirement holds for stop joints also, there is actually no difference in design but only in method of oil

connection. The stop-joint connection definitely shuts off oil flow across the joint while the feed-joint connection allows this flow by means of a controlled by-pass. These joints will be referred to merely as stop joints.

Prior to the 66-kv Chicago installations, the conventional stop-joint design consisted of 2 porcelain shell terminals placed end to end on a horizontal axis, connected electrically together and enclosed in an oil-filled cylindrical copper casing. Each shell assembly is similar in internal construction and appearance to the usual porcelain cable terminal, except that the petticoats are omitted.[2] A stop joint of the porcelain shell design for the 66-kv Chicago installations would be 9 inches in internal diameter and 49 inches in length. This is too large to fit in standard manholes and too costly for frequent intermediate feed points. The development of a smaller and less costly design was an important requirement.

In designs of this type, Herkolite has decided advantages over porcelain. It consists of paper laminations impregnated and cemented together under heat and high pressure. It is only recently that the art of constructing this material in such shapes as required for stop-joint shells has been perfected. It is stronger than porcelain, both mechanically and electrically, and can be molded and machined to exact dimensions. Another advantage is that longitudinal oil-feed channels can be machined on the inner surface of the shell, whereas, with porcelain a clear annular space of much larger dimensions, and with a corresponding reduction in allowable stressing of the oil gap, is necessary.

Changing to Herkolite shells resulted in a material reduction in diameter and length of stop joint. This in turn allowed simpler and more compact methods of compressing the sealing gaskets at each end of the shell. The result has been a stop-joint design retaining the proved ruggedness of the gasketed shell principle but sufficiently compact for standard-sized manholes and little larger than a normal joint.

Figure 4 shows the new Herkolite shell design. The joint dimensions are 5 inches by $40^1/_2$ inches and its internal volume is only 25 per cent of that of the old porcelain design. Its small size allows the incorporation of a sheath insulator in the joint casing, which is another advantage.

When used as a stop joint, it must have one end hydraulically connected to the central casing enclosure for purposes of maintaining oil pressure in this enclosure. If oil feed to the cable in one or both directions is desired with the stop-joint connection, it is necessary to connect separate reservoirs to one or both ends of the joint. When used as an intermediate feed joint, both ends and the central enclosure are connected to a common reservoir.

In the past, the latter connections consisted of short sections of external by-pass piping with necessary fittings and control valves. This method of connection was followed for the joints developed for the first Chicago 66-kv installation. Further study showed, however, a more economical and better mechanical assembly could be realized by incorporating the by-pass connections directly in the joint casing, as illustrated in figure 4. Oil passages connect the end enclosure to the central enclosure at both ends of the joint. The passages can be shut off or left open at will by means of threaded, gasketed plugs, as shown.

### Condenser Joint

The condenser principle of controlling longitudinal and radial stresses in electrical designs is well known. It consists of intermediate electrodes, usually sheets or strips of metal foil, incorporated in the main body of insulation and resulting in a series of small capacities that divide the electrical stress, with a resulting reduction in dimensions. The condenser principle lends itself to stop-joint design, and the details of earlier developments have been described.[3] The condenser unit, representing the main insulation, of the joint, is factory made and materially reduces the field application of insulation wrappings.

The condenser joint designed for the 66-kv system in Chicago meets the main requirement of fitting in standard-sized manholes. It is $5^3/_8$ inches in internal diameter and $42^7/_8$ inches long. This makes it much smaller than previous similar designs. A porcelain sheath insulator is incorporated in the casing by the method of metal-to-porcelain soldering. The oil stop tubes used in the earlier design of joint were eliminated and the oil stop was obtained at the center of the joint by means of an oil-resistant rubber gasket between the connector and the metal tube forming the central inner surface of the condenser unit; the rest of this inner surface is of insulation. Two spring valves in the connector, one on each side of the oil-stop gasket, control the oil passages between the cores of the 2 cable ends and the 2 halves of the joint. The valves are manipulated during joint construction by treated cloth ribbons threaded along the oil-feed space to levers directly under plug openings in the ends of the joint casings; and the ribbons have no function during service as the valves are then open. Passages for by-passing the oil-stop are incorporated in the joint assembly.

The condenser stop-joint design requires more straight cable in the manhole and more care in assembly than the Herkolite shell design, and requires less time for assembly.

## Reservoir Feed System

Considerable time and expense has been given to the possibility of developing new and more economical designs of oil reservoirs. So far, the cell-type reservoir, consisting of a stack of individual cells with corrugated metal diaphragms enclosed in a cylindrical tank, has proved the best. There are 3 modifications of the cell-type reservoir available, all of which are described elsewhere[4] in detail.

The type *CC* gravity-feed reservoir has all cells connected to a common manifold, with the cells filled with oil. The enclosing tank is open to the atmosphere through a breather. It is, consequently, necessary to elevate this reservoir to obtain pressure feed to the cable. On level ground such as exists in Chicago, this involves expensive feed towers.[1] In the present 66-kv Chicago system, type *CC* reservoirs are used only at the vertical terminal ends where the desired elevation is already available on the switching structure.

The type *DC* balanced-pressure reservoir is similar to the type *CC* except that the enclosing tank has extra length and is sealed full of gas. The gas pressure may be adjusted as desired, and so it is not necessary to elevate this type of reservoir. Rather exact control of the oil feed can be obtained even with reservoirs at different elevations.[5,6] In making the type *DC* reservoir, there is a great deal of brazing and other hand work in paralleling the cells to the manifold, which increases cost.

The type *AC* reservoir has a simpler and more economical cell arrangement. The cells are individually sealed off full of air at atmospheric pressure by automatic welding. Elimination of manifold connections materially reduces hand work and cost. The oil is in the enclosing tank instead of the cells. The pressure on the oil is obtained by forcing in enough oil to compress the air cells, and for this reason is not under complete control. Unlike the type *DC* reservoir, a relatively high oil pressure cannot be obtained when the reservoir is nearly empty, or a relatively low pressure when the reservoir is nearly full. The maximum safe operating pressure is about the same as the limit dictated by the strength of the sheath, i.e., 15 pounds per square inch.

**Table I. Economics of 2,100,000-Circular-Mil 66-Kv Lines in Fall of 1935**

Figures Include Indirect Costs

| | Type of Insulation | |
|---|---|---|
| | Oil Filled | Ordinary |
| **Costs per Mile of Line** | | |
| INVESTMENT: | | |
| Cable | $ 55,900 | $ 71,800 |
| Accessories | 15,740 | 6,010 |
| Installation | 12,800 | 9,580 |
| Conduit, prorated | 21,870 | 21,000 |
| | $106,310 | $108,390 |
| ANNUAL CHARGES: | | |
| Fixed: Cable at 11½ per cent | $ 9,700 | $ 10,040 |
| Fixed: Conduit at 10½ per cent | 2,300 | 2,210 |
| Copper losses | 1,550 | 1,490 |
| Dielectric losses | 320 | 250 |
| Maintenance | 440 | 330 |
| | $ 14,310 | $ 14,320 |
| **Emergency Carrying Capacity, Kilovolt-Amperes** | | |
| Summer | 115,000 | 105,000 |
| Winter | 135,000 | 115,000 |
| **Annual Charges per Kilovolt-Ampere of Carrying Capacity** | | |
| Summer: cents | 12.4 | 13.6 |
| Summer: per cent | (100) | (109) |
| Winter: cents | 10.6 | 12.5 |
| Winter: per cent | (100) | (118) |

In spite of its simplicity, the type *AC* reservoir is not so economical as the type *DC* on hilly contour because the hydrostatic head pressure on the reservoirs at low elevations causes them to become partly filled with oil, thus wasting much of the capacity. With type *DC* reservoirs, it is only necessary to pump up the gas pressure to avoid this.

On reasonably level contour, as in Chicago, a material saving may be realized by using type *AC* reservoirs, even though the efficiency is rather low. The ratio of useful to total capacity of the *AC* reservoirs in Chicago is 50 per cent.

This means that about twice as much manhole space is required for the *AC* reservoirs as for corresponding *DC* reservoirs. In the past it has been customary to install *DC* reservoirs for all 3 phases of single-conductor cable in the same manhole. There is not room to do this with *AC* reservoirs without having a great number of feed points, and so a staggered feed system has been adopted. The reservoirs and the feeder joint for one phase are installed in a given manhole with those for the other 2 phases in usually the next manhole on each side. This method gives ample space with standard-sized manholes and results in economy in the use of feeder joints. Figure 5 illustrates diagrammatically some typical arrangements of stop joints, intermediate feeder joints, and reservoirs for various lengths of line sections used in Chicago.

From 2 to 4 9-gallon type *AC* reservoir units were connected in parallel at each feed point, depending upon the ground contour and the length of cable to be fed. In each section the total useful reservoir capacity was calculated to take care of the thermal expansion of the oil in the cable and accessories over the full annual temperature range, and without exceeding an allowable pressure range for the cable and reservoirs. Thirty per cent or more surplus reservoir capacity was added to the cable oil requirement for emergency use. The pressure limits were 0.5 pound per square inch above atmospheric pressure at the highest point of the section with all surplus exhausted and 17 pounds at the lowest point in the cable at maximum load temperature. In addition, it was necessary to make sure that the available reservoir pressure was sufficient to take care of maximum pressure drop in oil piping connections and along the cable core under all conditions of oil demand by the cable and accessories,[7] due both to temperature changes and exchange of oil between reservoirs caused by the semibalanced system of feed adopted.

Semibalanced pressure feed of the type just described makes the calculation of reservoir settings as a function of cable temperature more difficult and complicated than balanced pressure feed. The general mathematical formulas involved have been published,[6] but yet it is necessary also to resort to a cut-and-try method.

As previously explained, the reservoir oil pressure is practically equal to the gas pressure in the cells. This means that the ambient temperature of the reservoir affects the pressure. The complete pressure-volume-temperature characteristic of the 9-gallon *AC* reservoir is shown in figure 6 (curves slanting upward to right). Using this characteristic, oil pressures and corresponding oil volumes satisfying the following conditions are determined (by cut-and-try):

1. The total volume of oil in all the reservoirs on a phase of a line section at a given cable temperature must be in accordance with the calculated thermal expansion of the cable and accessories at that temperature.
2. The corresponding pressures in each group of reservoirs must lie within the allowable range, and the differences in pressure between reservoir groups must be equal to the hydrostatic pressures due to the differences in elevation.

After a sufficient number of such points has been determined, they are plotted on the reservoir characteristic, and points for equal cable temperature are connected by the vertical cross-lines shown in figure 6. One of these graphs is prepared for each feed point along the line. With the help of these, it is easy to determine the correct reservoir pressure for all stable conditions of cable and reservoir temperature. A short circuit heat run on the first Crawford-Humboldt line showed the calculated reservoir pressures to agree closely with the actual.

## Oil Relay Protection

Oil-filled cable furnishes an opportunity that usually does not exist with solid-type cable to detect leaks in the system, by means of oil relays, before electrical service failures develop from entrance of impurities. Such leaks as slight defects in the sheath, pipe fittings, or lead wipes, may be slow and require weeks to exhaust the reservoirs. Practically all of the leaks that have developed in previous oil-filled lines have been of this type. As long as the reservoirs are not exhausted, positive pressure is maintained and leakage of oil outward prevents entrance of impurities. Fast leaks may be caused by electrical failure or direct mechanical rupture of oil piping. Such fast leaks may exhaust the reservoirs in from 1 to 4 hours, depending upon restrictions offered and oil viscosity, and require a well-organized emergency repair system to prevent such exhaustion.

Regardless of the type of leak that develops, it is obviously desirable that the station operator learn of it as soon as possible. Relays set for minimum oil reservoir volume or pressure are necessarily slow in action, the reservoirs being fairly well exhausted before an alarm comes into the station. With 3-conductor cable, minimum setting relays are the only type that are economically acceptable. For gravity feed with single-conductor cable, differential-volume relays are fast and satisfactory. For single-conductor cable with balanced or semibalanced pressure reservoir feed, fast relay action is obtained by utilizing differential oil pressure between phases.

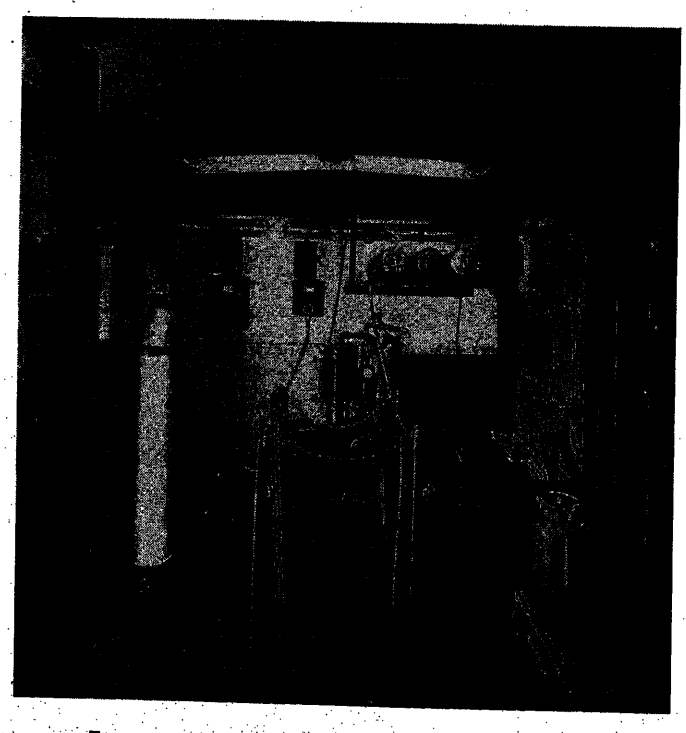

**Figure 8. Trailer over manhole during jointing**

Under normal balanced load conditions, the oil pressure in the different phases varies in the same way at any given point in a section. In case of oil leakage, the pressure decreases in the faulty section. The possibility of pressure in all 3 phases decreasing at exactly the same rate due to leakage is so remote that differential pressure between phases furnishes a reliable way of obtaining fast oil-relay action. It was necessary, however, to devise a phase differential relay that would do 2 things. First, means had to be found for compensating for differences in hydrostatic head pressure between different phases or at different points in any one section, caused by differences in elevation. Second, the reservoir pressure normally varies over a relatively wide range from no load in winter to full load in summer, which in extreme cases might be from one pound to 15 pounds. A differential setting of a small fraction of one pound would be necessary to properly take care of no load conditions, but this same setting would be too sensitive and lead to false alarms under full load conditions. What was desired was a differential relay having an operating differential pressure that would increase proportionately with the line oil pressure.

Both of these things are accomplished in the design shown diagrammatically in figure 7, first used in the 66-kv Chicago system. The relay consists essentially of 2 small opposing sylphon bellows having predetermined differences of area (the smaller has 25 per cent less area than the larger). Each opposing bellows is connected by oil piping to cable or reservoirs in different phases. At any point in the working pressure range the oil pressure in the large bellows must drop 25 per cent below the oil pressure in the small bellows to actuate the mercury switch shown This switch is connected through relay wiring to any desired type of alarm system at the station. By connecting 3 pairs of opposing bellows as shown in figure 7, not only will the relay operate if the pressure in any phase drops 25 per cent below that in the other 2 phases, but it will also operate if there is a 33 per cent increase in any phase, the operation in this latter case being reversed.

Since the compensating spring across each of the large bellows may be adjusted to compensate for and nullify hydrostatic head pressure, the relay is actuated entirely by variable working pressure, or rather by a constant percentage differential pressure within this working range.

## Bonding of Sheaths

With such large lines, the ratio of sheath losses to copper losses in case the sheaths are solidly bonded together would be about 225 per cent. Since experience showed that satisfactory insulating sleeves and methods of bonding had been developed to eliminate sheath losses, they were used.

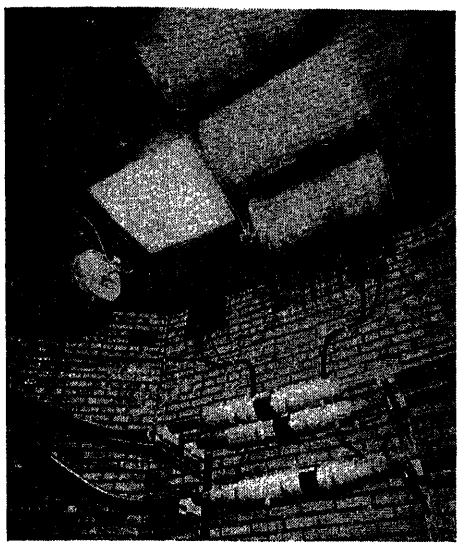

**Figure 9. Accessories installed in manhole**

Lower center—Two normal joints in upper position and Herkolite shell-type feeder joint in lower position. Note sheath insulators in joint casings and porcelain insulators under cables

Top—Four type AC 9-gallon reservoirs connected to feeder joint; reservoirs are placed with valves accessible from manhole opening

Upper center—Two bonding transformers, one connected on each side of sheath insulators in joint casings

Note: Cable and joints are fireproofed before line goes in service

Operating experience in Chicago indicated that for normal maximum loads of about 95,000 kva, the maximum allowable induced sheath voltage to ground from the standpoint of avoiding a-c electrolytic corrosion was about 11 volts. For emergency loading, the corresponding potential is about 15 volts. If the ordinary schemes of bonding were used, such as cross-bonding, then the maximum allowable length of cable between insulating sleeves would be about 320 feet based on normal loading, and somewhat less if based on emergency winter loads. The use of sheath bonding transformers[8] to reduce the voltage to ground to about 50 per cent of the induced voltage between insulating sleeves made it possible to use conduit sections up to 615 feet. During emergencies, the induced voltage from sheath to ground is about 16 volts, but the flow of exciting current through the sheath and bonding transformers reduces this potential to 15 volts with negligible sheath losses.

Cable lengths of the order of 615 feet are satisfactory also from the standpoint of allowable cable movement because during normal loading the daily cable movement at a duct mouth would be 0.4 to 0.55 inch and during emergencies the movement would be 1 to $1^1/_4$ inches. Chicago experience indicates that movements 40 or 50 per cent larger would be safe from the standpoint of obtaining long life of the sheath in the manhole without cracking.

The 3 phases of the lines had to be transposed frequently in order to minimize the induction of voltages and currents in other cables in the same conduits. The piping from the reservoirs was connected to the joints through pipe insulators. On end laterals, the practice was to ground the potheads and to have an insulating sleeve in the first joint.

## Installation

Theory and experience have indicated that special care must be exercised, not only in the factory but also during installation and operation, to avoid the ingress of impurities in oil-filled cable. In view of this situation, and the need for considerable engineering work on development of suitable accessories and on the reservoir layout system, it was found desirable to have more engineers employed in connection with the new lines than would have been the case with cable of the ordinary type. Such engineers also follow the work continuously during installation and are of considerable assistance to the field force.

The installation of the various types of joints requires in each case more than the usual working day of 8 hours. As a matter of efficiency in the use of equipment and man power, a new method of underground work was developed, that is, to construct in series all 3 joints and related work in a manhole on a continuous basis. In the 1937 work, 2 field crews each comprising 3 gangs and substitutes worked continuously 7 days a week, night and day, doing manhole work. By this means, the overtime payroll is kept down to a negligible amount and the efficiency of supervisors and splicers is not impaired by long working hours. Another advantage is that practically all the work in a manhole is completed in *one* set-up with a substantial saving in transportation and labor costs.

A further improvement adopted is the use of 2 specially built trailers. The trailer is set over a manhole opening, access to which is provided by means of an opening in the floor. This arrangement provides increased protection for the men against inclement weather and traffic hazards, in addition to keeping moisture and dirt from entering the manhole. See figure 8. Gasoline-engine-driven generators were used for power supply for equipment such as oil heater, water pump, air blower, and vacuum pump. Excellent lighting, which is conducive to good workmanship and a minimum of fatigue, was also provided thereby.

The following items briefly outline checks or procedures in the field to carry out the principle of preventing the ingress of impurities in the lines:

1. A final expulsion test and pressure check are made on each reel of cable immediately before installation.

2. The oil pressure in temporary reservoirs is frequently checked to make sure that the cable is under positive pressure and adequate oil supply is available for the flushing during jointing.

3. Care is taken during the installation to maintain the cable oil pressure *above* atmospheric pressure at all times. Only 2 short-time exceptions to this rule are permissible, namely:

(*a*) At the end of the time of installing the cable in the duct, when the source of oil feed to the cable is transferred from the reel reservoir to the temporary reservoir in the manhole.

(*b*) On soldering the connectors onto the conductors.

4. Vacuum tests are made on each completed joint prior to final filling with degasified oil.

5. The application of vacuum is always localized, i.e., the principle of not subjecting a cable length to vacuum in the field is followed.

6. Flow checks are made shortly after completion of each line section in order to determine the presence, if any, of partial or complete restrictions to oil flow in the joints or in the connecting piping.

7. Impregnation checks are made shortly after completion of joint work on each section, as an over-all check on the presence of air.

Tests and procedures used in the field designed to prevent the use of contaminated or overheated oil are as follows:

1. All degasified oil used in constructing the joints, filling the temporary oil reservoirs, and for additions to the permanent reservoirs is treated in Chicago. Such oil is the same as that furnished in cable and in reservoirs. Each lot of treated oil is required to meet the following requirements:

| Item | Temperature | Limiting Values | |
|---|---|---|---|
| | | Maximum | Minimum |
| Power factor—per cent | 100 deg C | 0.50 | |
| Resistivity—ohms per $cm^3$ | 100 deg C | | $15 \times 10^{12}$ |
| Gas content—per cent | Room | 1.0* | |
| Dielectric strength | Room | | 25 kv 1 min. |
| Color number | | | 1½ minus |
| Organic acidity—mg KOH/g | | 0.020 | |

* Reduce to 0 degrees centigrade and 76 centimeters mercury.

2. The maximum temperature to which the oil is subjected in the degasifying plant is 100 degrees centigrade.

3. After each soldering operation during installation of joint connectors, oil is drained from the cable to remove overheated oil and residual flux.

4. Dried oil used for flushing purposes during the construction of joints is heated by indirect means to 110–125 degrees centigrade. The supply of heated oil is changed daily and the tank is cleaned frequently.

5. The principle of not soldering accessories or piping containing oil that could thereby be overheated is followed.

6. Hot flushing oil is admitted to the joint casings after wiping and before proceeding with the vacuum and filling treatment.

7. All piping is swabbed, flushed, and temporarily sealed preparatory to installation. Wherever possible, the piping is vacuum treated and filled with oil at the time the joints are treated. When this cannot be done, the tubing is treated and filled separately and then joined to the filled joint with oil flowing out of the fittings to preclude entrance of air or moisture.

A view of completed construction work, excepting fireproofing, in a manhole is shown in figure 9.

Before the installation of the 1936 line was considered completed, a thorough load test at reduced voltage was made. One purpose of the load test was to heat the line and distribute any traces of moisture that might have entered the joints or oil system. Records of load currents, conductor temperatures, oil volumes and pressures in reservoirs, induced sheath voltages, cable movement, and performance of oil-pressure signal system equipment were obtained. The results were satisfactory, inasmuch as the performance under load agreed closely with the calculations on which the line design was based.

When the load test was made on the 1936 line, other future lines of the same type were under consideration and it was felt desirable to check thoroughly the many new developments incorporated in the line. Such was not considered necessary for the 1937 installations. In general, it appears probable that, for future oil-filled lines, special heat runs will be unnecessary.

The installation tests of 140 or 150 kv direct current for 15 minutes were made with the permanently installed kenotrons of the utility.

## Italian State Railway Acquires New Electric Trains

The first of several new electric trains, being constructed by Società Breda for the Italian State Railway system, recently was placed in service. Said to be capable of attaining a maximum speed of 180 kilometers (about 112 miles) per hour, the train consists of 3 intercommunicating cars resting on 4 2-axle carriages, is 62.5 meters long, has a maximum breadth of 2.92 meters, and weighs 100 tons. The motive power is supplied by 6 3,000-volt series-wound d-c motors with a total rating of 1,200 horsepower. Two motors are mounted on each of the end carriages, and each of the middle carriages carries one motor. Air braking is used. Each of the 3 cars is air conditioned; the middle car contains a single first-class salon with 35 seats, and the end cars contain second-class compartments with seating accommodations for 59 passengers. The kitchens are in one end car, and the baggage and mail compartments in the other.

# Insulation Strength of Transformers

## Purpose

THIS PAPER is presented to review the work of the transformer subcommittee in setting up standards for the insulation strength of transformers. An effort will be made to present the steps in the development of the insulation co-ordination problem in regard to transformers and to clarify certain points on which misunderstandings have arisen. The present insulation strength standards and tests will be given so that the margin between the protective level and insulation strength as demonstrated by test may be given proper consideration.

As the transformer subcommittee has before it a proposal for changes in standards necessary for the use of kilovolts as the basis for impluse tests instead of the use of the spacing of the test (rod) gaps, these proposals will also be given.

## General

Transformers have an impulse insulation strength as actually demonstrated by the standard insulation tests, and an ultimate breakdown strength somewhat higher. The margin between the demonstrated strength and the ultimate breakdown strength represents the safety factor which is provided by the designer. Logically, only the strength as demonstrated by test should be used in the application and co-ordination of transformers. In the operation of the transformers, a reasonable margin between the tested strength of the transformer and the protective level should be established and maintained as an additional safety factor in view of unpredictable conditions.

The insulation strength of transformers may be considered from 2 points: the 60-cycle strength and the impulse strength. The 60-cycle strength determines the ability of a transformer to withstand continuous 60-cycle voltages, most switching surges, and arcing ground overvoltages. The impulse strength is that strength which resists lightning overvoltages and the higher switching surges. Initially the insulation was determined by 60-cycle tests as a measure of ability to withstand all normal service requirements but as experience was gained more attention was given to the impulse strength. The present 60-cycle insulation test level has been in existence for some time and appears to have been adequate.

Before the present knowledge with regard to lightning and transformer insulation properties was obtained experience was the only guide. In the development of transformer insulation to withstand lightning overvoltages, changes in design were made where experience indicated it was necessary. Accordingly, when sufficient knowledge of lightning overvoltages and transformer insulation properties were obtained insulation levels and the corresponding insulation tests could be intelligently set up. The 60-cycle test has been retained and an impulse test has been added as a means of demonstrating impulse strength of the transformer.

## Historical

The standards for insulation tests have had a varied history. The first insulation standards were adopted June 26, 1899, and were as follows, as applicable to transformers:

**38.** The following voltages are recommended for apparatus not including transmission lines or switchboards

| Rated Terminal Voltage | Capacity, Kilowatts | Testing Voltage |
|---|---|---|
| Not exceeding 400 | Under 10 | 1,000 |
| Not exceeding 400 | 10 and over | 1,500 |
| 400 and over, but less than 800 | Under 10 | 1,500 |
| 400 and over, but less than 800 | 10 and over | 2,000 |
| 800 and over, but less than 1,200 | Any | 3,500 |
| 1,200 and over, but less than 2,500 | Any | 5,000 |
| 2,500 and over | Any | (Double the normal rated voltages) |

Modifications were made from time to time during the intervening years until the present insulation standards for the low frequency tests were issued May 1930. These are essentially as given below:

### Dielectric Test

**13–400 Standard Test Voltage to Be Applied Between Windings and Between Windings and Ground.** Transformers and other induction apparatus, except as listed below, shall be tested by applying between each winding successively and ground an alternating voltage from an external source of twice the rated voltage of the circuit to which the winding under test is to be connected plus 1,000 volts. All other electric circuits and metal parts shall be grounded during this test.

**13–401 Standard Test Voltage Between Turns to Be Induced in the Windings.** Transformers and other induction apparatus, except as listed below, shall, in addition to the tests provided in 13–400, be tested by applying between the terminals of one winding a voltage of twice the normal voltage developed in that winding, corresponding voltages being induced in the free windings.

### Exceptions:

(*n*) Transformers with graded insulation: Transformers, if for use on circuits of 66,000 volts and above, and having windings directly and permanently grounded and designed to take advantage of the fact that the neutral or other point of the circuit is to be directly and permanently grounded,* shall be tested by induced voltage with connections so made that the ungrounded or line

A report of the transformer subcommittee of the AIEE committee on electrical machinery compiled by J. E. Clem and A. C. Monteith; recommended for publication by the AIEE committees on power transmission and distribution, protective devices, and electrical machinery. Manuscript submitted March 20, 1937; released for publication April 24, 1937.

Personnel of transformer subcommittee of AIEE committee on electrical machinery: I. W. Gross, *chairman;* J. E. Clem, *secretary;* B. S. Bundy, L. H. Hill, V. M. Montsinger, A. C. Monteith, J. R. North, M. S. Oldacre, H. B. Scholz, and F. J. Vogel.

* A circuit shall be considered directly grounded when transformer connections and characteristics are such that not less than twice the combined rated line currents from the bank or banks of transformers supplying the circuit will flow to ground when a line is grounded at a terminal of any of the transformers supplying the circuit.

## Table I. Progress of Requirements for Impulse Strength* of Transformers

| Limit of Rated Trans. Voltage (Kv) | November 1930 | | December 1932 | | January 1933 | | December 1934 | | January 1937 | |
|---|---|---|---|---|---|---|---|---|---|---|
| | No. of Line Insulators | Impulse Flashover (Kv) | Co-ordination Gap Spacing (Inches) | Impulse Flashover (Kv) | Test Gap Spacing (Inches) | Impulse Flashover (Kv) | Test Gap Spacing (Inches) | Impulse Flashover (Kv) | Test Gap Spacing (Inches) | Impulse Flashover (Kv) |
| 1.2 | | | | | | | 0.8 | 32 | 0.8 | 32 |
| 2.5 | | | | | | | | | 1.6 | 53 |
| 5.0 | | | | | 2.25 | 63 | 2.2 | 63 | 2.2 | 63 |
| 8.7 | | | | | 3.375 | 81 | 3.3 | 80 | 3.3 | 80 |
| 15.0 | | | 4.25 | 95 | 4.75 | 102 | 4.5 | 100 | 4.5 | 100 |

| 287.5 | | | | | | | 88.0 | 1,360 | 88.0 | 1,360 |
| 345.0 | | | | | | | 105.6 | 1,620 | 105.6 | 1,620 |

* Flashover voltages lifted in table are present day values and are crest of $1\frac{1}{2} \times 40$ microsecond impulse wave with flashover on wave tail (minimum wave to produce flashover of square cut rod gap).

terminals shall receive test voltage to ground not less than 2.73 times the normal voltage developed by the winding, plus 1,000 volts.

If testing circuit conditions are such that the induced voltage test just specified does not at the same time produce between adjacent 3-phase line terminals twice the related voltage of the circuit, additional test with the same or other circuit connections shall be made to produce this voltage between line terminals; i.e., twice the rated circuit voltage.

Transformers having graded insulation shall be so marked.

Some time prior to the 1930 revision it was realized that it was necessary to supplement the low-frequency test with an additional test to insure that transformers were insulated more in proportion to the overvoltages to which they might be subjected. In some cases line insulation was increased to reduce lightning outages. It was becoming more and more recognized that the most important source of the damaging overvoltages was lightning and that some effort should be made to correlate the insulation strength with the lightning overvoltages. Considerable discussion on this problem took place in the transformer subcommittee and a series of reports have been issued from time to time, the essential features of which are given in table I and discussed in the following paragraphs.

In November 1930[31] the first report was issued in which it was required that

> Apparatus conforming with the standards of dielectric test should be so designed that their impulse strength against lightning is greater than the impulse flashover voltage to earth of nonshielded suspension type insulators. . . .

and it was also proposed that no line entering the station have insulation exceeding these values for half a mile from the station.

The manufacturers tried to design to these levels but in as much as there was no established testing procedure, it is not possible to know whether they were successful.

This was the first effort at what for a long time has been called "co-ordination of transformer insulation." The use of insulators as the basis of comparison did not last very long for many reasons, the most important being the obvious disadvantage of the large and inflexible steps and the fact that the proposed reduction of the last half mile of line insulation to these values was not generally adopted.

In December 1932[21] a revision was published in which the impulse strength against lightning was given in terms of the spacing of a rod (co-ordination) gap of specified construction and the tabulation was extended to include the 15-kv circuit.

The previous proposal of November 1930 balanced the transformer insulation strengths against a specified number of line insulators in half a mile of line adjacent to the station while the revision of December 1932 balanced it against the "co-ordination gap." It was thought if one flashover point was established where the lines entered the station instead of 3 or 4 spaced one half a mile out that the single gap should be about 10 per cent less in flashover value to establish the same level on account of attenuation. Consequently, the spacing of co-ordination gap was selected to give about 10 per cent less flashover than the line insulators. However, in comparing the impulse flashover values in table I it should be remembered that the numerical values on which the comparison was made then was not the same as those used today.

The transformer subcommittee continued its studies and in January 1933 presented[16] a tentative test code. In this test code the use of the term "co-ordination gap" was definitely abandoned as a means of expressing transformer insulation strength. The use of test gaps at 110 per cent of the co-ordination gap spacing was introduced, the tabulation was extended to include the 4,600-volt class, a standard test wave was established, and a schedule of 5 tests adopted. These tests are as follows:

TESTS TO BE APPLIED

Each terminal of the transformer to be tested should be tested with waves of positive polarity having respectively:

1. A voltage not more than 10 per cent less than the minimum impulse voltage permitted by the specified test gap directly connected to ground.

31. For all numbered references see list at end of paper.

2. A voltage just sufficient to flashover the specified test gap directly connected to ground.

3. A crest voltage at least 10 per cent greater than the minimum flashover voltage of the test gap directly connected to ground.

4. A voltage of sufficient magnitude to flashover the bushing.

5. A voltage as great as that specified in number 3 or 4, but with the means for maintaining the excitation voltage across all parts of the winding.

In December 1934[9] the number of impulse tests was reduced from 5 to 3 and the tabulation was extended up to 345 kv and down to 1.2 kv. A slight modification of the impulse test gap spacings, and a change in the low-frequency test voltage for transformer ratings 23 kv and below were also reported.

At this time a standard bushing level was considered. The values adopted were 15 per cent above the co-ordinating gap for distribution transformers. The power transformer bushings 69 kv and above followed the values, but on account of past practice with power transformers in the lower voltage classes, it was felt that the bushing should have a higher level and values essentially those of table III were adopted.

In January 1937[2] some slight changes were reported. These changes consisted in the correlation of circuit voltages with corresponding maximum apparatus voltage

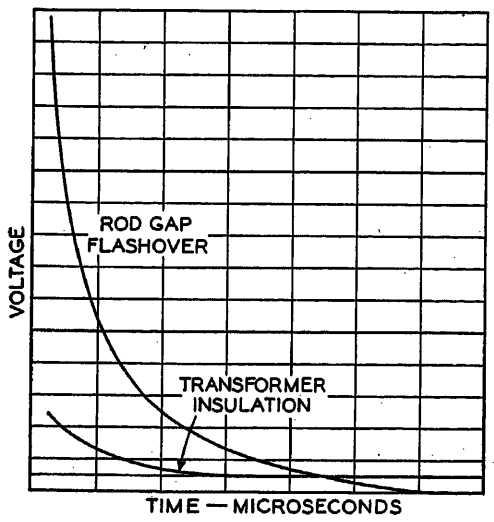

**Figure 1. Typical volt-time characteristics of rod gap and transformer insulation**

ratings and the conclusion of the low-frequency test voltage in the tabulation. The wording of the 3 impulse tests were changed slightly to read as follows:

IMPULSE TESTS

(*a*) Apply a wave just sufficient to cause flashover of the specified test gap under existing conditions of humidity and air density.

(*b*) Apply a wave sufficient to cause flashover of the bushing. For this test the applied voltage must be at least 5 per cent in excess of the standard minimum flashover voltage for the standard bushing under standard conditions of humidity and air density.

*Note*—When oversized bushings are used they shall be equipped with suitable gaps to provide the same standard minimum impulse flashover as for the standard bushing.

(*c*) Apply a wave having a crest not less than 90 per cent of the standard minimum flashover voltage of the standard bushing under existing conditions of humidity and air density. No flashover of the bushing shall occur during the test.

## Comments

### INSULATION STRENGTH "YARDSTICK"

It has frequently been asked why insulators and rod gaps were initially used as a means of expressing insulation levels. The reason is as follows: Impulse testing was a new development and the technique had not been established. The impulse flashover of a given number of insulator units or of a given gap spacing was reported differently by different laboratories. It was felt that the actual voltage required to flashover a specified rod gap or a specified number of insulators would be the same in all the laboratories regardless of the variation in reported values. Consequently it was felt that if the impulse strength level of a transformer was specified in terms of the impulse flashover of a given number of line insulators or a given gap spacing, it would result in a common "yardstick" for expressing the insulation strength of transformers.

### POLARITY OF TEST WAVE

Many have asked why the positive polarity wave was selected instead of a negative polarity wave. These questions were prompted by the fact that it was later definitely established that the severest lightning overvoltages on transmission lines were of negative polarity. At the time the positive wave was selected, which actually was some time prior to the issuance of the proposed impulse test code, it was not generally accepted that the negative waves were predominant in the lightning overvoltages on transmission lines. The reason for the adoption of a positive polarity is the fact that the problem of impulse testing was in the development stage at the time, and laboratory technique was being built up with the use of positive polarity. As a result, by far the greater amount of impulse data had been obtained with positive waves and it was felt that co-ordination could be accomplished to better advantage if the positive wave was selected for transformer testing.

### CO-ORDINATION GAP AS PROTECTIVE DEVICE

When the problem of co-ordination was first considered the reduced line insulation as proposed in November 1930 or the "co-ordination gap" as proposed in December 1932 was presumed to offer adequate protection to transformers. The expression "co-ordination gap" signified not only a particular type of gap, but also a particular spacing for each voltage. This idea that the "co-ordination gap" was an adequate protective device has persisted in spite of the increased knowledge of the divergence of volt-time characteristics of rod gaps and transformer insulation.

The volt-time characteristic of rod gaps and transformer insulation may be the same in general, but they are decidedly different in detail. As the time to flashover becomes shorter the flashover voltage of the gap increases considerably faster than the breakdown voltage of the transformer insulation. This is illustrated in figure 1, and it is very evident from the curves that the "co-ordination gap" offers no protection when the time to gap flashover is short and when protection will most likely be needed. In order to establish the same margin of protection at half a micro-

second, it would be necessary to reduce the gap spacing to about $^1/_2$ to $^1/_3$ of the co-ordination gap; If this was done the number of service interruptions would very likely be increased.

In general it may be said that plain air gaps or rod gaps will limit by flashover the magnitude of the stress applied to station apparatus but their volt-time characteristics are so different from transformer insulation that they may be considered as affording a definitely limited amount of protection. The economics of the situation and the grade of service acceptable are the governing factors.

### Standard Insulation Levels for Transformers

The transformer subcommittee at its meeting January 27, 1937, authorized the change from gap spacing to kilovolts as the measure of transformer insulation strength. A new tabulation is presented in table II which converts the present test code values from inches to kilovolts, and omits the minimum flashover voltage of the gap. There is given, also, the low-frequency test voltage values. The kilovolt values are practically identical with those required by the present test code through the requirement of bushing flashover, although the testing procedure has been altered. A discussion of the impulse test values in the light of the present test recommendations and basic insulation levels adopted by the EEI-NEMA joint committee on insulation co-ordination may be helpful.

The present impulse test code provides for application of 3 1.5x40 positive test waves to transformers, with specified tolerances, one a full wave at 90 per cent of the flashover voltage of the proposed standard bushing, one a wave chopped late on the tail by the test gap, and one a wave chopped early on the tail by bushing flashover with an applied voltage of 105 per cent of the standard flashover voltage of the bushing. Expressed in per cent these are:

Applied voltage—test gap flashover = 100 per cent
Applied voltage—bushing flashover = 110 per cent
Applied voltage—full wave test = 95 per cent

except for power transformers rated 69 kv and below where the bushings have an impulse flashover higher than on distribution transformers which results in correspondingly higher impulse test voltages being applied to power transformers. This higher impulse strength of power transformers in the 69 kv class and below is inherent in these transformers and is required by the present test code which bases maximum impulse tests on the flashover of the transformer bushing.

It should be noted that the basic insulation levels adopted January 1937 by the EEI-NEMA joint insulation committee on system insulation correspond to the test gap flashover (minimum impulse flashover—full wave) of 100 per cent given above. The test gap flashover voltages are listed in table I in the January 1937 columns. Therefore in order to insure that when the tests are expressed in kilovolts they shall be of the same severity as when formerly ex-

**Table II. Standard Insulation Test Level—Distribution and Power Transformers**

| 25,000 | 25.0 | 140 | 165 | 2.5 | 112 | 130 | 2.0 | 34 |
| 34,500 | 34.5 | 185 | 210 | 3.0 | 153 | 180 | 3.0 | 51 |
| 46,000 | 46.0 | 240 | 275 | 3.0 | 195 | 225 | 3.0 | 70 |
| 69,000 | 69.0 | 340 | 395 | 3.0 | 245 | 290 | 3.0 | 93 |
| 92,000 | 92.0 | 445 | 515 | 3.0 | 345 | 405 | 3.0 | 139 |
| 115,000 | 115.0 | 540 | 625 | 3.0 | 445 | 515 | 3.0 | 185 |
| 138,000 | 138.0 | 645 | 750 | 3.0 | 540 | 625 | 3.0 | 231 |
| 161,000 | 161.0 | 750 | 870 | 3.0 | 645 | 750 | 3.0 | 277 |
| 196,000 | 196.0 | 900 | 1,055 | 3.0 | 750 | 870 | 3.0 | 323 |
| 230,000 | 230.0 | 1,050 | 1,210 | 3.0 | 900 | 1,055 | 3.0 | 393 |
| 287,500 | 287.5 | 1,290 | 1,495 | 3.0 | 1,050 | 1,210 | 3.0 | 461 |
| 345,000 | 345.0 | 1,540 | 1,785 | 3.0 | 1,290 | 1,495 | 3.0 | 576 |
| | | | | | 1,540 | 1,785 | 3.0 | 691 |

* These circuit voltages are those agreed upon by the "NEMA-NELA Preferred Voltage Ratings for A-C Systems and Equipment," NELA publication No. 043, page 12, and supplemented by the AIEE transformer subcommittee, Electrical Engineering, January 1937, page 32, table I.
** These values represent the maximum transformer voltage rating normally associated with the corresponding insulation level. These figures may be used to designate the insulation class.

pressed in terms of gap spacing, the following percentages apply:

| | |
|---|---|
| Basic insulation level | = 100 per cent |
| Applied voltage—chopped wave test | = 110 per cent |
| Applied voltage—full wave test | = 95 per cent |

When the impulse flashover of the bushing is higher than the required minimum standard of 105 per cent of the test gap flashover, as for power transformers 69 kv and below, the applied voltage for the chopped wave and full wave test is 105 per cent and 90 per cent respectively of the actual bushing flashover voltage recommended as standard.

In table II a minimum time to flashover is given. This is to insure a reasonable length of wave so as to retain the severity of the present tests.

## Insulation Level

DISTRIBUTION (500 KVA AND LESS) TRANSFORMERS
POWER (LARGER THAN 500 KVA) TRANSFORMERS

*A. Insulation Level*

1. Table II gives the proposed standard relationship between the established rated circuit voltages and corresponding limits of rated transformer voltage, and the standard insulation level for distribution (500 kva and less) and power (larger than 500 kva) transformers.

2. The standard insulation levels are expressed in terms of the full wave impulse test voltage, the chopped wave impulse test voltage with minimum time to flashover, and the low-frequency test voltage. The impulse test voltage is the crest value of the standard 1.5x40 microsecond impulse test wave.

*B. Choice of Insulation Level*

1. The insulation level for a given installation should be selected in accordance with the operating conditions, the volt-time performance characteristic of the protective equipment, and economics.

BUSHING CHARACTERISTICS

1. Table III gives the minimum impulse flashover voltage (full wave) with the positive 1.5x40 microsecond wave, and the guaranteed 60-cycle dry and wet flashover voltage, for distribution and power transformers. These values are for standard atmospheric conditions.

2. The impulse flashover voltage and the guaranteed 60-cycle flashover voltages are subject to a tolerance of minus 5 per cent.

To keep the impulse flashover voltage of transformer bushings 5 per cent above the impulse flashover of the transformer test gap, a slight revision in bushing characteristics is being considered. All changes have resulted in slight increases in bushing impulse flashovers.

BUSHING GAPS

The practice of supplying transformers with bushings gapped to meet the recommended flashover standards has been in use some 3 years or so. It has been maintained by some users of such transformers that the gaps are undesirable in many cases, particularly in the lower voltage power transformer class. It would be particularly helpful to the transformer subcommittee to get the opinion of others on the desirability of equipping transformer bushings with gaps.

**Table III. Bushing Characteristics—Distribution and Power Transformers**

| Rated Circuit Voltage (Volts) | Limit of Rated Trans. Voltage (Kv) | Bushing Flashover in Kilovolts: Distribution Trans. 500 Kva and Smaller — Impulse* Flashover Average | 60-Cycle Guaranteed Flashover — Dry | 60-Cycle Guaranteed Flashover — Wet | Power Transformers Larger than 500 Kva — Impulse* Flashover Average | 60-Cycle Guaranteed Flashover — Dry | 60-Cycle Guaranteed Flashover — Wet |
|---|---|---|---|---|---|---|---|
| 120, 240, 480, 600 | 1.2 | 34 | 11 | 7 | 66 | 25 | 12 |
| 2,400, 2,500 | 2.5 | 56 | | | | | |
| 4,160, 4,330, 4,800 | 5.0 | 66 | 27 | 18 | 84 | 40 | 27 |
| 6,900 | 8.66 | 84 | 40 | 27 | 105 | 50 | 35 |

* 1½x40 microsecond positive full wave.

## Proposed Standard Impulse Tests

IMPULSE TEST

A proposal is being considered to simplify the present impulse test code as follows:

The standard impulse test shall consist of 2 applications of a specified chopped wave followed by one application of a full wave. Either a positive or a negative wave may be used. The chopped wave may be obtained by flashing over either the bushing or an external rod gap.

1. *Chopped Wave.* For this test the applied voltage wave shall have a crest voltage and time to flashover in accordance with table II, columns 4 and 5 or columns 7 and 8 respectively for distribution transformers (500 kva and less) or power transformers (larger than 500 kva) respectively.

2. *Full Wave.* For this test the applied voltage wave shall have a crest value in accordance with table II, column 3 or column 6 for distribution and power transformers, respectively. For this test bushing gaps may be removed and negative wave can be used.

## Standard Low-Frequency Tests

The standard low-frequency test consists of an applied potential test followed by an induced potential test.

1. *Applied Potential Test.* The applied potential test shall be made by applying between each winding successively and ground, a low-frequency alternating voltage from an external source in accordance with table II, column 9. All other electric circuits and metal parts shall be grounded during the test.

2. *Induced Potential Tests.* The induced potential test shall be made by applying between the terminals of one winding a voltage of twice the normal voltage developed in that winding.

If testing circuit conditions are such that the induced voltage test just described does not at the same time produce twice the rated voltage of the circuit between adjacent line terminals of a 3-phase transformer an additional test with the same or other circuit connections shall be made to produce this voltage between line terminals.

## The AIEE Summer Convention This Month at Milwaukee, Wis.

ALL ARRANGEMENTS have been made for the fifty-third annual summer convention which will be held at Milwaukee, Wis., June 21–25, 1937, with headquarters in the Schroeder Hotel. The summer convention committee, under the chairmanship of K. L. Hansen, has arranged an attractive program of sports, inspection trips and entertainment built around the annual business meeting, 10 technical sessions, and 1 general session. The convention also affords opportunity to combine business with a few days vacation. For a more complete account of the convention features, including a schedule of events and the tentative technical program, see ELECTRICAL ENGINEERING for May, pages 635–9.

### TECHNICAL PROGRAM

The tentative technical program as announced in the above reference is complete with the following changes. The paper "Approximating Potier Reactance" by Sterling Beckwith, Allis-Chalmers Manufacturing Co., has been added to the session on power generation and electrical machinery scheduled at 10:00 a.m., Thursday, June 24. The date for scheduling the conference on field problems has been interchanged with the date for scheduling the conference on electrical apparatus for 3-phase arc furnaces. The programs for these conferences are as follows:

**Wednesday, June 23**

**2:30 p.m.—Conference on Field Problems, Ernst Weber, presiding**

1. Introduction: The field concept in physics and engineering
2. Topics:
   - (*a*) Graphical field plotting (special applications to magnetic fields)
   - (*b*) Analytical solutions of fields (special applications to heat problems)
   - (*c*) Conformal representation (special applications to electric fields)
   - (*d*) Experimental methods of field exploration (special applications to hydrodynamics)

**Thursday, June 24**

**2:30 p.m.—Conference on Electrical Apparatus for 3-Phase Arc Furnaces**

1. Introduction: Modern arc furnace apparatus—lantern slides—Samuel Arnold
2. Discussions:
   - (*a*) Kilovolt-ampere ratings—Frank Brooke
   - (*b*) Voltages—C. C. Levy
   - (*c*) Reactance—F. V. Andreae
   - (*d*) Regulation—F. E. Ackley
   - (*e*) Protective equipment—E. L. McClure
   - (*f*) Methods of supplying power—L. W. Clark

### DOCTOR VANNEVAR BUSH TO SPEAK

One of the high lights of the summer convention will be a lecture Tuesday evening by Doctor Vannevar Bush on the subject "The Engineer and His Relation to Government." This meeting very appropriately precedes the general session Wednesday morning on economic aspects of engineering and Institute activities.

This evening lecture will be open to the public, fellow-engineers from other founder

Vannevar Bush

and local societies and the ladies as well. The Engineers' Society of Milwaukee has already chosen to dispense with its regular June meeting and join with the Institute on this occasion. Special plans are also being made for groups to come from Chicago and Madison for this evening lecture.

Doctor Vannevar Bush is noted for his achievements in research and his contributions to engineering progress and to technical education. For the development of the product integraph he was awarded the Levy Medal of the Franklin Institute in 1928. For "his development of methods and devices for application of mathematical analysis to problems of electrical engineering" he was awarded the AIEE Lamme Medal for 1935. He has lectured at Cambridge, England, at the International Congress of Applied Mechanics and he has delivered the Josiah Willard Gibbs lecture of the American Mathematical Society. Doctor Bush designed the differential analyzer and under his direction the network analyzer at Massachusetts Institute of Technology was built. He is also known for his contributions to the development of vacuum tubes and for his investigations in electric power transmission, transients in machines, and dielectric phenomena.

The career of Doctor Bush as a teacher has been no less notable than his work in research and in 1932 he was appointed vice-president and dean of the school of engineering of the Massachusetts Institute of Technology.

### SPORTS

Excellent facilities will be available for golf and tennis enthusiasts. Golf events will include competition for the Mershon, Lee, and District Team Trophies and special events. Golf on Monday and Tuesday will be on the course of the Tripoli Country Club, on Wednesday and Thursday at the Ozaukee Country Club, and on Friday at the Bluemound Golf and Country Club. Qualifying play for the Mershon Trophy, which is on a handicap basis, will be on Monday with match play rounds on Tuesday, Wednesday, and Thursday. The Lee Trophy in golf which is on a handicap basis, 36 holes of medal play, will be on Monday and Tuesday.

The District team event, the winner of which is decided on the basis of the gross medal score for the 4 lowest out of a team of 6 players from each District for 36 holes will be played Monday and Tuesday. It is suggested that each District organize a team before leaving for the convention.

The annual tennis tournament for the Mershon Tennis Trophy will be held on the clay courts of the Milwaukee University School. Numerous prizes for both golf and tennis have been provided and these will be awarded at the informal farewell dinner to be held Friday evening at the Bluemound Golf and Country Club.

In order to facilitate imposing fair handicap, the sports committee has requested that those who intend to play golf furnish the following information: average of their 5 best scores in 1936; par of their regular courses.

### WOMEN'S ENTERTAINMENT

While the men are busily engaged in the technical sessions and inspection trips the women will not be overlooked. A committee, under the leadership of Mrs. A. C. Flory, has provided a wide variety of interesting and entertaining events. These include a varied assortment of parties, a tea, luncheon, inspection and shopping trips, golf, and a day at a country club. These, of course, are in addition to the combined events—the boat trip on Lake Michigan, the trip to the Schlitz Brewery, president's reception and dinner dance Thursday evening, and the farewell party at the Bluemound Golf and Country Club Friday night. The aim of the women's committee is to make every woman visitor feel Milwaukee's traditional and gracious hospitality and to let no one leave the convention without learning the real meaning of *gemutlichkeit* (see May 1937 issue, page 638).

# Institute Prize Awards Announced for 1936 Papers

THE committee on award of institute prizes has announced the award of 4 national prizes for papers presented during the calendar year 1936. Personal presentation of the prizes will take place during the summer convention to be held in the Hotel Schroeder, Milwaukee, Wis., June 21–25, 1937. The personnel of the committee consists of H. S. Osborne (A'10, F'21), *chairman*, O. W. Eshbach (A'17, M'30), W. B. Kouwenhoven (A'06, F'34), W. R. Smith (M'18, F'30), and I. Melville Stein (A'18, M'27).

Rules governing the award of future prizes were published in ELECTRICAL ENGINEERING for April 1937, page 492. In accordance with these rules, papers for the District Branch paper prize and the newly established graduate student prize, will be awarded on the basis of the academic year, and must be submitted on or before July 15, 1938. The Branch papers which have been presented from January to June 1937, may also be submitted at that time for consideration.

### NATIONAL PRIZES

After due consideration of all highly recommended papers, the committee on award of Institute prizes made the following awards of national prizes for papers presented in 1936:

#### BEST PAPERS

*Best Paper in Engineering Practice.* This prize was awarded to P. S. Millar (A'03, M'13) for his paper "The Qualities of Incandescent Lamps," published in ELECTRICAL ENGINEERING for May 1936, pages 516–23, and discussed at the summer convention, Pasadena, Calif., June 22–26, 1936.

Honorable mention was made of the following papers: "The Relation between Load, Capacity, and Service Continuity on an Electric Power System" by W. J. Lyman (A'25), presented before the Pittsburgh Section, December 8, 1936; "Modernization of Power Distribution Systems" by H. P. Seelye (A'19, M'28), published in ELECTRICAL ENGINEERING for January 1936, pages 75–84, and discussed at the winter convention, New York, N. Y., January 28–31, 1936.

*Best Paper in Theory and Research.* This prize was awarded to H. E. Edgerton (A'27, M'32) for his paper "High Speed Motion Pictures," published in ELECTRICAL ENGINEERING for February 1935, pages 149–53, and discussed at the winter convention, New York, N. Y., January 28–31, 1936.

Honorable mention was made of the following papers: "Pull-In Characteristics of Synchronous Motors" by D. R. Shoults (A'35), S. B. Crary, Jr. (A'31), and A. H. Lauder (A'24), published in ELECTRICAL ENGINEERING for December 1935, pages 1385–95, and discussed at the winter convention, New York, N. Y., January 28–31, 1936; "Laboratory Studies of Conductor Vibration" by J. S. Carroll (A'24), published in ELECTRICAL ENGINEERING for May 1936, pages 543–7, and discussed at the summer convention, Pasadena, Calif., June 22–26, 1936.

*Best Paper in Public Relations and Education.* In view of the fact that only 2 papers eligible for this prize were presented last year the committee deemed it advisable to make no award under this classification. Under the rules these 2 papers will be eligible for consideration the next time prizes are awarded.

#### INITIAL PAPER

Prize for initial paper was awarded to D. H. Rowland (A'26) for his paper "Porcelain for High Voltage Insulators," published in ELECTRICAL ENGINEERING for June 1936, pages 618–26, and discussed at the summer convention, Pasadena, Calif., June 22–26, 1936.

Honorable mention was made of the following papers: "Induction Heating at Low Temperatures" by E. L. Bailey (A'19, M'25), published in ELECTRICAL ENGINEERING for November 1935, pages 1210–12, and discussed at the winter convention, New York, N. Y., January 28–31, 1936; "Earth Resistivity and Geological Structure" by R. H. Card (A'22, M'35), published in ELECTRICAL ENGINEERING for November 1935, pages 1153–61, and discussed at the winter convention, New York, N. Y., January 28–31, 1936.

#### BRANCH PAPER

Prize for Branch paper was awarded to W. James Walsh for his paper "Heat Transfer Efficiency of Electric Range Surface Units," presented at a joint meeting of the Portland Section and Oregon State College Branch, AIEE, Corvallis, Ore., May 16, 1936.

Honorable mention was made of the following papers: "A Direct Reading Linear Accelerometer" by Harry B. Fuge, presented at a meeting of the Polytechnic Institute of Brooklyn Branch, AIEE, April 1936; "Tidal Power," by D. R. Barney, presented at the annual student convention District No. 3, AIEE, New York, N. Y., April 22, 1936; "A High-Speed Vibration Analyzer," by William R. Harry, presented at the North Eastern District Meeting, New Haven, Conn., May 6–9, 1936; "Frequency Multipliers," by Ronald F. Huminski and Everard M. Williams, presented at the North Eastern District Meeting, New Haven, Conn., May 6–9, 1936.

The committee has considered all the eligible papers and in connection with papers in all classifications except Branch papers had the benefit of the recommendations of the technical committee chairmen relative to the best papers in their respective fields.

### DISTRICT PRIZES

District prizes as announced by 4 Districts to date include 3 awards of $25 each, together with appropriate certificates. Other District awards will be announced later, as the information becomes available.

#### DISTRICT 1

Prize for best paper was awarded to E. M. Hunter (A'28, M'36) for his paper "Tests on Lightning Protection for A-C Rotating Machines," published in ELECTRICAL ENGINEERING for February 1936, pages 137–44, and discussed at the North Eastern District Meeting, New Haven, Conn., May 6–9, 1936.

Prize for initial paper was awarded to E. A. Harty (A'22, M'36) for his paper "Aging in Copper Oxide Rectifiers," presented at the North Eastern District Meeting, New Haven, Conn., May 6–9, 1936.

Prize for Branch paper was awarded to W. R. Harry for his paper "A High-Speed Vibration Analyzer," presented at the North Eastern District Meeting, New Haven, Conn., May 6–9, 1936.

#### DISTRICT 2

Prize for initial paper was awarded to A. C. Herweh for his paper "An Open Arc Type of Stroboscope," presented before a joint meeting of the Cincinnati Section and University of Cincinnati Branch, AIEE, May 19, 1936.

#### DISTRICT 7

Prize for Branch paper was awarded to J. H. Treadwell for his paper "A Rotating Ball Slip Meter," presented at the South West District Meeting, Dallas, Texas, October 26–28, 1936.

#### DISTRICT 9

Prize for Branch paper was awarded to W. James Walsh for his paper "Heat Transfer Efficiency of Electric Range Surface Units," presented at a meeting of the Oregon State College Branch, AIEE, Corvallis, Ore., May 16, 1936.

**ASTM Annual Meeting.** The fortieth annual meeting and fourth exhibit of testing apparatus and related equipment of the American Society for Testing Materials will be held in New York, N. Y., from June 28 to July 2, 1937, with headquarters at The Waldorf-Astoria Hotel. A program of entertainment and inspection trips will supplement the technical program. Many companies will display and demonstrate the latest developments in instruments for various phases of the production, control, and testing of materials and products of all kinds. Certain educational and research institutions will also be invited to display special equipment and devices which they have developed for unusual testing and research in the materials fields.

# Coast IRE and AIEE Plan Joint Convention at Spokane

An innovation in Pacific Coast convention procedure that is being enthusiastically developed by the local committees in charge will bring together for a concurrent convention in Spokane, Wash., the Pacific Coast members of the Institute of Radio Engineers and of the AIEE. The annual Pacific Coast AIEE convention is scheduled to be held from August 30 to September 3, inclusive. The IRE Pacific Coast convention, the first to be held, is scheduled for September 1 and 2.

Plans in progress as announced by the committee in charge provide for a joint technical session to be held September 2, to which both AIEE and IRE members will contribute technical papers of common interest. Other sessions of the AIEE Pacific Coast convention program will be held as usual, and separate technical sessions are being planned by the radio engineers.

# 1937 Lamme Medal Nominations Due Nov. 1

Special attention is directed to the fact that the names of Institute members who are considered eligible for the Lamme Medal, to be awarded in the fall of 1937, may be submitted by any member in accordance with Section 1 of Article VI of the by-laws of the Lamme Medal committee, as quoted in the following:

The committee shall cause to be published in one or more issues of ELECTRICAL ENGINEERING, or of its successors, each year, preferably including the June issue, a statement regarding the "Lamme Medal" and an invitation for any member to present to the national secretary of the Institute by November 1, the name of a member as a nominee for the medal, accompanied by a statement of his "meritorious achievement" and the names of at least 3 engineers of standing who are familiar with the achievement.

Each nomination should give concisely the specific grounds upon which the award is proposed, and also a complete detailed statement of the achievements of the nominee to enable the committee to determine its significance as compared with the

achievements of other nominees. If the work of the nominee has been of a somewhat general character in co-operation with others, specified specific information should be given regarding his individual contributions. Names of endorsers should be given as specified above.

The Lamme Medal, founded as a result of a bequest of the late Benjamin Garver Lamme, chief engineer of the Westinghouse Electric and Manufacturing Company (deceased July 8, 1924), provides for the annual award by the Institute of a gold medal —together with bronze replica thereof— to a member of the AIEE "who has shown meritorious achievement in the development of electrical apparatus or machinery"; and for the award of 2 such medals in some years if the accumulation of funds warrants.

The ninth (1936) Lamme Medal has been awarded to Doctor Frank Conrad (A'02, F'37), assistant chief engineer of the Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa., "for his pioneering and basic developments in the fields of electric metering and protective systems." Presentation will be made during the AIEE summer convention at Milwaukee, Wis., June 21–25, 1937. A biographical sketch of Doctor Conrad appeared in ELECTRICAL ENGINEERING for March 1937, pages 395–6.

## Additions to Member-for-Life List

Membership for life is granted by the Institute for either of the following 2 reasons: a member has paid annual dues for 35 years; or has reached the age of 70 and has paid dues for 30 years.

The fiftieth anniversary issue of ELECTRICAL ENGINEERING published in May 1934 and the September 1935 number included lists of all members who had been enrolled upon the Institute records as Members for Life during the period up to May 1, 1935. Those who became Members for Life between 1935 and 1936 were listed in the June 1936 issue.

The list that follows indicates those members who have become Members for Life since the publication of the list in the June 1936 issue:

Addicks, L.
Aitken, William
Atkinson, A. A.
Atkinson, W. S.
Averrett, A. E.
Barnes, W. J.
Beam, Victor S.
Bell, A. C.
Bennett, Edward
Bennett, W. S.
Blakeslee, H. J.
Brown, Carlton E.
Brown, R. C.
Brown, W. E.
Butler, W.
Carpenter, H. C.
Coldwell, O. B.
Conwell, W. L.
Cowles, J. W.
Dick, W. A.
Dixon, James
Dodge, K.
Edmonston, E. D.
Eglinton, W. M.
Erwin, F. B.
Everit, E. H.
Feldmann, C.
Ferguson, L. A.
Ferguson, S.
Firman, L. D.
Foster, W. J.
Gear, H. B.
Gibson, J. J.
Gill, Frank
Graham, W. P.
Graling, V.
Harisberger, J.
Hodgkinson, F.
Hunt, F. L.
Keller, C. A.
Kingsbury, Albert
Kruesi, P. J.
Lanphier, R. C.
Lesley, Hugh
Leyden, H. R.
Lillibridge, R. D.
Lincoln, J. C.
Lowenberg, L.
Magie, L. D.
Manville, C. B.
Marburg, L. C.
McAllister, A. S.
McGrath, W. H.
Medbery, S. C., Jr.
Moody, W. S.
Morris, J. W.
Nash, L. R.
Pearson, E. R.
Pierce, A. L.
Potts, L. M.
Pratt, W. H.
Rea, N. L.
Reber, H. L.
Reynolds, W. H.
Roberts, T. M.
Rosenthal, L. W.
Ruckgaber, A. F.
Ruffner, C. S.
Rugg, W. S.
Sage, D.
Sawyer, W. H.
Schildhauer, E.
Schluederberg, C. G.
Smith, F. W.
Smith, W. N.
Soren, T. H.
Sporborg, H. N.
Stevenson, F. L.
Storer, S. B.
Stovel, R. W.
Tuttle, H. B.
Van Dyck, W. V.
Waddell, C. E.
Wagoner, P. D.
Waldo, E. H.
Warren, H. E.
Waters, W. L.
White, F. J.
Whittemore, G. W.
Wilder, S.
Wilson, R. L.
Winslow, C. G.

## AIEE Sections Members of Indiana Engineering Council

Growing out of a reorganization of the Indiana Engineering Society, the Indiana Engineering Council has been formed to function in the State in the same manner in which the American Engineering Council functions nationally. The Indiana Engineering Society was in operation for many years, and was composed principally of members of the 3 national societies: American Society of Civil Engineers, American Society of Mechanical Engineers, and the AIEE. This society was an incorporated body with the objective of bringing together these engineers and the land surveyors of the State to encourage professional intercourse and the development and advancement of its membership.

In the opinion of the officers of this society it would serve its purpose better if organized in the manner of American Engineering Council. Accordingly, at the last annual meeting of the society held February 16, 1937, and through the counsel of Dean A. A. Potter of Purdue University, president of AEC, steps for a reorganization were taken which resulted in the formation of the Indiana Engineering Council.

Both the Central Indiana and the Fort Wayne AIEE Sections are participating in the new organization.

According to Foster L. Stanley, chairman of the AIEE Central Indiana Section, who supplied the information for this news item, organization plans are now being developed by the following officers:

**President:** M. R. Keefe, chief engineer, Indiana State Highway Commission.

**Vice-President:** F. R. Weaver, vice-president, ASME, and an influential engineer in the State.

**Secretary-Treasurer:** Homer Ruppard, assistant chief engineer, Indianapolis Water Company.

**Executive Board:** Harry O. Garman (A'08, M'23) consulting engineer, past-president of the Indiana Engineering Society and past-chairman of the Central Indiana Section (1917–18). Charles Brossman (M'28) chief engineer, Indianapolis Water Company; Professor F. C. Hockema, assistant to president of Purdue University, chairman Central Indiana Section, ASME; Foster L. Stanley (A'34) plant extension engineer, Indiana Bell Telephone Company.

**Map of Illinois Lines.** A comprehensive map of electric transmission and distribution lines in Illinois has been prepared by the state rural electrification committee which shows all rural electric lines, transmission lines, points of interconnection, generating stations, and other electric facilities. All lines built up to January 1, 1937, are included. Copies of the map are printed in 3 colors and 30 inches by 50 inches in size may be obtained directly from the State Rural Electrification Committee, 220 Centennial Building, Springfield, Ill., at nominal cost.

## Membership—

Mr. Institute Member:

Vacation season is here! Many of our Sections have held their last meeting until fall and the membership committees have done the major portion of their work. They have done well too for the AIEE has the largest membership reported for the past 4 years, as of May first.

Now is the time when the help of the Institute members is most needed in membership work. Do not wait until fall to get your prospective member an application blank, but send his name to New York headquarters if your local membership committee is away on vacation. Your prospect will appreciate being "in" on the beginning of the new Section year and the Institute will appreciate your co-operation.

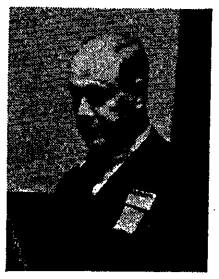
Fred B. Doolittle

Vice-Chairman, District No. 8
National Membership Committee

# Industrial Applications and Power System Problems Discussed at Buffalo—Students Also Hold Busy Session

A DISTINCTLY industrial flavor was one of the more attractive features of the AIEE North Eastern District meeting held May 5–7 at Buffalo, N. Y. Supplementing and giving point to 2 special informal papers that were devoted to a discussion and explanation of current trends in the design and application of the electrical equipment that is playing so vital a part in modern steel-mill electrification, was a correlated inspection trip through the new 72-inch continuous hot- and cold-strip mill of the Bethlehem Steel Company at nearby Lackawanna.

That lightning still holds its interest for power system operating engineers, electrical equipment manufacturers, and others was evidenced by the scope and character of the active discussion resulting from the presentation of 3 papers pertaining in one way or another to this subject. Other power-system problems were touched upon by papers describing the operating performance of a relay protective system for a large interconnected power system, operating performance of one of the newer steam-electric generating stations, experimental study of "dancing" cables, and the organization and operating procedure incident to the conduct of research and test work by 2 large electric utilities. An interesting informal paper describing the steps involved in surveying telephone requirements for a large industrial or commercial user gave an insight into some of the engineering and traffic problems incident to the modern facility of communication that today is taken very much for granted.



President MacCutcheon was an interested and active participant in practically all phases of the District meeting program. Presiding at the various sessions were: C. T. Sinclair, Pittsburgh, Pa., opening session; Robert Treat, Schenectady, N .Y., first general session; R. W. Graham, Lackawanna, N. Y., second general session; D. C. West, Buffalo, dinner meeting. J. Leo Scanlon, chairman of the Niagara Frontier Section, Buffalo, acted on behalf of the Section as host and general factotum.

### Steel Mill Electrification

Speaking on "Design Trends in Steel Mill Electrification," L. A. Umansky (A'16, M'27) of the General Electric Company, Schenectady, N. Y., graphically illustrated and dramatically described the ever-increasing extent to which modern sheet-steel production is directly dependent upon electric driving and controlling mechanisms. He pictured briefly the evolution of sheet rolling from the old simple single stand for sheets now regarded as small, to a modern mill where sheets 100 feet or more in length pass simultaneously through several rolls in tandem, to emerge at speeds of from 1,200 to 2,000 feet per minute. The intricacy and the importance of the electric driving and controlling equipment involved in such an operation can be understood when it is realized that each successive stand of rolls operates at a different speed in accordance with the progressive elongation of the strip, all being interlocked to maintain a predetermined setting.

Mr. Umansky's talk served also to emphasize the decisiveness of a trend, noted also in other branches of industry, toward an increasingly wider use of d-c machinery, because of its flexibility and susceptibility to precise control.

F. D. Egan (M'34) of the Bethlehem Steel Company described in some detail the "electrical applications" in that company's 72-inch continuous hot- and cold-strip mill at Lackawanna, N. Y. Although other mills now are under construction, this is one of the newest of the large mills now in operation, and is regarded as a typical example of a modern electrified steel mill. It has an annual capacity of 800,000 tons of hot-rolled strips, sheets, and light plates, of which 360,000 tons can be converted into cold-rolled finished products, and is capable of producing strips up to 72 inches in width by 0.078 inch in thickness, as well as light plates up to $1/2$ inch in thickness. It is designed to handle stock slabs ranging from 20 to 40 inches in width, from 3 to 6 inches in thickness, and from 5 to 15 feet in length.

R. W. Graham of Lackawanna, N. Y., presided at one of the general sessions

Electrically as well as mechanically, heavy-duty equipment is a prominent characteristic of such a mill. Mr. Egan emphasized the vital importance of a continuity of electric service, pointing out that the power supply for the Lackawanna mill is obtained from 3 different sources over 6 lines from 2 different directions. One of the problems incident to serving the 22,500 horsepower of d-c finishing-mill motors was that, under short-circuit conditions, currents of the order of 300,000 amperes might be expected on the 600-volt d-c bus. Special designs were adopted, including wide separation of the positive and negative busses, to reduce or control the resulting tremendously heavy physical forces that would be exerted on the bus conductors and fittings under short-circuit conditions.

### Lightning

In areas where lightning prevails, it still appears on system operating records as the Number 1 cause of interruptions to electric-power circuits, as confirmed by the discussion of the subject at Buffalo. Consequently, there is a prevalent active interest in the subject, although the outward manifestation of the studies that have continued for so many years has shifted gradually from heated debates over conflicting theories to colder analyses of accumulating operating statistics and observed test data. Authorities seem pretty well agreed that, although effective progress has been made in the development of practical preventives or palliatives, further progress in the prevention or control of lightning disturbances on electric-power systems will come from extensive correlation of existing data as well as from a continuation of laboratory and field investigations.

I. W. Gross (A'12) of the American Gas and Electric Company, New York, N. Y. S. K. Waldorf (A'27, M'36) of the Pennsylvania Water and Power Company, Baltimore, Md.; and G. A. Powell (A'23) of the New York Power and Light Corporation, Albany, N. Y., presented, respectively, the following papers, which were published as noted in earlier issues of Electrical Engineering:

Lightning Currents in 132-Kv Lines, Philip Sporn and I. W. Gross. Published in February issue, pages 245–52.

Probable Outages of Shielded Transmission Lines, S. K. Waldorf. Published in May issue, pages 597–600.

Special Uses for the Automatic Oscillograph, G. A. Powell and R. E. Walsh. Published in April issue, pages 438–40.

These presentations, and the conclusions drawn by the authors, brought forth a variety of discussion. K. B. McEachron (A'14, M'20) of Pittsfield, Mass., commented at some length on the quantity and variety of statistical data that has been accumulated and now is available concerning the operation of electric power systems under lightning-storm conditions, the character of lightning strokes, the probability of lightning disturbances affecting a given line, and other aspects of the subject. He emphasized the present need for correlation among these various data and between them and weather-bureau data pertaining to the number of storm-days experienced in various areas. Discussing the question of ground resistance as it might affect the operation of equipment installed for protection against lightning damage, Mr. McEachron observed that data received from London, England, indicate definitely that the higher the tower the less important the matter of ground resistance becomes; this is because for very high towers the time required for the wave to travel down the length of the tower is enough to permit the wave to approach crest value at the tower top, thus causing flashovers.

W. F. Davidson (A'14, M'26) of the Brooklyn (N. Y.) Edison Company, urged that "further thought be given to the matter of 'silent discharges.'"

Speaking with reference to the "zone of protection," usually assumed to be afforded by a high grounded structure, S. K. Waldorf described troubles that had been experienced by a certain street railway company wherein flashovers occurred across insulators on which trolley feeders were supported from buildings along either side of a "downtown"

street flanked by buildings several stories high. He reported that a study of this situation indicated that lightning impulses were conducted down through the buildings to points where the resistance to ground was lower across the trolley-feeder insulators than it was down through the frame of the building, resulting in flashovers from building to trolley feeder and on to ground through railway equipment. An increase in the insulation at these points overcame the trouble.

Commenting on the characteristics of lightning, R. E. Walsh observed that waves resulting from lightning strokes "do not rise nearly as rapidly nor as steeply as some theories and some studies have indicated."

### Power System Operation

Four special presentations featured a general session devoted to power system problems:

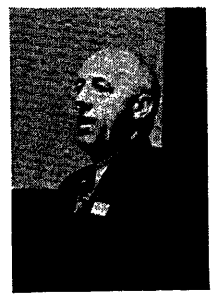
Development and Operating Performance of a Relay System, L. J. Audlin (M'35), Syracuse, George Steeb (A'26, M'34), Buffalo, and G. A. Powell (A'23) of Buffalo, who constitute the relay committee of the Niagara-Hudson operating companies.

Operating Performance of C. R. Huntley Station. Presented in 2 parts: Electrical, J. M. Geiger (A'28, M'34); Mechanical, Donald Scranton; both of the Buffalo General Electric Company

Research and Testing in a Large Electric Utility, W. F. Davidson (A'14, F'26) director of research and test of the Consolidated Edison Company of New York, Inc.

Research and Testing in the Hydro-Electric Power Commission of Toronto, W. P. Dobson (A'13, M'19) chief testing engineer, Hydro-Electric Power Commission of Ontario, Canada.

These papers were developed especially for the Buffalo meeting, and have not been published in Electrical Engineering.



L. J. Audlin described briefly the operating, switching, and relaying problems involved in the gradual evolution of several distinct operating systems into what is in effect a single coordinated interconnected system covering a large portion of the State of New York. Extensive calculating-board studies of short-circuit conditions were described as having revealed the principal difficulties to be overcome for successful operation: that more rapid relay and circuit breaker operation would be required to avoid system instability; that phase relays would not provide adequate protection against certain types of ground faults. Replacements of circuit breaker and relay equipment have been effected until now about 44 per cent of the 140 or so switch positions on the interconnected transmission system are equipped with "distance" relays and high-speed oil circuit breakers (8-cycle) of heavy interrupting capacity. Further improvements now under way will bring this figure to about 54 per cent of the total line-switching positions. For main transmission circuits, differential protection (pilot relaying) for each individual circuit is considered to be the "ideal." This ideal is approached between the generating sources of the Niagara-Hudson power system and New York City by the supplemental use of carrier relay equipment for the control of directional relays. Operating records for the period 1933 to 1936 inclusive, showed a total of 1,185 disturbances, of which the 3 most prominent causes were: lightning, 56.1 per cent; sleet, wind, and jumping conductors, 12.4 per cent; and closing in on faults, 11.4 per cent. Relay operating records for the same period showed a total of 2,764 disturbances, of which 92.2 per cent were correct and desired, 5.3 per cent correct, but undesired, and 2.1 per cent incorrect or faulty, and 0.4 per cent failure to operate. A point raised for discussion was whether or not to separate 2 parts of an interconnected transmission system when synchronism is lost between them, some operating experiences indicating the possibility of re-establishing synchronism without interruption and without damage to equipment.

Robert Treat of Schenectady, N. Y., presided at one of the general sessions

The Huntley steam-electric generating station No. 2 was built in 1929, expressly for the purpose of providing for the change-over in the domestic and commercial load in the Buffalo area from 25-cycle to 60-cycle service. In describing the electrical operation of the station, J. M. Geiger pointed out that inasmuch as the bus bars of this one station would have to carry, for at least several years, all the 60-cycle energy for a large metropolitan area, provision for the highest order of reliability in the electrical equipment was a necessity. The station generating equipment comprises 2 8,000-kw 12,000-volt generators, each tied solidly to an autotransformer, the 22-kv windings of which normally are connected to opposite busses. This "split bus" scheme also is applied to the large transformers for the 110-kv transmission ties, for the frequency changer connections, and for the outgoing 22-kv feeders. The neutral leads of the generators and large transformers are connected to a common neutral bus and grounded through a 5-ohm resistor to limit fault currents to ground. Experiments with this resistor in service and out of service indicate that its use has no bearing on the rate of electric cable failures in the local system. Circuit arrangements and operating procedures were such, according to the report, that since the station was built there has not been a single interruption in the low-voltage-network service that is wholly dependent upon the station.

Research and test work are as vital to the effective and economical operation of the electric service utilities as they are to the success of other industrial enterprises. Descriptions of their respective organizations, methods of procedure, and types of work were given by W. F. Davidson of the Consolidated Edison Company of New York and W. P. Dobson of the Hydro-Electric Power Commission of Ontario. In Mr. Davidson's organization, all testing, except that involving mechanical equipment in generating stations, is assigned to the test bureau of the system engineering department. The scope of this department includes all testing of the transmission and distribution system and associated substations, all electrical equipment in the generating stations, maintenance of the standards laboratory and portable test instruments, and the testing of materials and such apparatus as require special laboratory facilities. The production department has a test organization in each generating station to handle the testing of mechanical equipment. A research bureau in the system engineering department is responsible for the conduct of research connected with the electrical operations (as distinguished from gas operations). To insure effective co-ordination of these separate agencies, the heads of research bureau and the test bureau report to the director of research and tests, and the station test groups report to the production economy engineer. These 2 men jointly handle those cases which concern more than one unit of the testing organization. For convenience and administration, the test bureau of the system engineering department is organized into 2 divisions: laboratory, and field tests, the names of which indicate the general scope of their activities and responsibilities. An important function of the laboratory division is the maintenance of reference standards. Another important function is the performance of acceptance tests on materials and apparatus. As to the research work, new problems constantly are arising, each to be dealt with in accordance with its requirements and importance.

President A. M. MacCutcheon was an interested and active participant

In the Hydro-Electric Power Commission of Ontario, the testing and research department is responsible for the testing and inspection of all materials and equipment purchased, and for the conduct of special investigations and research. W. P. Dobson pointed out that a comprehensive inspection and testing policy is followed and applied not only to new material and equipment, but also to material in service, with the object of detecting signs of failure and of devising remedial measures. Research problems are suggested by the difficulties encountered in construction and operation, and the work is carried on under the general direction of a research committee composed of 5 department heads. Projects are assigned to subcommittees containing representatives from all departments interested. Results accomplished were reported as including improved methods of operation, improved methods of treating materials to prolong their life, the development of new specifications or improvements of existing specifications for the purchase of materials, and the development of new equipment for special applications.

### Dancing Cables

"Dancing" or "galloping" cables on transmission and distribution lines have been observed under certain weather conditions for many years. At the Buffalo meeting, D. C. Stewart (A '25, M'35) assistant electrical engineer for the Buffalo, Niagara, and Eastern Power Corporation, presented the results of an experimental study of this condi-

tion. During dancing periods the cables had been observed to oscillate violently with amplitudes and motions of alarming proportions. As the cables do not move in synchronism, there is a resulting threat of contact or flashover and consequent interruption to service. Mr Stewart, in discussing the various theories that have been offered mentioned that propounded by A. E. Davison (A'13) of Toronto at the AIEE convention held in that city in June 1930 which was to the effect that the wind acting on irregular icy formations adhering to the cables exerts aerodynamic forces that initiate and maintain the cable motion. Mr. Stewart stated that although this theory failed to explain some cases where cable dancing has been reported when no ice was on the cable it does seem to account for the great bulk of reported cases. For his experimental span, Mr. Stewart reported the use of a 104-foot span of number 4 ACSR 7-strand cable strung at right angles to the direction of the prevailing wind. To this cable were affixed wax formations to simulate ice or snow deposits that had been observed under storm conditions when dancing prevailed. With special arrangements for observation and measurement, Mr. Stewart found that the cable on this test span under storm conditions swung in a path of approximately elliptical proportions and having a vertical axis of some 3 feet and a horizontal axis of some 2 feet, which swing carried the cable at midspan to a point considerably above the axis of support at the ends of the span. He found also that there was a periodic twisting of the conductor to the extent of more than 180 degrees above its longitudinal axis, as it swung in its elliptical path. With a wind velocity of about 61 feet per second, the cable traveled around its elliptical path at an average speed of some 14 feet per second. The experimental results reported were considered to confirm the theory that cable dancing results from wind blowing against irregular ice formations adhering to the cables; further, that the varying twists in the cable plays its part in the vibration phenomena. In the resulting discussion it was suggested that electromagnetic phenomena sometimes might be responsible for the initiation of vibration. The scope and character of this discussion indicated a broad interest in the problem as a possible cause of circuit interruption and seemed to indicate conclusively the desirability of further research and analysis.

### Student Technical Sessions

Although many students attended the other technical sessions, principal student attention was focused upon the session devoted to the presentation and discussion of the following student papers:

The Design, Construction, and Testing of a Miniature Cathode-Ray Oscilloscope, N. I. Korman, Worcester Polytechnic Institute.

A Transmission-Line Slide Rule, R. R. Gay and C. H. Hunter, Cornell University.

Television, D. O. Wood, Massachusetts Institute of Technology.

A High-Voltage Electrostatic Voltmeter, E. M. Williams (graduate student), Yale University.

Power-Circuit Filters for A-C Generators, Abner Crumb (graduate student) Worcester Polytechnic Institute.

The Iconoscope, the Eye of Television, S. S. Dufford, Rensselaer Polytechnic Institute.

Single-Phase Railway Motors, W. Malthamer, Jr., Rensselaer Polytechnic Institute.

The Sliding Electrical Contact, D. P. Miles, Rensselaer Polytechnic Institute.

Under the excellent chairmanship of R. W. Kunkle, engineering student, Cornell University, this busy session was conducted with order and dispatch, with the time carefully budgeted between presentations and discussions. Many of the approximately 150 students that attended the session took an active part in the discussion of the papers.

President MacCutcheon, in addressing the group, paid tribute to the student authors for the general excellence of their papers, and the effectiveness with which they were presented, to Student Chairman Kunkle for his efficient handling of the meeting, and to Professor F. N. Tompkins, counselor of the Brown University Student Branch and chairman of the student activities committee for the North Eastern District meeting under whose general supervision the program was arranged and presented. A committee of judges made up of Professors A. R. Powers of Clarkson, E. A. Walker of Tufts, and C. W. Henderson of Syracuse, returned the verdict awarding prizes *for presentation* as follows: first, to Mr. Korman; second, to Messrs. Gay and Hunter; and third, to Mr. Miles. Mr. Williams and Mr. Crumb were awarded honorable mention.

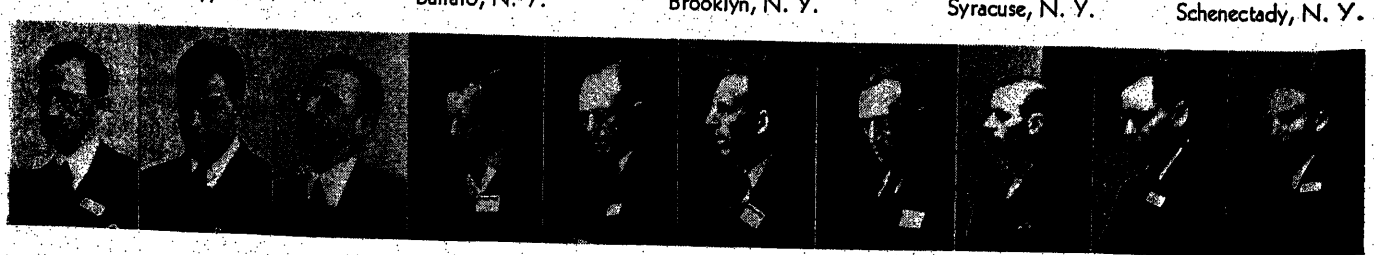
### Conference on Student Activities

At a luncheon business conference held Friday, May 7, a total of 36 persons interested in Student Branch activities gathered together for a discussion of the problems incident to that phase of the Institute's activity in the North Eastern District. This group included student and faculty representatives from 13 of the 16 Student Branches in the North Eastern District, District Secretary R. G. Lorraine of Schenectady, Editor G. R. Henninger of New York, Vice-President A. C. Stevens of Schenectady, National Secretary H. H. Henline of New York, President A. M. MacCutcheon of Cleveland, Professor T. H. Morgan of Worcester Polytechnic Institute, Professor Lynn C. Holmes, counselor-elect of the Branch at Rensselaer Polytechnic Institute, and the following representatives:

**Student Branch Counselors and Alternates**

F. N. Tompkins, Brown University, Providence, R. I.
A. R. Powers, Clarkson College of Technology, Potsdam, N. Y.
E. M. Strong, Cornell University, Ithaca, N. Y.
J. D. Cobine, Harvard University, Cambridge, Mass.
W. H. Bliss, University of Maine, Orono
W. H. Timbie, Massachusetts Institute of Technology, Cambridge
L. W. Hitchcock, University of New Hampshire, Durham
F. M. Sebast, Rensselaer Polytechnic Institute, Troy, N. Y.
C. W. Henderson, Syracuse University, N. Y.
E. A. Walker, Tufts College, Tufts College, Mass.
E. R. McKee, University of Vermont, Burlington
Victor Siegfried, Worcester Polytechnic Institute, Mass.
A. G. Conrad, Yale University, New Haven, Conn.

**Student Branch Chairmen or Alternates**



Gerald Smithson, Brown University, Providence, R. I.
J. F. Frazier, Clarkson College of Technology, Potsdam, N. Y.
F. J. Skinner, Cornell University, Ithaca, N. Y.
L. P. Winsor, Harvard University, Cambridge, Mass.
H. O. Saunders, Massachusetts Institute of Technology, Cambridge
H. C. Kenneson, University of Maine, Orono
R. W. Tolles, University of New Hampshire, Durham
J. S. Dufford, Rensselaer Polytechnic Institute, Troy, N. Y.
F. C. Tuck, Syracuse University, N. Y.
F. A. Spindell, Tufts College, Mass.
J. R. Tozer, Jr., University of Vermont, Burlington
R. P. Day, Worcester Polytechnic Institute, Mass.
R. D. Scott, Yale University, New Haven, Conn.

Among the various items of business discussed, principal attention was given to: (*a*) the desirability of providing more and better housing arrangements and entertainment features for students attending these District student conventions; (*b*) the desirability of divorcing the student conventions from District meetings; (*c*) the question of a proper basis for the competitive grading of student papers.

The weight of student opinion was to the effect that adequate attention already is being given to the provision of facilities for students in connection with District meetings, and that any further efforts in that direction would nullify some of the educational benefits accruing to the students by virtue of having to do a bit of caring for themselves in a strange community, a situa-

**A group of authors who presented papers at the Buffalo meeting**

S. K. Waldorf, Baltimore, Md. — I. W. Gross, New York, N. Y. — Donald Scranton, Buffalo, N. Y. — W. P. Dobson, Toronto, Can. — D. C. Stewart, Buffalo, N. Y.
G. A. Powell, Albany, N. Y. — J. M. Geiger, Buffalo, N. Y. — W. F. Davidson, Brooklyn, N. Y. — R. E. Corey, Syracuse, N. Y. — L. A. Umansky, Schenectady, N. Y.

R. W. Kunkle, chairman, Cornell — P. H. Hunter, Cornell — S. S. Dufford, Rensselaer — Abner Crumb, Worcester — D. P. Miles, Rensselaer

N. I. Korman, Worcester — D. O. Wood, M.I.T. — E. M. Williams, Yale — W. Malthaner, Jr., Worcester

**A group of student authors who presented papers at the Buffalo meeting**

tion they all expect to face upon graduation. The general consensus of opinion among both students and counselors was to the effect that electrical engineering students do not need to be "spoon fed." Likewise, the suggestion to separate the student conventions from the regular District meeting program was talked down by a wide margin, 2 important facts being stressed by several speakers: first, that many advantages to students from attending such meetings would be lost if the opportunity to attend the general technical sessions and otherwise mingle with the practicing engineers were eliminated; second, that any need or desire for conclaves devoted wholly to student matters could be satisfied by arranging such conclaves without interferring with the joint District student convention and District meeting which was regarded as having been highly successful over a period of years.

Referring to the basis for the competitive grading of technical papers as published on page 492 of the April 1937 issue of ELECTRICAL ENGINEERING, there was a strongly expressed and apparently widely held opinion among Student Branch counselors that the published basis was not satisfactorily applicable to student papers. Two factors were pointed out as being of particular significance in connection with the grading of student papers: first, "the broad interpretation and importance of 'originality' " ; second, "the lesser expectancy of 'value' to the profession in student papers and the unimportance of attempting to segregate it into the present 'value in its field,' and 'value to electrical engineering.' " A committee of counselors that has been studying this matter recommended the following basis for grading student papers:

| | |
|---|---|
| Preliminary analysis | 20 per cent |
| Logical presentation | 20 per cent |
| Originality in handling subject | 20 per cent |
| Unity of composition | 20 per cent |
| Value to electrical engineering | 20 per cent |

This report and recommendation was accepted by a vote. Also there was expressed a desire for continued study of grading "in favor of more drastic revision" and Chairman Tompkins was requested to appoint a committee for the purpose.

### ENTERTAINMENT—ATTENDANCE

The principal feature of the entertainment program at the Buffalo meeting was a very nicely arranged dinner held the evening of the second day, and departing from common practice in that it was not a dinner dance. President and Mrs. A. M. MacCutcheon were the guests of honor. Entertainment as well as instruction was afforded through an interesting demonstration lecture "Kodachrome Colored Film," given by L. D. Mannes of the Eastman Kodak Company, Rochester, N. Y., co-inventor of a color photography process in which a single negative comprises 3 successively deposited sensitized films, each sensitive to a different primary color, and each separated from its neighbors by a neutral deposit which enables the complicated developing process to be carried on step-by-step, progressively bringing out the several layers, the composite of which is an accurate color reproduction. The reported attendance was 273.

### DISTRICT EXECUTIVE COMMITTEE MEETS

A luncheon meeting of the North Eastern District executive committee was held Thursday, May 6, during the Buffalo meeting. After routine matters had been disposed of, there was considerable discussion concerning the registration of professional engineers in connection with the discussion of the general topic of "broadening" of Institute activities. Pittsfield, Mass., was selected as the site for the 1938 District meeting.

The meeting was attended by the following delegates:

A. C. Stevens, vice-president, AIEE
R. G. Lorraine, secretary, North Eastern District
F. N. Tompkins, chairman, District Committee on student activities
R. F. Chamberlain, chairman, Ithaca Section
C. L. Dawes, chairman, Boston Section
C. M. Foust, chairman, Schenectady Section
E. M. Hunter, secretary, Schenectady Section
K. B. McEachron, chairman, Pittsfield Section
R. M. Pfalzgraff, chairman, Lynn Section
H. C. Rankin, chairman, Providence Section
J. Leo Scanlon, chairman, Niagara Frontier Section
V. Siegfried, vice-chairman, Worcester Section
B. M. Werly, secretary, Rochester Section

The meeting was attended also by President A. M. MacCutcheon, Chairman W. H. Timbie of the Sections committee, National Secretary H. H. Henline, Editor G. R. Henninger, Chairman V. G. Smith of the Toronto, Ontario, Section, Chairman-Elect Ralph M. Darrin of the Niagara Frontier Section, and B. K. Northrop of the Ithaca Section.

During the dinner meeting, Vice-President A. C. Stevens announced the following winners of District prizes for 1936 technical papers, and made awards accordingly: (1) for the best Student Branch paper, William A. Harry of Cornell, now with the Bell Telephone Laboratories; (2) for first paper prize, Edgar A. Harty (A'22,M'36) in charge of design and manufacture of copper oxide rectifiers for the General Electric Company, Lynn, Mass.; (3) for the best paper prize, E. M. Hunter (A'28, M'36) central station engineering department, General Electric Company, Schenectady, N. Y. Details of these awards are covered in the formal report on paper prizes published elsewhere in this issue.

Another interesting demonstration lecture was delivered the evening of the first day by L. W. W. Morrow (A'13, F'25) general manager of the fiber products division of the Corning Glass Works, Corning, N. Y., on the subject of "Fibrous Glass." This is a new product of amazing characteristics. Although glass in every sense of the word manufactured by a secret process, the fibers look and feel not unlike silk, and lend themselves to the manufacture of all manner of fabrics through the use of regular textile manufacturing machines, in addition to having the inherent characteristics of glass, such as fireproofness and nonabsorbence of liquids. This new product is essentially an alloy, as is glass in any form, and has many properties similar to metallic alloys. A temperature of some 1,200 or 1,400 degrees centigrade is required to melt and mix the constituents preparatory to drawing the fibers. The fibers are about 0.0004 inch in diameter, and from 1.5 to 20 inches long, are heat-resistant, nonabsorbent, and strong (reputedly the equivalent of about a million pounds per square inch in the smaller fibers). It is a product of recent research and already is being used in the manufacture of textiles, insulating and other tapes, insulating pipe coverings, and house insulation, and the future seems wide open with possibilities for application in the manufacture of electrical equipment.

Registration is reported and analyzed in the accompanying tabulation.

**Analysis of Registration at Buffalo Meeting**

| | Location | | | |
|---|---|---|---|---|
| Classification | Buffalo | District 1* | Other Districts | Totals |
| Members | 63 | 80 | 44 | 187 |
| Students | 2 | 71 | 5 | 78 |
| Men guests | 22 | 35 | 11 | 68 |
| Women guests | 8 | 9 | 2 | 19 |
| Totals | 95 | 195 | 62 | 352 |

* Outside of Buffalo.

**Refrigerating and Air Conditioning Machinery Manufacturers Meet.** The Refrigerating Machinery Association met on May 12 and 13, 1937, at Hot Springs, Va., and immediately following, on May 14 and 15, the Air Conditioning Manufacturers' Association held its annual meeting.

# Section and Branch Activities

## Annual Report for 1936-37

THE following constitutes the annual report on Institute Section and Branch activities for the fiscal year which ended April 30, 1937. Similar information for 3 preceding fiscal years appeared in ELECTRICAL ENGINEERING for June 1936, pages 752–54; June 1935, pages 674–75; and June 1934, pages 1027–29.

The names of our present members of the Sections committee and the committee on Student Branches, which supervise the 2 important divisions of Institute activities covered by this report, are: Sections—W. H. Timbie, *chairman*, W. M. Dann, Mark Eldredge, O. W. Holden, E. T. Mahood, H. H. Race, I. M. Stein, and, *ex-officio*, the chairmen of all Sections of the Institute. Student Branches—F. Ellis Johnson, *chairman*, Edward Bennett, L. A. Doggett, E. E. Dreese, O. E. Edison, O. W. Eshbach, T. W. Fitzgerald, E. A. Loew, Charles F. Scott, R. W. Sorensen, and, *ex-officio*, all Student Branch counselors.

### SECTION ACTIVITIES

The East Tennessee Section was organized in September and enthusiastically began carrying on a normal amount of activity. This brought the total number of Sections to 62. Three prospective new Sections are being actively discussed.

Practically all the 62 Sections carried on at least normal amounts of activity, and many were unusually active. The total number of meetings reported was 621, or 81 more than the total for the preceding year.

President MacCutcheon visited about 40 Sections prior to April 30, and will visit several others, bringing the total number to about 47. He was enthusiastically welcomed, and his visits contributed much to the success of Section activities.

The outstanding development in Section activities in recent years is the inauguration of special types of meetings designed to meet as fully as possible the desires of the members. Eighteen Sections have adopted plans for holding technical group, technical committee, special technical, or other types of meetings devoted to more highly specialized subjects than those usually presented at regular Section meetings. The types of such activities usually have been chosen after receipt of replies to questionnaires requesting members to express their principal technical interests.

In 3 Sections, Alabama, Montana, and Toronto, local group meetings were held at points in their territories from which few members could attend regular Section meetings.

Table I contains tabular information on the meetings of all Sections and of their technical groups, technical committees, discussion groups, and other subdivisions. Information on many of these special activities has appeared in ELECTRICAL ENGINEERING during the past year. In the following statements, particular attention is given to some of the more recent developments, and especially to those of newer types.

The Toronto Section established a discussion group having as its purpose the development of engineers in the preparation and presentation of 5-minute talks and discussions. Meetings 40 minutes in length were held immediately preceding regular Section meetings and at the same place. Three talks and general discussion constituted the program of each. It is expected that this plan will be continued next year for the purpose mentioned and also to improve the knowledge of the members in economics and human relations in engineering.

The Toronto Section also formed a technical discussion group which met at supper on the evenings of Section meetings, and then held its discussions between 6:05 and 7:45. The general subject was "Control and Protective Practice"; 3 or 4 papers were presented at each meeting.

The Seattle Section sent a questionnaire

## Table II. Courses of Instruction Offered by Sections

| Section | Subject | Member Fee | Duration | Enrollment |
|---|---|---|---|---|
| Lynn | Electronics | $10.00 | October-December | 21 |
| New York | | | | |
| Power group | Electrical engineering | 10.00 | 20 weeks—September | 53 |
| | | | (Repeated)—January | 45 |
| | Structural planning and design | 10.00 | 20 weeks—September | 170 |
| | | | (Repeated)—January | 200 |
| | Industrial control lectures | 2.00 | 8 weeks | 120 |
| | Public speaking | 15.00 | 16 weeks—September | 17 |
| | | | (Repeated)—January | 15 |
| Communication group | Electronics lectures | 2.00 | 8 weeks | 300 |
| Niagara Frontier | Applied structural design | | October-January | 50 |
| Philadelphia | Electrical theory review | 15.00 | September-May | 23 |
| | Mathematics review | 15.00 | September-May | 25 |
| | Electronics (repeat) | 12.00 | January-May | 27 |
| | Any 2 courses | 25.00 | | |
| Springfield | Electronics | 10.00 | January-May | 30 |
| Vancouver | Electronics and electron tubes | 7.50 | 20 weeks | 27 |

to its members and to the members of the University of Washington Branch, in October 1936, asking whether they would be interested in taking part in technical group meetings devoted to 6 subjects which were named or to other subjects which they were invited to suggest. After a tabulation of the responses, the executive committee decided to organize technical groups covering the 4 subjects in which the greatest interest had been shown: transmission and distribution, power generation, communication, and electronics and electron tubes. Free discussion was encouraged. Attendance was very good, comparable in many cases with that at regular Section meetings.

The Schenectady Section junior discussion group held dinner meetings to which the younger members of the local Sections of several engineering societies were invited. Opportunities were presented for open discussions on technical and general subjects. It also held a technical discussion series of dinner meetings for members of the Sections. Subjects were chosen by use of a postal card interest finder.

The Columbus Section held a series of lectures on technical subjects of special interest to its members.

The Pittsfield Section held a colloquium series for brief presentations by specialists of published papers of interest to electrical engineers and general discussions of them.

The Philadelphia Section arranged near the end of the year for 2 technical discussion groups: one on system characteristics under fault conditions, the other on industrial applications of electricity.

The Rochester Section organized communication and power groups.

The power group of the Chicago Section continued its work with notable success, and an industrial group was formed.

The Cleveland Section continued its industrial motor and control group, and organized an electronics group.

The Denver Section organized a technical committee, and the Detroit-Ann Arbor

**Table VI. Conferences on Student Activities**

| District or Section | Location | Date |
|---|---|---|
| 7 | University of Arkansas, Fayetteville | 5/2/36 |
| 1 | New Haven, Conn. (North Eastern District meeting) | 5/8/36 |
| 8 & 9 | Pasadena, Calif. (Summer convention) | 6/23/36 |
| 7 | Dallas, Texas (South West District mtg.) | 10/27/36 |
| 2 | Ohio State University, Columbus | 11/13–14/36 |
| Pittsburgh Section | Pittsburgh, Pa. | 1/12/37 |
| 4 | Alabama Polytechnic Institute, Auburn | 4/2/37 |
| 6 | South Dakota State College, Brookings | 4/23/37 |

and Los Angeles Sections adopted plans for special technical meetings. The Lynn Section had several technical lectures. The Minnesota Section formed a power committee in the spring of 1936. The communication, illumination, power, and transportation groups of the New York Section continued their highly effective activities. The Portland Section communication, electrochemistry and electrometallurgy, illumination, and transmission and distribution groups were continued with excellent results. The San Francisco and Sharon Sections continued their special technical meetings.

The Lynn Section held a technical paper competition on April 6, 1937, offering 3 prizes of $15, $10, and $5, with the decisions based 1/3 on written papers, 1/3 on oral presentation, and 1/3 on ballot by the audience. The Springfield Section announced, in March 1937, a prize paper contest, opening at that time and closing on September 13, 1937, the subject being "Ways and Means to Improve the Springfield Section of the AIEE." The prizes are $25 and $10. Several Sections continued the prizes offered annually in the past.

The Pittsfield and Schenectady Sections held their annual competition in 2 joint meetings, one in each city, with 3 speakers representing each Section at each of the meetings. Prizes of $15 and $10 were awarded at each meeting.

The Schenectady Section held its fourth annual competition among men in the General Electric Company testing department, having 6 speakers selected from the original group of 21. Prizes of $10 and $5 were presented.

Sections that have been sponsoring student conventions and holding joint meetings with neighboring Branches continued the arrangements. The Baltimore Section sponsored a convention of the Student Branches in the eastern part of District 2 on April 19, 1937.

Table II contains information regarding courses of instruction offered by 6 Sections. In some cases the courses are open to nonmembers at higher fees. The fees were established at amounts that would meet the expenses involved. The Philadelphia Section reported that its courses have been valuable in building up interest in the Section, and have been responsible for obtaining a considerable number of new members and reinstatements. Other Sections reported keen and well-sustained interest in the courses.

Table III contains numerical information on Section meetings held during the past 3 years.

## Branch Activities

Two new Student Branches were organized during the year, one at Columbia University, New York, N. Y., on February 19, and the other at Tulane University, New Orleans, La., on March 1; both have been very active.

Nearly all Branches carried on a normal amount of activity, 87 having held 8 or more meetings each, and only 6 having held fewer than 4 meetings. Comprehensive information on many phases of Branch activities appears in Tables III to VIII, inclusive.

The total number of Branch meetings held during the year, as reported to headquarters, was 1,363, by far the largest number ever held in a fiscal year. The largest previous number was 1,137 for the year 1930–31, and the number for 1935–36 was 1,045.

The number of talks by students was also the largest number ever reported—1,130, as compared with 772 for the preceding year, and the largest previous number, 1,085, for the year 1930–31. However many Branches had few or no student talks, and this phase of the activities should receive more attention in the future.

Students have continued to show very

**Table VII. Student Conventions**

| Sponsored by District or Section | Location | Date | No. of Student Papers |
|---|---|---|---|
| 7 | University of Arkansas, Fayetteville | 5/1/36 | 13 |
| 1 | New Haven, Conn. (North Eastern District mtg.) | 5/8/36 | 9 |
| 8 & 9 | Pasadena, Calif. (Summer convention) | 6/24–26/36 | 10 |
| 7 | Dallas, Texas (South West District mtg.) | 10/27/36 | 9 |
| Pittsburgh Section | Pittsburgh, Pa. | 1/12/37 | 6 |
| 4 | Alabama Polytechnic Institute, Auburn, Ala. | 4/2/37 | 6 |
| Baltimore Section | Johns Hopkins University, Baltimore, Md. | 4/19/37 | 4 |
| New York Section | New York University, New York, N. Y. | 4/28/37 | 5 |

**Table VIII. Section or Joint Section and Branch Meetings With Active Student Participation**

| Sections | Schools | Date | Student Talks | Attendance |
|---|---|---|---|---|
| Minnesota | University of Minnesota | 5/13/36 | 4 | 54 |
| New Orleans | Louisiana State University | 5/15/36 | 2 | 105 |
| St. Louis | Missouri School of Mines and Metallurgy, University of Missouri, Washington University | 5/15/36 | 6 | 93 |
| Portland | Oregon State College | 5/16/36 | 3 | 60 |
| Cincinnati | University of Cincinnati | 5/19/36 | 4 | 100 |

| Vancouver | University of British Columbia | 3/1/37 | 4 | 52 |
| Dallas | Southern Methodist University | 3/1/37 | 3 | 70 |
| Houston | A. & M. College of Texas, Rice Institute | 3/11/37 | 2 | 60 |
| Atlanta | Georgia School of Technology | 3/15/37 | 4 | 40 |
| East Tennessee | University of Tennessee | 3/16/37 | 1 | 30 |
| Florida | University of Florida | 3/19/37 | 1 | 177 |
| Worcester | Worcester Polytechnic Inst. | 4/6/37 | 5 | 51 |
| Seattle | University of Washington | 4/12/37 | 2 | 57 |
| Washington | University of Maryland, George Washington University, Catholic University of America | 4/13/37 | 3 | 140 |
| Los Angeles | University of Southern Calif. Calif. Inst. of Technology | 4/13/37 | 5 | 203 |
| Cleveland | Case School of Applied Science | 4/15/37 | 2 | 117 |
| Minnesota | University of Minnesota | 4/21/37 | 4 | 55 |
| San Francisco | University of California, University of Santa Clara, Stanford University | 4/23/37 | 3 | 152 |
| Spokane | University of Idaho, State College of Washington | 4/30/37 | 2 | 108 |
| Totals—20 Sections, 30 Branches | | | 68 | 1,859 |

keen interest in opportunities to take part in joint Section and Branch meetings and in student conventions. Details regarding such meetings appear in tables VII and VIII.

Students presented 9 papers in one session of the North Eastern District meeting in New Haven, Conn., May 6–9, 1936; 10 papers in 2 sessions of the combined summer and Pacific Coast convention in Pasadena, Calif., June 22–26, 1936; and 9 papers in 2 sessions of the South West District meeting in Dallas, Texas, October 26–28, 1936. They have keenly appreciated these opportunities, and the quality of material and the presentations has inspired numerous favorable comments by Institute members.

About 54% (674) of the Enrolled Students whose terms expired on April 30, 1937 (1,253) applied for admission as Associates, this being the highest percentage during the past several years.

## Engineers' Club Organized at Fort Wayne, Ind.

To provide a medium "for closer co-operation in the engineering profession" in Fort Wayne, Ind., the Fort Wayne Engineers' Club has been organized. Many members of the AIEE Fort Wayne Section have played important parts in formulating the organization plans according to Section Chairman D. H. Hanson who supplied the information for this news item. Although its organization meeting was held in January of this year, the club already has some 350 members representing all branches of the profession and all industries and utilities in the Fort Wayne area.

The primary objects of the club are: "(1) The advancement of the arts and sciences connected with engineering by the presentation and discussion of subjects, and by the participation in matters of interest to the engineering profession; (2) to advance the interest of individual members and to enhance the prestige of the profession within the community; and (3) to promote closer union and co-operation among the members by professional and social intercourse." Civic co-operation is said to be one of its chief purposes.

As temporary officers, the following have been serving:

**President:** H. M. Witherow (A'28, M'36) electrical engineer, General Electric Company, past-chairman (1935–36) of the Fort Wayne Section.

**Vice-President:** W. M. Carroll, mechanical engineer, S. F. Bowser Company.

**Secretary:** P. H. Daily, chemical engineer, International Harvester Company.

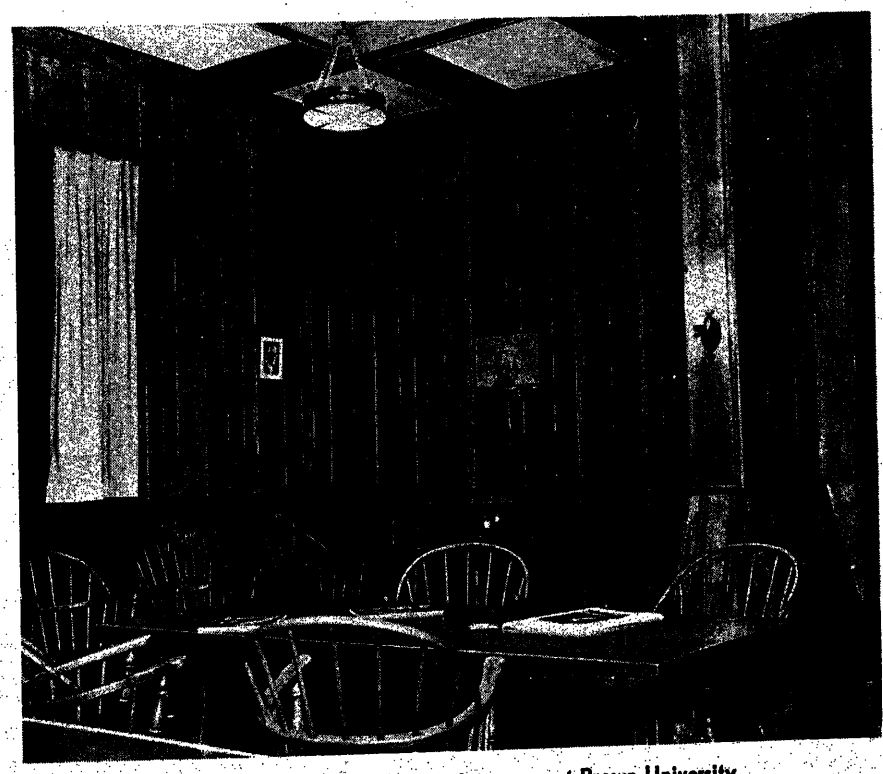
**Treasurer:** Otto Gumpper, civil engineer, City of Fort Wayne.

**Temporary Directors:** J. I. Cornell, radio engineer, Magnavox Company; M. H. Merritt, chemical engineer, Kopper's Construction Company; J. Kuttler, automatic engineer, International Harvester Company; E. W. E. Kamm, engineer and patent attorney, S. F. Bowser Company; L. D. Nordstrum (A'04, M'13) electrical engineer, General Electric Company (Section chairman 1914–15); and John McKay, civil engineer, Indiana Service Company.

Regular election will take place at the May meeting of the club.

## Engineering Society Room Constructed at Brown University

TO MEET the need of a social room for engineering students at Brown University, Providence, R. I., a small classroom was remodeled in such manner as to make it an attractive meeting and lounging place. This room, located in the engineering building, is the headquarters of the student engineering societies, and as such forms the natural social center for all engineering students at the university. The following description of the project was supplied by Professor Frederick N. Tompkins, counselor of the AIEE Brown University Branch:



The engineering society organization, as operating at Brown, closely follows that of the Providence Engineering Society. The parent society is the Brown Engineering Society, to which all engineering students are eligible and which serves as a co-ordinating society for the branches of the AIEE, ASME, and ASCE. Practically all the juniors and seniors join one of the branches of the national societies while the freshmen and sophomores seldom do so. Thus, since members of the branches are automatically members of the Brown Engineering Society, membership adapted to all students is provided. Joint meetings are almost always held, small meetings taking place in the society room, larger gatherings in one of the class rooms; and several times each year an evening meeting, including dinner, is held at the University Camp, which is in the country within easy motoring distance of Providence.

As the money for this project was limited, student help was used in the construction under the guidance of members of the staff. An old colonial design was decided upon, and since the room was originally part of a laboratory with a very high ceiling and walls of whitefaced brick, a total reconstruction was necessary. A new beamed and paneled ceiling was hung from the orginal. The panels, which are of Celotex, lift out since the piping and wiring above may need servicing at some time. The walls were sheathed with knotty pine laid vertically, boxes and grills being built around the existing heating coils on two walls. The windows originally were not built to be opened, swinging transoms being provided at the top for ventilation. As the new ceiling was dropped below these, it was necessary to rebuild the windows to the casement type and they were fitted with attractive drapes.

A lally column support for the floor above was boxed in and a leather-covered seat built around its base, thus removing what otherwise would have been an eyesore and detriment to the appearance of the room. The walls were stained with a mixture of oak and walnut stain and finished with a hand-rubbed wax finish. The door did not fit the architecture of the room, so that it was sheathed to correspond and fitted with hand-made antique latches.

Special hand-made ceiling lighting units and antique-type wall brackets were made by a member of the staff who makes a hobby of constructing such material. The question of suitable furniture then arose; it was decided to buy Windsor chairs, but to make the other pieces in so far as possible. Suitable reading and study tables were designed and built, as was a ping-pong table.

A suitable floor covering for the concrete

A view of the engineering society room at Brown University

floor being beyond the budget possibilities at the time, the floor was filled and painted to serve until some future date when a linoleum covering could be purchased.

This room represents one of the finest investments ever made from the standpoint of student morale and usefulness. It is in use nearly all the time and is of particular help to freshmen and sophomores who, since they do not have much work in the laboratories of the engineering division, are apt to feel a lack of contact with their fellow students, particularly with upper classmen.

## Telephone Building for 1939 World's Fair

The American Telephone & Telegraph Company, through its president, Walter S. Gifford (A'16), has contracted with the New York World's Fair Corporation for a building site of more than 3 acres for an exhibit at the fair in 1939. "We plan to erect an imposing structure on the site allocated to us," Mr. Gifford said. "Inspired by the theme of the fair ('building the world of tomorrow'), we intend to construct a building in which we shall give exhibitions of the fascinating forces underlying modern electrical communications. . . . The fair will give our industry the opportunity to tell our story to millions of visitors, and when the fair opens its gates I am sure that the roster of industrial America will be there blazing the trail to a better tomorrow."

The agreement is the first exhibit contract into which the fair corporation has entered; an area of about 75 acres is available for private buildings and is expected to be allocated to exhibitors by similar contracts. Other exhibit space will be available in buildings to be erected by the corporation. The cornerstone of the $900,000 administration building, the first to be erected on the site of the fair at Flushing Meadow in the borough of Queens, was laid April 27, 1937.

## NEMA Welding Section Aids AWS Expansion

The electric welding section of the National Electrical Manufacturers Association, recognizing the important functions of the American Welding Society as a technical spokesman for the welding industry, voted at its January 1937 meeting to furnish financial support to the extent of $10,000 for the expansion program which the AWS recently proposed. A matter of immediate importance is the co-ordination of tests of men, machines, and filler metal, so as to relieve some of the unnecessary burden which a great duplication of test requirements has brought about.

At the March meeting of the NEMA welding section a co-ordinating committee was appointed to work with the management committee of the AWS and to make the fund available as it is required for support of the new activities.

# American Engineering Council

## Report of Patents Committee as Adopted by AEC Assembly

A REPORT of the patents committee of American Engineering Council for the year 1936, as adopted by the assembly of AEC at its annual meeting held January 15, 1937, is presented herewith. In approving the report, the assembly left to action of its executive committee the matter of a budget for financing further studies subject. The personnel of the AEC patents committee for 1936 was: R. S. McBride, *chairman;* David Beecroft, J. H. Critchett, William Grosvenor, F. B. Jewitt (A'03, F'12, past-president) and Warner Seely. Full text of the report follows:

The committee on patents during 1936 considered the 2 major problems assigned to it by action of the assembly in January 1936, and has given brief attention to various legislative hearings and proposed Federal enactments. By correspondence and conference the committee has formulated certain recommendations which it suggests as a basis for action of the staff of the Council during the coming legislative session. It also recommends a somewhat modified plan for future work of the committee.

A number of bills were introduced in the last session of Congress and Congressional hearings held with a view to determining what Congress might do to regulate pooling or cross-licensing of patents. Additional proposals of legislation are contemplated in the next session of Congress. Exploration of this field leads the committee to renew the recommendations of last year and to suggest the adoption of the following resolution by the assembly:

1. American Engineering Council opposes enactment of any forms of legislation thus far introduced into Congress to limit or to regulate pooling or cross-licensing of patents.

The committee feels that the public interest has been much more served than harmed by patent pools and by cross-licensing. Such evils as may have been experienced would not have been corrected by any of the proposed forms of legislation. The committee feels that administration of present laws, including proper and reasonable application of antitrust legislation, would suffice to correct those types of evils of pooling which have been disclosed or charged as bad practice.

Further investigation of this important subject is necessary. It will require considerable work, first in the gathering of information as to past experience of successful pools and cross-licensing plans. The committee believes that such study should be made the major activity of the committee on patents during 1937, and recommends the following resolution:

2. American Engineering Council should provide as a part of the 1937 budget a small allotment of funds in order that specialists and clerical assistance can be secured to make a survey of past experience as the basis of a further study by the patents committee on the subject of pooling and cross-licensing of patents.

At its last annual meeting the assembly of the American Engineering Council expressed its support for the idea of the single Court of Patent Appeals. A definite bill providing for such a court was introduced in the last Congress. Such bill will be reintroduced, probably in several modified forms. The committee believes that Council should give support to the general idea, with such limitations as should be suggested in order to secure the highest standard of technical proficiency in the selection of judges, by the following resolution:

3. American Engineering Council reiterates its approval of the proposed single Court of Patent Appeals to review decisions of the lower courts as applied to facts presented to the lower courts but not for introduction of new evidence. It looks with favor upon the idea of having the judges named to such court selected by the President only after careful review of their special and technical competence with the advice of the engineering and scientific societies as well as advice of the patent bar and the legal profession.

Scientific advisers to the courts have been recommended by a number of agencies, but not all with the same purpose. Most often quoted is the suggestion of a special patents committee of the Science Advisory Board. That committee recommended that scientific advisers be made available to aid *trial* court justices. In this conclusion the committee agrees. The patents committee looks with some favor on such an idea if a suitable method of selecting advisers free from preconceived opinions were fixed and if a sufficiently diversified list of skilled scientific and engineering talent were made available. However, the committee has doubted the wisdom of having such scientific advisers named permanently as a part of a new single Court of Patent Appeals. It feels that the idea of naming 3 such advisers who would serve for all classes of cases would not afford such highly skilled aid in all divisions of science and technology as courts really require. Furthermore, the committee gravely questions whether an appellate court could properly utilize scientific advisers under circumstances that would deny to the litigants all right of examination or cross-examination of such witnesses as to their experience, disinterestedness, reasons for their recommendations, and factual basis for their opinions. The committee recommends the following resolution:

4. American Engineering Council recommends that no provision be made for the naming of scientific advisers to the proposed Court of Patent Appeals.

A wide variety of legislative proposals were before the last Congress intending limitation of life of patents or restriction on freedom of use of patents by owners. Among the varied subjects of legislation were the following: (*a*) taxation during nonuse, and at increasing rates; (*b*) compulsory working; (*c*) compulsory licensing; (*d*) prompt (3-year) final action in the Patent Office;

(*e*) publicity in the Patent Office 3 years from the date of filing; (*f*) expiration of patents 20 years from date of filing; (*g*) free Government use of patents and freedom of Government infringement in times of emergency; (*h*) provision for Government employees patents, with or without free public use; (*i*) validation of patents 5 years after issue, if uncontested.

The committee on patents is unanimously opposed to all these legislative proposals under present circumstances. It believes Council should take some formal action regarding these matters on the following lines:

5. American Engineering Council opposes all the various types of proposals which would restrict the freedom of owners of patents to use them constructively under present laws. It opposes them as not necessary for the public welfare, and prospectively objectionable both from the standpoint of the inventor and the public need for stimulation of progress by inventions. It regards such offenses as are now charged against the patent system as the result of defects in administration of present laws and not as evidence of the need for more legislation.

The committee believes that every effort should be made by industry as well as by the engineering profession to increase the presumption of validity of patents as issued. It feels that engineers generally should assist patent examiners whenever possible to keep abreast of the arts with respect to which they are examining patent applications. The committee has not found any legislation, proposed to date, sufficiently constructive to feel that it deserves support of the American Engineering Council. It does, however, hope that some means may be developed for increasing the standards of competence and experience of the staff of examiners.

Most promising of the proposals for this purpose thus far presented appears to be the suggestion that the number of higher rank and better paid examiners be increased, if necessary at the expense of the number of junior examiners engaged. By this change it is hoped that the more competent and efficient members of the examiner's staff may be advanced in salary and positions more rapidly. It is hoped that there would then be less tendency for the better members of the examiner's staff to resign from the Patent Office early in their career because of unwarranted delay before promotion, such as now often experienced.

The committee does not believe that this matter requires formal action but does suggest that the membership of the engineering profession can well give encouragement to this or any other means found practical for advancing the standards and increasing the technical knowledge of the Patent Office staff.

# Standards

## Railway Motors

A complete revision of AIEE Standard No. 11, "Railway Motors" has been completed by a sectional committee working under the rules of procedure of the American Standards Association and the sponsorship of the Institute. The new American standard is now available in pamphlet form; it is known as No. 11 "Railway Motors and Other Rotating Electrical Machinery for Rail Cars and Locomotives," the new title being indicative of the increased scope of the standard.

A detailed description of the changes that have taken place was covered in an article published in ELECTRICAL ENGINEERING, March 1936, pages 312–13 Copies of the standard are available at 50 cents each with 50 per cent discount to members on single copies. Address AIEE, 33 West 39th Street, New York, N. Y

## Wires and Cables

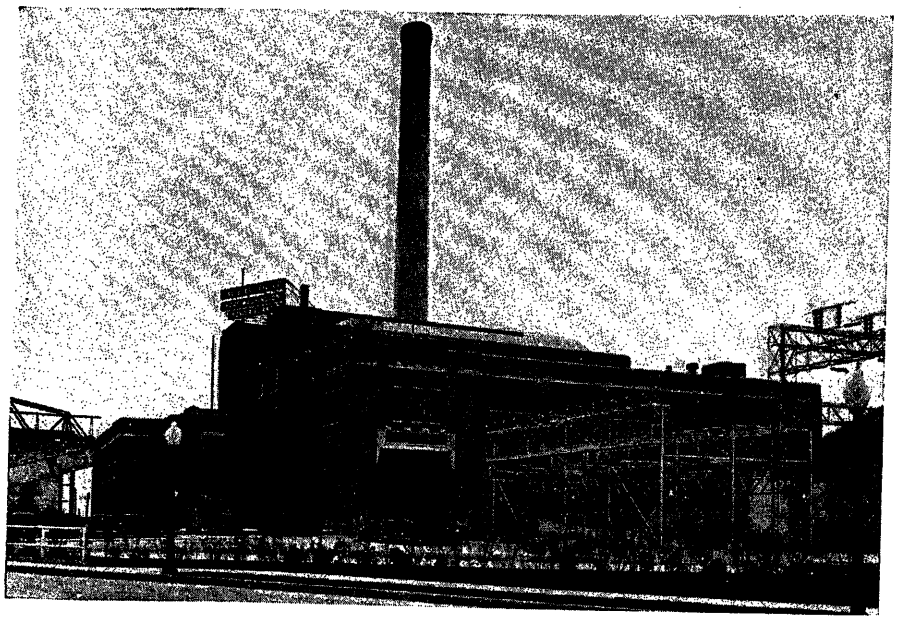
In the standards for wires and cables 8 new specifications have been added, 5 of these representing entirely new developments and 3 being extensive revisions of former standards. All have the status of American Standard or Tentative Standard. A listing of the 8 follows:

*Nos. C8.5, C8.6, C8.7* (published as one pamphlet superseding former AIEE Nos. 69, 70, and 71) Cotton Covered, Silk Covered, and Enameled Round Copper Magnet Wire, respectively. Price 30 cents per copy with 50 per cent discount to members on single copies. Address AIEE, 33 West 39th Street, New York, N. Y.

*C8.11 Code Rubber Insulation for Wire and Cable for General Purposes* is based on the requirements for the rubber insulation in the Underwriters' Laboratories' Standard for Code Wire. It is in agreement with the 1936 edition of that standard. Price 20 cents each with 50 per cent discount to members on single copies. Address AIEE, 33 West 39th Street, New York, N. Y.

*C8.12 Cotton Braid for Insulated Wire and Cable for General Purposes.* These specifications cover braids as applied to rubber and varnished cloth insulated wires and cables. They do not cover "fancy" or special braids or braids for fixture wire or weather resisting wire and cable. Three classes of braids are covered, namely: heavy, for outdoor or rough service; standard, for indoor or protected service; and code, for installation under the National Electric Code. Price 20 cents each with 50 per cent discount to members on single copies. Address AIEE, 33 West 39th Street, New York, N. Y.

*C8.16 Tree Wire Coverings.* Tree wire is a cable having a solid or stranded conductor insulated with a material such as a rubber compound and having a weather- and abrasion-resistant covering. These specifications provide that the coverings shall be of such quality and characteristics that they will not substantially deteriorate with age and proper usage except for a minimum amount of wear due to rubbing against the branches of trees. Price 20 cents each with 50 per cent discount to members on single copies. Address AIEE, 33 West 39th Street, New York, N. Y.



*C8.17 Class OA 30 Per Cent Rubber Insulation for Wire and Cable for General Purposes.* This new standard corresponds to the insulation requirements in ASTM Standard *A27-55T* entitled "Insulated Wire and Cable: Class *OA* 30 Per Cent, Hevea Rubber Compound." The clauses with respect to thickness, chemical requirements, and electrical requirements are identical with those for Class *A* 30 Per Cent Compound (*C8.4*—former AIEE No. 63), but the tensile strength and elongation requirements are somewhat higher. Also, there are 2 additional tests not in the class *A* standard: namely, moisture absorption and accelerated aging. Price 20 cents each with 50 per cent discount to members on single copies. Address AIEE, 33 West 39th Street, New York, N. Y.

*C8.18 Weather Resistant Wire and Cable URC Type.* These specifications cover weather-resistant (weatherproof) wire and cable, the conductors, the materials used for the fibrous coverings, and the saturating and finishing compounds. They are a further development of specifications originally proposed to the industry by the Utilities Research Commission, Inc. Price 20 cents each with 50 per cent discount to members on single copies. Address AIEE, 33 West 39th Street, New York, N. Y.

**Indicating Electrical Measuring Instruments and Instrument Transformers.** This new publication issued by the National Electrical Manufacturers Association contains the material, revised and augmented that was last published in the NEMA apparatus standards. Of particular interest are the new sections devoted to standard dimensions of indicating instruments and the accuracy limits of current and potential transformers. Price 60 cents each. Address National Electrical Manufacturers Association, 155 East 44th St., New York, N. Y.

**Household Electric Refrigerator Standards.** This pamphlet published by the National Electrical Manufacturers Association covers household electric refrigerators and includes such material as the standard method of computing gross volume and food-shelf area, and also the test code for conducting and reporting such tests as "no load" and "ice making." Price 40 cents each. Address National Electrical Manufacturers Association, 155 East 44th Street, New York, N. Y.

**Test Code on Apparatus Noise Measurement.** The standards committee on April 30 authorized the publication of a "Proposed Test Code for Apparatus Noise Measurement." This code has been prepared under the auspices of the subcommittee on sound of the AIEE standards committee, P. L. Alger, chairman. This test code is intended for use as a guide in the measurement of sound levels and the investigation of the various elements that contribute to the total noise produced. It is an aid to the establishment of reasonably uniform methods of conducting and reporting sound-level tests, so that results will be of value for record and will be comparable with tests made at other times and places. As soon as it is possible to complete the work of publication, notice of availability of the code will be made.

**Port Washington plant of the Milwaukee (Wis.) Electric Railway and Light Company, which may be visited by those attending the Institute's 1937 Summer Convention. For the first 10 months of operation, the average fuel consumption was 11,094 Btu per kilowatt-hour of station output**

# Letters to the Editor

CONTRIBUTIONS to these columns are invited from Institute members and subscribers. They should be concise and may deal with technical papers, articles published in previous issues, or other subjects of some general interest and professional importance. ELECTRICAL ENGINEERING will endeavor to publish as many letters as possible, but of necessity reserves the right to publish them in whole or in part, or reject them entirely.

ALL letters submitted for consideration should be the original typewritten copy, double spaced. Any illustrations submitted should be in duplicate, one copy, to be an inked drawing but without lettering, and other to be lettered. Captions should be furnished for all illustrations.

STATEMENTS in these letters are expressly understood to be made by the writers; publication here in no wise constitutes endorsement or recognition by the American Institute of Electrical Engineers.

## Heaviside Calculus and Carson's Integral

*To the Editor:*

The Heaviside operational calculus is finding increasingly widespread application. Accordingly, any device to shorten the work involved in its use would appear of value. In the present note is described a simplification which was found by the writer to greatly facilitate his own computations.

The Heaviside calculus has as its fundamental problem[1] the determination of what is known, in electrical theory, as the "indicial admittance" of a linear physical system. This is simply the response of the system, initially in equilibrium, to a unit disturbance suddenly applied at time zero and maintained constant thereafter. In dynamics, the indicial admittance might correspond to the velocity of a system resulting from a suddenly imparted unit acceleration. In electricity, it is usually the current resulting from a suddenly applied electromotive force of unit magnitude.

Having determined the indicial admittance, the characteristics of a system are then completely determined mathematically, except for a single integration.[1] Adopting electrical terminology, we have the following equation for the current as a function of time, $t$:

$$I(t) = E(0)\,A(t) + \int_0^t A(t-\tau)\,\frac{dE(\tau)}{d\tau}\,d\tau$$

where $I$, $E$, and $A$ represent, respectively, current, electromotive force, and indicial admittance, and $\tau$ is the time variable of integration. In other words, knowing the indicial admittance of a circuit, the response of the circuit at any time, $t$, to an arbitrarily varying electromotive force can be determined (at least formally) by application of the above integral. The integral was independently derived by J. R. Carson, but has long been known in dynamics as Duhamel's integral.

The writer had occasion to use the operational calculus in problems involving fairly arbitrary disturbances. The determination of the unit response of "indicial admittance" was a routine application of the Heaviside expansion formula. (This will not be treated here but can be found in all works on the principles of operational calculus.) However, attempts to apply this in the Carson integral, as given above, proved tedious. Graphical solution was no more economical of time, although it must be employed in some form when the disturbance is given by an arbitrary curve. The writer then noticed that the integral could be made considerably less complex. The step taken was extremely simple and obvious, but does not appear to have been made heretofore. By cancelling the $dt$'s, and correspondingly changing the limits of integration, the integral becomes

$$I(t) = \int_0^{E(t)} A(t-\tau)\,dE(\tau)$$

(The term $E(0)\,A(t)$ is now included by the lower limits of integration.)

To evaluate this graphically it is only necessary to plot $A(t-\tau)$ against corre-

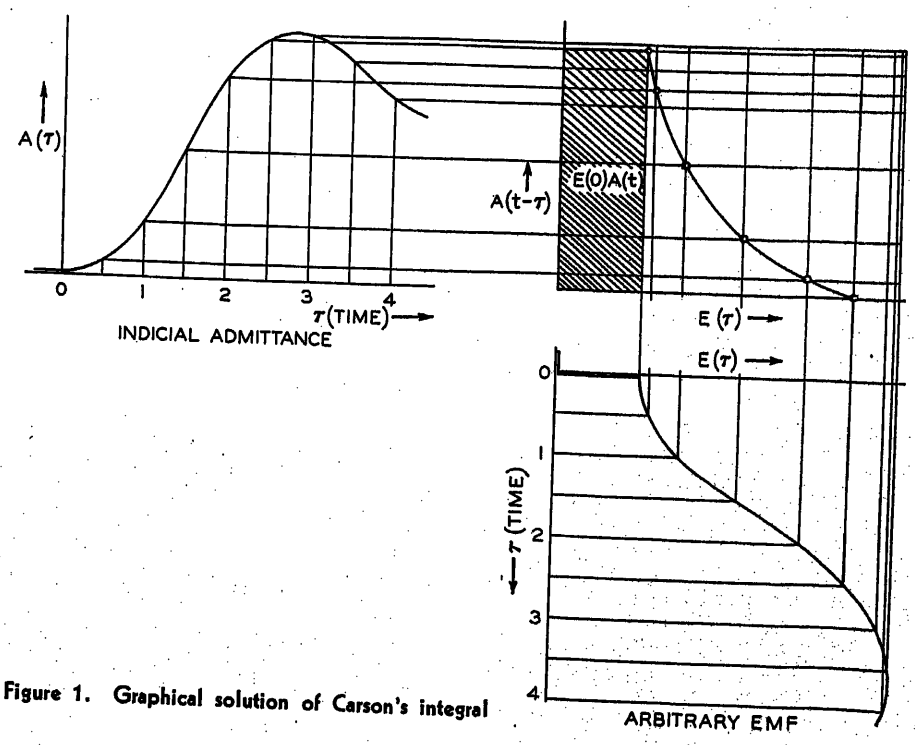


**Figure 1. Graphical solution of Carson's integral**

sponding values of $E(\tau)$ and then measure the area under the curve. A procedure has been developed that makes the work almost mechanical and very rapid. Referring to figure 1, $A(\tau)$ and $E(\tau)$ are plotted so that the $\tau$ axes are perpendicular. Horizontal lines are drawn through points of the $A$ curve corresponding to a series of regularly spaced values of $\tau$. Vertical lines are similarly drawn through points of the $E$ curve corresponding to the same values of $\tau$. Both the vertical and horizontal lines are designated by the corresponding values of $\tau$ and each intersection of a vertical and a horizontal line is designated by the sum of the 2 corresponding values of time, $\tau$. If $I(t)$ is desired for $t = t_1$ a curve is drawn through all intersections designated by the sum $t_1$. The area under this curve is $I(t_1)$. On the diagram, the curve is drawn for $t_1 = 2^1/_2$ seconds. A separate curve evidently results for each instant $t$ at which the value of $I$ is desired. With some care, however, as many as 10 curves can be plotted on a single sheet.

For those interested in the fundamentals of the Heaviside operational calculus, including the application of the above graphical solution of Carson's integral, reference 2 is suggested.

## Invention of the Watt-Hour Meter

*To the Editor:*

In the January 1937 issue of ELECTRICAL ENGINEERING, in the paper "Development of a Modern Watt-Hour Meter" by I. F. Kinnard and H. E. Trekell, page 172, lines 6 to 8, the origin of the a-c induction watt-hour meter is ascribed to Shallenberger, in 1894. There is no doubt about Shallenberger's inventing in 1888 (simultaneously with Borel and Paccard in Switzerland) the a-c induction *ampere*-hour meter, but the induction *watt*-hour meter is my invention; see U.S. Patent 423,210, filed October 7, 1889, and issued March 11, 1890. The principle is very clearly explained in lines 88–95 in the first page of specification: ..."the inductive resistance of the shunt winding is very great as compared with its ohmic resistance, its phase of magnetization will be displaced for nearly one quarter of a phase from that of the series magnet..."

To get exact quadrature between the 2 magnetic fields, all modern meters have also a shunt path for part of the magnetic flux produced by the voltage coil. Though this was not expressly put forth in the specification, the numerous figures in the patent show it clearly: large pole surfaces provide a considerable amount of stray fields not acting on the meter disk.

In fact, even the first type of meters manufactured by Ganz & Co., from 1889 onwards, had approximately quadrature

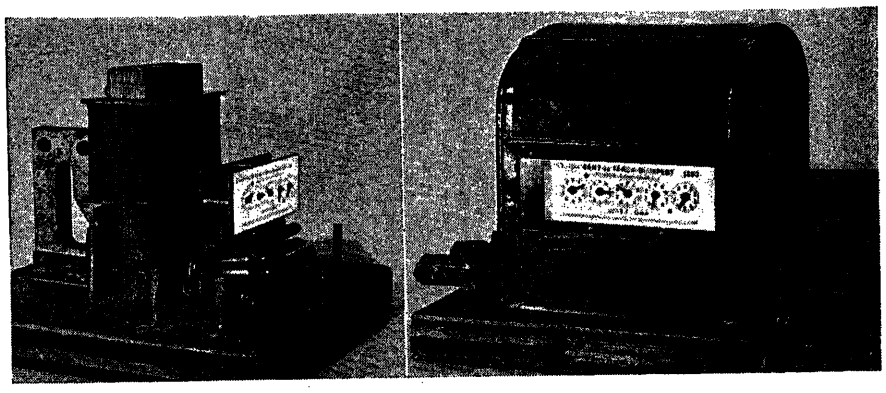

**Figure 1. An a-c induction watt-hour meter manufactured in 1893**

phase difference between current and voltage fields, though at that remote date this was of no great importance, as loads were nearly exclusively glow lamps and even the earliest meters were sufficiently satisfactory in this respect.

Meter number 2,157, made in 1893, came back into our museum after about 25 years of service; retested, without adjustment, and taking the 100 per cent load at $\cos\varphi = 1.0$ as unity, it gave the following indications:

| | | | | | | |
|---|---|---|---|---|---|---|
| $\cos\varphi$ | 1.0 | 0.9 | 0.8 | 0.7 | 0.6 | 0.5 |
| slow, % | 0 | 1.6 | 2.5 | 3.5 | 4.5 | 7.0 |

Meter number 52, made in 1889, but with the air-gap of the current field magnet increased from the original 10 millimeters to 20 millimeters (this was usual about a few years afterward, to straighten out the constant curve), everything else unchanged, came back after about 20 years of service; retested, without adjustment, and taking 100 per cent load at unity power factor as unity, it gave the following readings:

| load, % | 10 | 25 | 50 | 75 | 100 |
|---|---|---|---|---|---|
| $\cos\varphi = 1.0$ | 1.006 | 1.002 | 1.005 | 1.000 | 1.000 |
| $\cos\varphi = 0.5$ | 1.04 | 1.002 | 1.017 | 1.005 | 1.025 |

Meter number 2,157 is shown in figure 1; "watt-ora" means watt-hours. The torque of these early meters was from 60 to 100 centimeter-grams (600 to 1,000 millimeter-grams). Weight of the rotor was about 100 grams.

One of these earliest induction watt-hour meters is in The Edison Institute at Dearborn, Mich.

Very truly yours,

DOCTOR OTTO T. BLÁTHY
Ganz & Co. Ltd.
Budapest, Hungary

## Electronic Tube Nomenclature

*To the Editor:*

I notice on page 284 of the February 1937 issue of ELECTRICAL ENGINEERING a tabulation of electronic tube nomenclature that is being studied by the American Standards Association.

As comments have been invited, I submit the following point of view:

In connection with the names "kenetron" and "pliotron," would it not be wiser to dispose of these terms and adopt simply the terms "diode," "triode," etc.? This would pave the way for tubes with larger numbers of grids and is in conformity with the present-day practice where we have ascended the scale up to the point of pentode.

If we are to adopt certain terms, such as "pliotron" which have arisen in the industry subsequent to the pioneer work, I wonder if we are keeping pace with the early group of experimenters and inventors. I have in mind, for example, the idea or rather term introduced by DeForest, "the audion." The audion was originally applied by DeForest to the 2-electrode tube or diode and later to his triode. Were we to consider giving credit to DeForest for his invention of the 3-electrode tube, then certainly it would seem that it should carry the term "audion" into our present-day nomenclature. On the other hand, this would naturally raise a question as to whether or not Edison should be associated with the triode and perhaps it will raise a question on the part of some whether or not Fleming should be associated with the diode. Edison gave no term to his 2-electrode tube. However, when Fleming used this particular instrumentality, later, it became popularly known as "the Fleming valve." Since the 2-electrode tube used by Fleming and the 2-electrode hard diode of today are so very nearly the same as Edison's original tube, it would seem to me that any type of personal designation would need to reflect proper credit upon Edison.

An endeavor to give individual inventors credit or individual scientists credit certainly leads to difficulty. Nevertheless, out of deference to these pioneers, we should not adopt comparable terms of a commercial character which, it seems to me, have the unfortunate effect either of making the origin of the devices obscure or leading to a gross misunderstanding.

The great contributions of our telephone company, the Westinghouse Company, the General Electric Company, and others to the vacuum tube art are, of course, well recognized. However, I wonder if it is wise to adopt a term originated by one of these companies if that term carries no more significance with it than just the name. It would seem far better in this case to go over to the impersonal terms, diode, triode, tetrode, pentode, etc. which can raise no question in the minds of many contributors to this art.

Very truly yours,

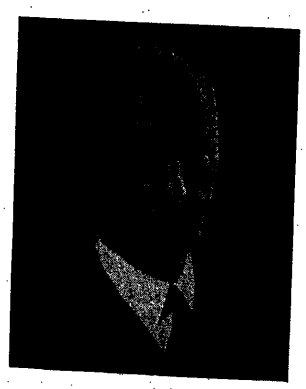
EDWARD L. BOWLES (A'22, F'33)
Associate Professor of Electrical Communications, Massachusetts Institute of Technology, Cambridge.

# Personal Items

J. W. WHITE (A'29) general manager of the Westinghouse Electric International Company, New York, N. Y., has been elected vice-president and general manager of that company. Mr. White was born at Indianapolis, Ind., in 1889, and received his early education at Randolph-Macon Academy; later, while engaged with the Westinghouse company at East Pittsburgh, Pa., he attended Carnegie Institute of Technology. He joined the Westinghouse Electric & Manufacturing Company, East Pittsburgh, in 1905, and continued at the main works until 1912. In 1917 Mr. White filled the position of manager of the central station and transportation divisions of the Detroit, Mich., offices of that company. His first connection with the export business was in 1918, when he was assigned the managership of the Westinghouse offices at Havana, Cuba. In 1925 he was made managing director of the Westinghouse Company of Japan, with his staff offices at Tokyo. In 1931 Mr. White was made managing director of Cia. Westinghouse Electric International in Argentina, which position he held until he was returned to the United States in 1936 to become general manager of the Westinghouse Electric International Company.

F. W. SMITH (A'05, M'12) president, Consolidated Edison Company of New York, Inc., Brooklyn (N. Y.) Edison Company, Inc. and New York and Queens Electric Light and Power Company, has retired. Mr. Smith was born June 16, 1867, at Alden, N. Y., and began his career as an office boy for the United States Illuminating Company in 1880. His service with that company and its successors therefore has spanned a period of almost 57 years; he entered the electrical industry 2 years prior to the opening of the Pearl Street station of the Edison Electric Illuminating Company of New York, and 3 months after the introduction of the incandescent lamp by Thomas A. Edison. In 1883 Mr. Smith became a general clerk and remained in that position until 1889 when he was appointed paymaster for the United Electric Light and Power Company, successor to the United States Illuminating Company. In 1891 he was made assistant auditor of the company, and after remaining in that position for 8 years was elected assistant secretary. A year later he was elected secretary of The Brush Electric Illuminating Company, of which he subsequently became president and a director. In 1905 Mr. Smith was elected secretary of the United Electric Light and Power Company; in 1912 he became vice-president; in 1916, general manager. In 1926 he was elected chairman of the board of directors of the New York and Queens Electric Light and Power Company, and in 1929 became president of The Brush Electric Illuminating Company. Mr. Smith was elected president of The New York Edison Company, Inc., and the United Electric Light and Power Company in 1932; president of the Consolidated Edison Company of New York, Inc., in 1935; and president of the Brooklyn Edison Company, Inc., in 1936. He was active in the affairs of the former National Electric Light Association, and served as vice-president (1919), president (1922), and member and chairman of many of the committees of that organization. He is a member of several technical organizations.

L. B. FULLER (A'03) superintendent of power, Utah Power & Light Company, Salt Lake City, has been appointed chief engineer of the company. Mr. Fuller was born June 14, 1879, at Nelson, Ohio, received a diploma from Hiram College, attended Montana State College, and was graduated from Cornell University in 1906. He had been engaged in engineering work before receiving his formal technical education, and following his graduation was employed as construction superintendent of the Telluride Power Company's Grace, Idaho, hydroelectric plant; upon completion of that plant in 1908 he was transferred to the engineering department of the Telluride Power Company. In 1913 Mr. Fuller was appointed general construction foreman on power house and penstock construction during an extension of the Grace hydroelectric station by the Utah Power & Light Company, successor to the Telluride Company. During 1916–18 he served as construction superintendent on several hydroelectric projects, and in 1919 was appointed general construction superintendent of an extensive hydroelectric and steam-electric project executed by the Phoenix Utility Company for the Utah Power & Light Company. In 1927 Mr. Fuller was appointed assistant superintendent of power of the Utah Power & Light Company; he became superintendent of power in 1929.



J. A. HALE (M'26) formerly chief engineer of the Utah Power & Light Company, Salt Lake City, recently was appointed vice-president of both the Utah Power & Light Company and the Utah Light & Traction Company. Mr. Hale was born September 18, 1888, at Calloway, Va., and received the degree of bachelor of science in civil engineering at Virginia Polytechnic Institute. In 1911 he was appointed junior engineer in the United States Reclamation Service, remaining in that capacity until 1913, when he became affiliated with the Utah Power & Light Company as an assistant engineer. During 1918–19 he served as cost engineer for the United States Housing Corporation, but late in 1919 returned to the Utah Power & Light Company to continue his service with that company without interruption. Mr. Hale was appointed chief engineer in 1927.

E. G. CONROY (A'32) formerly superintendent of radio, City of San Antonio, Texas, now is associated with the bureau of municipal research at the University of Texas, Austin. Mr. Conroy is a native (1907) of San Antonio, and received the degree of bachelor of science in electrical engineering at the University of Notre Dame in 1930. Following his graduation, he entered the long lines department of the American Telephone and Telegraph Company at South Bend, Ind., as a student engineer, and remained with that company until he was appointed supervisor of radio of the City of San Antonio. Mr. Conroy is chairman of the AIEE San Antonio Section.

W. H. BURLESON (M'31) formerly assistant manager of the power utilities department of the Ohio Brass Company, Mansfield, Ohio, has been appointed manager of that department. Mr. Burleson was graduated from the Texas Agricultural and Mechanical College in 1913, following which he joined the engineering staff of the Texas Power and Light Company and eventually

J. W. WHITE

F. W. SMITH

L. B. FULLER

J. A. HALE

became assistant chief engineer of that company before associating himself with the Ohio Brass Company in 1922. His work with the Ohio Brass Company has required much traveling, and he has visited many utility companies throughout the United States and Canada. Mr. Burleson is chairman of the engineering committee of the high-voltage section of the National Electrical Manufacturers' Association, chairman of the United States Department of Commerce standing committee on simplified practice recommendation 73, covering one-piece insulators, a member of the American Standards Association committee on insulator standardization, and temporary chairman of the ASA subcommittee on suspension-insulator standardization.

L. J. BERBERICH (A'30, M'36) recently resigned his position as research engineer in charge of cable- and capacitor- oil development for the Socony-Vacuum Oil Company, Incorporated, Paulsboro, N. J., to become a research engineer in the insulation division of the research laboratories of the Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa. Doctor Berberich was born at Petersburgh, Va., in 1906, and received the degrees of bachelor of engineering (1928) and doctor of engineering (1931) at The Johns Hopkins University. In 1931 he was appointed to the faculty of The Johns Hopkins University, and served as a full-time research assistant, but in the following year he joined the research staff of the Socony-Vacuum Oil Company. He was placed in charge of cable- and capacitor-oil development in 1934. Doctor Berberich is a member of the National Research Council's committee on insulation and the American Society of Testing Materials committee D-9 on electrical insulating materials. He is a member of the American Association for the Advancement of Science and Sigma Xi.

A. J. JOHNSTON (A'32) engineer for the American Totalisator Company, Baltimore, Md., has been transferred to San Mateo, Calif., as manager of the Pacific coast division of that company. Mr. Johnston is a native (1897) of Milwaukie, Ore., and an electrical engineering graduate of Oregon State College. He spent several yeaas in design and application engineering of supervisory control and telemetering equipment for the General Electric Company before becoming affiliated with the American Totalisator Company, and is the author of a paper "The Torque Balance Telemeter," presented at the 1932 AIEE summer convention.

O. L. RIGGS (A'21, M'29) formerly superintendent of electric distribution, Lynn (Mass.) Gas and Electric Co., recently was appointed sales manager for the American Electric Service and Maintenance Company, Springfield, Mass. Mr. Riggs entered the employ of the United Electric Light and Power Company, New York, N. Y., as an inspector in 1920, where he remained until 1925 before becoming affiliated with the Lynn Gas and Electric Company.

PAUL NARBUTOVSKIH (A'32) teaching assistant in electrical engineering, Stanford University, Calif., has been appointed to the faculty of the mathematics department of San Jose State College, San Jose, Calif. Mr. Narbutovskih was born at Tiumen, Russia, in 1902, and received the degree of bachelor of arts at Stanford University in 1929, following which he remained at that institution as a graduate student and teaching assistant. He is the author of a paper, "Tooth-Frequency Eddy-Current Loss," published in the February 1937 issue of ELECTRICAL ENGINEERING, pages 253–6.

R. B. CAPRON (A'30, M'30) assistant distribution engineer, Utica (N. Y.) Gas and Electric Company, has been appointed distribution engineer for the St. Lawrence area of the Niagara Hudson Power Corporation, with headquarters at Potsdam, N. Y. Mr. Capron received the degrees of bachelor of arts (1926) and electrical engineer (1928) from Columbia University, following which he entered the employ of the Utica Gas and Electric Company as a cadet engineer. He became assistant distribution engineer in 1934.

H. R. ANDERSON (A'27, M'36) formerly assistant electrical engineer for United States Engineers, Fort Peck, Mont., now is employed as transmission engineer for the Loup River Public Power District, Columbus, Nebr. Mr. Anderson, a native (1900) of Huron, S. D., and an electrical engineering graduate of Iowa State College, has had experience in engineering and construction work with several public utility companies.

ALEXANDER WILSON (A'15) assistant to the vice-president in charge of operations Philadelphia (Pa.) Electric Company, has been made operating manager of the company. Mr. Wilson was born at Philadelphia in 1887 and received the degree of mechanical engineer at Cornell University in 1910. Almost immediately following his graduation, he entered the employ of the Philadelphia Electric Company and has since served that company as construction engineer (1918–27), assistant chief engineer (1928–30), and assistant to the vice-president in charge of operations since 1930.

E. H. COLPITTS (A'11, F'12) retired vice-president of the Bell Telephone Laboratories, Incorporated, New York, N. Y., recently was awarded the Japanese Fourth Order of Merit of the Sacred Treasure, in recognition of his promotion of electrical engineering in Japan and his furthering of good relations between Japan and the United States. A biographical sketch of Doctor Colpitts appeared in the April 1937 issue of ELECTRICAL ENGINEERING at the time of his retirement.

C. C. LONG (A'14, M'30) mechanical and electrical construction engineer, Riegos y Fuerza del Ebro, Barcelona, Spain, has returned to the United States. Mr. Long has been in Spain since early in 1930, during which time he has had complete charge of the planning, design, purchase of materials, and construction of a series of hydroelectric stations featuring completely automatic control.

H. H. KRUEGER (A'21) who has been assistant superintendent of power of the Utah Power & Light Company, Salt Lake City, has been appointed superintendent of power. Mr. Krueger entered the employ of the Utah Power & Light Company in 1914 and in the following 2 years served as operator or maintenance engineer of many of the generating stations and major substations of the interconnected system of that company. After serving as chief dispatcher and as a member of the production and transmission department, he became assistant superintendent of power in 1930.

WILLIAM KELLY (F'25) president of the Buffalo, Niagara, and Eastern Power Corporation, Buffalo, N. Y., has been elected a vice-president and director of the newly formed Buffalo Niagara Electric Corporation. A biographical sketch of Colonel Kelly appeared in the February 1937 issue of ELECTRICAL ENGINEERING, page 290.

N. I. KORMAN (Enrolled Student) North Attleboro, Mass., who is enrolled at Worcester Polytechnic Institute, Worcester, Mass., has been awarded a Charles A. Coffin fellowship. Mr. Korman, a native (1916) of Providence, R. I., will pursue research in ultrahigh-frequency measurements at Massachusetts Institute of Technology.

N. R. GIBSON (M'32) vice-president of the Buffalo, Niagara, and Eastern Power Corporation, Buffalo, N. Y., has been elected a vice-president and director of the recently organized Buffalo Niagara Electric Corporation. A biographical sketch of Mr. Gibson appeared in the February 1937 issue of Electrical Engineering, page 290.

D. L. HERR (Enrolled Student) University of Pennsylvania, Philadelphia, has been awarded a Charles A. Coffin fellowship. Mr. Herr is a native (1916) of Ephrata, Pa. He will remain at the University of Pennsylvania to study oscillation in nonlinear circuits.

J. F. BRINER, JR. (A'36) has resigned his position as an under clerk in the Electric Rate Survey, Federal Power Commission, New York, N. Y., to become affiliated with the engineering department of the Niagara, Lockport, and Ontario Power Company, Buffalo, N. Y.

S. M. ZUBAIR (A'27, M'34) formerly an assistant electrical engineer for the Buffalo, Niagara, and Eastern Power Corporation, Buffalo, N. Y., now is employed by The Tata Hydro-Electric Power Supply Co., Ltd., Bombay, India.

W. T. ELSTON, JR. (A'36) has resigned his position as a field engineer for the Central Hudson Gas and Electric Corporation, Kingston, N. Y., to join the research engineering department of the Speer Carbon Company, St. Marys, Pa.

G. S. ONORY (A'33) formerly an electrical engineer for the consulting engineering firm of Ford, Bacon, and Davis, New York, N. Y., now is an assistant valuation engineer for the New York State Public Service Commission, with headquarters at Rochester.

R. R. MCGEE (A'28) formerly employed in the switchgear engineering department of the General Electric Company, Philadelphia, Pa., now is associated with the Trumbull Electric Manufacturing Company, Plainville, Conn.

ROBERT LOEWE (A'32) who has been a surveyor for the Works Progress Administration, Chicago, Ill., now is employed as a transformer design engineer for the Westinghouse Electric & Manufacturing Company, Sharon, Pa.

R. V. CREASY (A'36) who has been an electrical draftsman for the Newport News Shipbuilding and Dry Dock Company, Newport News, Va., now is an equipment engineer for the Western Electric Company, Chicago, Ill.

H. E. STAFFORD (A'13, M'25) formerly electrical superintendent of the Canadian International Paper Company, Nipigon, Ont., now is employed in the consulting engineering firm of John Stafford, Toronto, Ont.

E. A. ROTHFUS (A'35) formerly an electrician, United States Engineers, Fort Peck, Mont., now is employed as an electrical tester for the Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.

F. P. Rosso (A'36) city electrical engineer, Cherokee, Okla., Municipal Light and Water Department, now is associated with the Public Service Company of Oklahoma, McAlester, in the commercial lighting department.

J. L. BLACKBURN (A'36) graduate student, Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa., recently was transferred to the Newark, N. J., offices of that company.

C. T. GOHN (A'35) clerk, Westinghouse Electric & Manufacturing Company, Philadelphia, Pa., has been transferred to the test engineering department of the East Pittsburgh, Pa., works of that company.

# Obituary

ARTHUR WILLIAMS (A'97, M'08, F'13, member for life) former vice-president of The New York (N. Y.) Edison Company, Inc., died April 14, 1937. Mr. Williams was born August 14, 1868, at Norfolk, Va., and was educated in private schools at New York. He served The New York Edison Company for 42 years, starting as a repair boy in 1885 and retiring in 1928 as vice-president in charge of commercial relations. He became general commercial manager of the company in 1915 and held that position until 1924, when he was made vice-president in charge of commercial relations. In 1917 Mr. Williams was appointed to the post of food administrator for the city of New York; he served in that capacity for 2 1/2 years before resigning in 1920. During the Spanish-American War he served as commanding officer of the New York Volunteer Forces, mining New York Harbor. In 1912 he was decorated by the King of Spain, receiving the rank of knight in the Royal Order of Isabel the Catholic, and in 1926 was made a chevalier of the French Legion of Honor. Mr. Williams was a past-president of the American Association for the Advancement of Science, Association of Edison Illuminating Companies, and the National Electric Light Association; he was also a member of the American Academy of Political and Social Sciences, American Electrochemical Society, American Association for Labor Legislation, International Industrial Relations Association, and Society of American Military Engineers.

EDDY CLIFFORD JERMAN (A'20) director of the educational department, General Electric X-Ray Corporation, Chicago Ill., died September 13, 1936, according to word just received at Institute headquarters. Mr. Jerman was born in Ripley County, Indiana, November 21, 1865, and attended Franklin College and Central Business College (Austin, Texas), following which he became associated with the Physicians and Surgeons Supply Company and Jones Brothers Electric Company, both of Cincinnati, Ohio, as an electrician. In 1891 he established his own business at Indianapolis, Ind., at first selling medical and dental electrical supplies; however, in 1896 he began to manufacture X-ray machines. Until 1903 Mr. Jerman acted as an instructor in medical electricity at the Physiomedical College of Indiana and the Central College of Physicians and Surgeons of Indiana; at that time he moved his offices to Topeka, Kans., where he continued the manufacture of electromedical equipment until in 1917 he joined the staff of the Victor X-Ray Corporation, which later became the General Electric X-Ray Corporation, to organize its educational department. Mr. Jerman's service as director of that department covered a period of almost 20 years.

GUY S. TURNER (A'18) president, Turner and Turner, Inc., Memphis, Tenn., died in March 1937. Mr. Turner was born April 2, 1876, at Water Valley, Miss. From 1896 to 1898 he served as a machinist for several companies in Texas and in Mexico, and following a year's service with the United States Army Signal Corps during the Spanish-American War, entered the employ of the Memphis Power and Light Company in 1899. He was first a machinist, but became successively electrical foreman, chief electrician, superintendent and mechanical engineer, and engineer in charge of manufacture, remaining with that company until 1920. At that time he established the firm of Turner and Turner, and served as its president for 16 years.

PHILIP A. LANG (A'88, M'88, member for life) retired engineer, London, England, died February 25, 1937. Mr. Lang was born in October 1856, in Mecklenburg, Germany, and started his technical career as an electrician for Siemens Brothers and Company, Woolwich, England, in 1880. In 1882 Mr. Lang came to the United States and secured a position as head of the testing department of Bergmann and Company, New York, N. Y., where he remained for 4 years before becoming associated with the Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa., first as an electrician and later as superintendent of the detail department. He was subsequently sent to England as a representative of the Westinghouse company, and eventually became managing director of the British Westinghouse Electric & Manufacturing Company, Trafford Park.

# Membership

## Recommended for Transfer

The board of examiners, at its meeting on May 12, 1937, recommended the following members for transfer to the grade of membership indicated. Any objection to these transfers should be filed at once with the national secretary.

**To Grade of Fellow**

Pratt, Haraden, vice-president and chief engr., Mackay Radio and Telegraph Co., New York.

1 to Grade of Fellow

**To Grade of Member**

Bewley, L. V., electrical engineer, General Electric Company, Pittsfield, Mass.
Dyer, L. L., superintendent of substations, Southern California Edison Company, Los Angeles.
Garin, A. N., electrical engineer, General Electric Company, Pittsfield, Mass.
Goodwin, V. E., managing engineer, lightning arrester, cutout and capacitor department, General Electric Company, Pittsfield, Mass.
Jackson, E. S., electrical distribution engineer, Consumers Power Company, Jackson, Mich.
Pettee, A. D., district engineer, General Cable Corporation, Chicago, Ill.
Pinder, K., electrical engineer, E. I. du Pont de Nemours and Co., Wilmington, Del.
Rey, W. J., electrical engineer, United States Department of the Interior, Washington, D. C.
Roser, J. O. K., assistant to manager, transformer division, General Electric Company, Pittsfield, Mass.
Schott, J. T., telephone engineer, Bell Telephone Laboratories, Incorporated, New York, N. Y.
Underwood, R. J., assistant engineer, New England Power Service Company, Providence, R. I.

11 to Grade of Member

## Applications for Election

Applications have been received at headquarters from the following candidates for election to membership in the Institute. If the applicant has applied for direct admission to a grade higher than Associate, the grade follows immediately after the name. Any member objecting to the election of any of these candidates should so inform the national secretary before June 30, 1937, or August 31, 1937, if the applicant resides outside of the United States or Canada.

Adams, E. V., British Columbia Electric Railway Company, Ltd., Vancouver, B. C., Canada.
Alexieff, V. M., Pacific Gas and Electric Company, San Rafael, Calif.
Anspacher, W. B., Union Electric Power and Light Company, St. Louis, Mo.
Arvidson, C. E., Commonwealth and Southern Corporation, Jackson, Mich.
Ballou, R. P. (Member) Allen Bradley Company, Milwaukee, Wis.
Beller, C. J. (Member) Cleveland Electric Illuminating Company, Cleveland, Ohio.

Benkesser, G. E. (Member), Bureau of Power and Light, Los Angeles, Calif.
Bragunier, C. E., Phoenix Engineering Corporation, New York, N. Y.
Brown, G. C. (Member), Cutler-Hammer, Inc., Milwaukee, Wis.
Brown, M. J., Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.
Buswell, M. P., Westinghouse Electric & Manufacturing Company, Seattle, Wash.
Cameron, D. G., General Electric Company, Lynn, Mass.
Campbell, J. F., Consolidated Edison Company, New York, N. Y.
Clay, L. J., Public Service Supply Company, Inc., Cleveland, O.
Cluff, T. W. (Member), Ottawa Electric Company and Ottawa Electric Railway Company, Ottawa, Ont., Canada.
Coburn, W. N., Green Mountain Power Corporation, Bellows Falls, Vt.
Coggeshall, I. S. (Member), Western Union Telegraph Company, New York, N. Y.
Condit, P. A., Pure Oil Company, Chicago, Ill.
Critchley, W. A. (Member), 1730 Ocean Avenue Brooklyn, N. Y.
Crosby, F. A., Otis Elevator Company, San Francisco, Calif.
Crosby, T. H. (Member), Canadian Westinghouse Company, Ltd., Vancouver, B. C., Canada.
Dailey, J. A. (Member), General Electric Company, Kansas City, Mo.
Dickinson, W. E., 7*D* Godfrey Court, Fort Riley, Kans.
Diemond, C. C., Bureau of Reclamation, Ephrata, Wash.
Ellerbeck, K. H., Pacific Telephone and Telegraph Company, Seattle, Wash.
Ennis, B. J., Burns and McDonnell Engineering Company, Kansas City, Mo.
Fisken, J. B. (Member), Water Division, City of Spokane, Wash.
Fleischer, F. H., General Electric Company, Fort Wayne, Ind.
Fuller, A. G., Phelps Dodge Corporation, Ajo, Ariz.
Gilman, B. E., L. E. Myers Company, Caro, Mich.
Gosal, G. S., 1731 Allston Way, Berkeley, Calif.
Graham, A. M., Western Union Telegraph Company, Washington, D. C.
Gratz, D. W., Glendale Public Service, Glendale, Calif.
Gronauer, C., Milwaukee Electric Railway and Light Company, Milwaukee, Wis.
Harrison, R. (Member), Scarborough Public Utilities Commission, Toronto, Ont., Canada.
Heiman, H. O. (Member), city engineer's office, Milwaukee, Wis.
Hiers, J. B., Jr. (Member), General Electric Company, Miami, Fla.
Hopwood, J. M., Globe Union, Inc., Milwaukee, Wis.
Howery, H. A. (Member), Kansas City Power and Light Company, Kansas City, Mo.
Hranac, F. V., Unites States Navy Department, Washington, D. C.
Huehnel, A. L., Square D Company, Milwaukee, Wis.
Hughes, M. McC., General Electric Company, Louisville, Ky.
Jones, R. L., Southwestern Bell Telephone Company, Oklahoma City, Okla.
Kalbach, J. F., General Electric Company, Fort Wayne, Ind.
Karg, W. R., Diehl Manufacturing Company, Elizabeth, N. J.
Kinser, J. H., Houston Lighting and Power Company, Houston, Texas.
Kokesh, F. P., Minneapolis-St. Paul Sanitary District, St. Paul, Minn.
Kunz, A. F., Ohio Bell Telephone Company, Cleveland, O.
Lauder, A., Phillips Electrical Works, Ltd., Brockville, Ont., Canada.
Mallett, M. B. (Member), General Electric Company, Pittsfield, Mass.
McCall, R. L. (Member), substations and water department, Jacksonville, Fla.
Meichel, C. B. (Member), Department of Public Utilities, St. Louis, Mo.
Mergenthaler, A. H. (Member), Alabama Power Company, Birmingham.
Merkel, N. M., Metropolitan Edison Company, Reading, Pa.
Meyers, W. N., Federal Shipbuilding and Drydock Company, New York, N. Y.
Miller, G. R., Metropolitan Water District of Southern California, Rice, Calif.
Myers, H. C., Government Printing Office, Washington, D. C.
Osborne, H. R., Ferranti Electric, Ltd., Toronto, Ont., Canada.
Osgood, D. T., Bell Telephone Laboratories, Incorporated, New York, N. Y.
Osterhout, E. W., New Jersey Zinc Company, Franklin, N. J.
Pacanins, A., Hilicrest Hotel, Toledo, O.
Penn, L., Travelers Insurance Company, New York, N. Y.
Pennington, C. C., Tennessee Valley Authority, Chattanooga, Tenn.
Perkins, W. S., General Electric Company, Bridgeport, Conn.
Pickles, S. B., Gardner Electric Manufacturing Company, Emeryville, Calif.
Ramadanoff, D. (Member), Cornell University, Ithaca, N. Y.
Ramien, C. H., Jr., Globe Union, Inc., Milwaukee, Wis.
Reeves, G. A., Jr., Oklahoma Gas and Electric Company, Oklahoma City, Okla.
Robbins, C. F., Cutler-Hammer, Inc., Milwaukee, Wis.
Rohlfsen, A. G., Johns-Manville Products Corporation, Lompoc, Calif.
Schmidt, I. F., Milwaukee Electric Railway and Light Company, Milwaukee, Wis.
Schnabel, J. F. (Member), Euclid Electric an Manufacturing Company, Euclid, Ohio.
Schoen, A. M., Commonwealth and Southern Corporation, Jackson, Mich.
Shuman, U. S., Philadelphia Electric Company, Philadelphia, Pa.
Smith, C., New York and Queens Electric Light and Power Company, Flushing, N. Y.
Smith, C. G., Smith Milligan Electric Company, Tulsa, Okla.
Spitler, C. H., Brown-Brockmeyer Company, Inc., Dayton, O.
Stark, O. P., Jr., Hoosier Engineering Company, Columbus, Ohio.
Steel, H. D., Herman D. Steel Company, Philadelphia, Pa.
Stevenson, R. B., Dollar Steamship Company, San Francisco, Calif.
Stodola, F. J., Milwaukee Electric Railway and Light Company, Milwaukee, Wis.
Thwaites, J. T., Canadian Westinghouse Company, Hamilton, Ont., Canada.
Tibbals, L., Colonial Radio Corporation, Buffalo, N. Y.
Tracy, J. B., Jr., Radio Experimental Laboratories, Taunton, Mass.
Ullman, F. (Member), Westinghouse Electric & Manufacturing Company, New York, N. Y.
Vialet, F. C., 2257—7th Avenue, New York, N. Y.
Wedge, R. E., General Electric Company, Fort Wayne, Indiana.
Wells, C. A., Southern California Telephone Company, Los Angeles, Calif.
Younger, D., American Telephone and Telegraph Company, Buffalo, N. Y.
Zigler, M. O., Federal Power Commission, Denver, Colo.

# Engineering Literature

## New Books in the Societies Library

Among the new books received at the Engineering Societies Library, New York, recently, are the following which have been selected because of their possible interest to the electrical engineer. Unless otherwise specified, books listed have been presented gratis by the publishers. The Institute assumes no responsibility for statements made in the following outlines, information for which is taken from the preface of the book in question.

MUNICIPAL YEAR BOOK. 1937. Edited by C. E. Ridley and O. F. Nolting. Chicago, International City Managers' Association, 1937. 599 pages, illustrated, 10x7 inches, cloth, $5.00. Contains articles on developments in various fields of municipal administration and gives statistics on cities over 10,000. Lists educational institutions giving courses in public administration and includes a directory of city officials in all cities over 10,000.

MEN of MATHEMATICS. By E. T. Bell. New York, Simon and Schuster, 1937. 592 pages, illustrated, 10x6 inches, cloth, $5.00. Biographical and critical information about the important men in the mathematical field, from the Greeks to the present time.

**Engineering Societies Library**
29 West 39th Street, New York, N. Y.

MAINTAINED as a public reference library of engineering and the allied sciences, this library is a co-operative activity of the national societies of civil, electrical, mechanical, and mining engineers.

Resources of the library are available also to those unable to visit it in person. Lists of references, copies or translation of articles, and similar assistance may be obtained upon written application, subject only to charges sufficient to cover the cost of the work required.

A collection of modern technical books is available to any member residing in North America at a rental rate of five cents per day per volume, plus transportation charges.

Many other services are obtainable and an inquiry to the director of the library will bring information concerning them.

FIRST ELEVATED RAILROADS in MANHATTAN and the BRONX of the CITY of NEW YORK. By W. F. Reeves. New York, New York Historical Society, 1936. 137 pages, illustrated, 10x7 inches, cloth, $3.00. Description of the development and progress of the early elevated railroads in Manhattan and the Bronx, including the various schemes proposed from 1825 up to the first actual construction in 1867.

JOURNAL of the ROYAL TECHNICAL COLLEGE, volume 4, part 1, January, 1937. Glasgow, Royal Technical College. 212 pages, illustrated, 10x7 inches, paper, 10s. 6d. Contains several papers of interest to electrical engineers, including a discussion of the sensitivity of the Schering bridge network and the commutation period in grid-controlled mercury-arc rectifiers.

THEORIE der WECHSELSTROMMASCHINEN in Vektorieller Darstellung. By W. Michael. Leipzig und Berlin, B. G. Teubner, 1937. 272 pages, illustrated 10x6 inches, paper, 16.50 rm.; bound, 18 rm. (in U.S.A.). Develops the theory of a-c machines by means of "space diagrams" and "space vector diagrams." Includes chapters on transformers, induction machines, commutator motors, auxiliary machines, and cascade connections between induction and commutator machines.

OBJECTIVE RATE PLAN for Reducing the Price of Residential Electricity. By W. F. Kennedy. New York, Columbia University Press, 1937. 83 pages, charts, tables, 9x6 inches, cloth, $1.25. Relates the history of the plan, the reasons for its adoption and the results obtained.

COMPENSATING INDUSTRIAL EFFORT. By Z. C. Dickinson. New York, Ronald Press Company, 1937. 479 pages, illustrated, 9x6 inches, cloth, $4.50. A study of the problem of work incentives. Covers the causes determining the amount of wages of occupations and individuals, the relative efficacy of various stimuli and factors in increasing production, and the social consequences of various work-and-pay situations.

ALTERNATING CURRENTS in RADIO RECEIVERS. By J. F. Rider. Published by author, 1440 Broadway, New York, N. Y., 1937. 94 pages, illustrated, 9x6 inches, paper, $0.60. A discussion of basic facts about alternating currents in radio receivers.

AMERICAN SOCIETY for TESTING MATERIALS. INDEX to PROCEEDINGS, volumes 31–35 (1931–35). Philadelphia, American Society for Testing Materials, 1937. 194 pages, 9x6 inches, cloth, $2.25; half leather, $3.00. Contains author and subject indexes for the *Proceedings* of 1931–1935 and of the symposiums presented at regional, local, and annual meetings, and not published in the *Proceedings*.

APPLICATIONS of the METHOD of SYMMETRICAL COMPONENTS. (Electrical Engineering Texts.) By W. V. Lyon. New York and London, McGraw-Hill Book Company, 1937. 579 pages, illustrated, 9x6 inches, cloth, $6.00. Designed to demonstrate the use of symmetrical components in the solution of problems in unsymmetrical polyphase circuits. The reader is expected to have a thorough grounding in single-phase and symmetrical polyphase circuits, transformers, and symmetrical operation of 3-phase induction and synchronous machines.

GÉNÉRATRICES et MOTEURS à courant continu. By E. Roth and J. Bardin. Paris, Librairie Armand Colin, 1937. 223 pages, illustrated, 7x5 inches, paper, 13 frs.; bound, 15.50 frs. Presents the principles of d-c machines, written in easily understood language and intended for students and designers.

# Industrial Notes

**Building Construction Still Upward.**—Not since May 1930 has residential building been undertaken in such heavy volume as was reported in April this year, according to F. W. Dodge Corp. The value of such operations started during April in the 37 states east of the Rocky Mountains amounted to $108,204,400, a gain of 20 per cent over the March figure and an increase of 61 per cent over April 1936. Besides residential building, the April 1937 figures show $96,179,300 for non-residential building and $65,741,500 for heavy engineering projects, i. e., public works and public utilities.

**U. S. Rubber Appoints Dr. Sturdevant.**—According to a recent announcement United States Rubber Products, Inc., has appointed Dr. Earl G. Sturdevant as consulting engineer of its electrical wire and cable dept. Dr. Sturdevant joined the company in 1929, being previously connected with the Western Electric Co. In 1931 he was appointed development manager of the electrical wire and cable department, where he contributed to the successful development of Laytex, the new dielectric.

**New Branch Manager for Weston.**—H. E. Held has recently been appointed to succeed the late C. F. Henderson as manager of the San Francisco agency of the Weston Electrical Instrument Corporation, with offices at 420 Market St. Mr. Held was previously assistant to Mr. Henderson for a number of years.

**Resistance Wire Division Sold.**—The C. O. Jelliff Mfg. Corp., Southport, Conn., has recently purchased the resistance wire division of George W. Prentiss and Co., of Holyoke, Mass.

**Century Electric Moves New York Office.**—The New York office of the Century Electric Co. has been moved from 50 Church St. into larger quarters in the Underwood Building, 30 Vesey St. James Larkin is district sales manager.

**Frigidaire Plants Enlarged.**—The erection of 2 new factory buildings, together with enlargement and rearrangement of the Moraine City, O., manufacturing facilities of Frigidaire Div., General Motors Corp., will be started shortly. The construction and plant layout program will involve an expenditure in excess of $4,000,000.

**New Oil Blast Circuit Breaker.**—A new oil blast circuit breaker, type FK-45, with 75,000 kv-a interrupting rating has been announced by the General Electric Co. The FK-45 unit is a non-oil-throwing breaker with plate steel rectangular tank with separating chamber, internal mechanism, silver-to-silver main contacts, easily renewable arcing contacts, oil blast baffles, and Herkolite bushings. It is available in three current sizes, 600, 1200 and 2000 amperes. A feature of the new breaker is its sturdy tank construction which makes it especially applicable where heavy duty and small space requirements are indicated.

**New Type Motor Starter.**—The Allis-Chalmers Manufacturing Co., Condit Works Boston, Mass., announces a new type of across-the-line air motor-starter, equipped with "Ruptors," known as type AP-7. The Ruptors are enclosing chambers which confine and depotentiate the arc formed by circuit interruption. These "arc-depotentiating chambers" greatly increase the interrupting ability of the contacts and form an isolating barrier between contacts of opposite polarity. The starter is furnished for $7\frac{1}{2}$ hp at 440 and 550 volts, 5 hp at 220 volts, and 3 hp at 110 volts.

**New G-E Building in Los Angeles.**—Contracts were recently awarded for the construction of a new $700,000 General Electric building at Los Angeles. The new building is designed to contain 6 stories and basement, 3 stories of which are planned to be completed for occupancy by September. The new structure will occupy approximately a city block in the downtown section of Los Angeles and will contain 250,000 square feet of floor space.

# Trade Literature

**Capacitors.**—Catalog 139A. Describes new pole-type capacitors for power correction of distribution systems. Cornell-Dubilier Corp., South Plainfield, N. J.

**Fire Alarm Systems.**—Bulletin 102, 16 pp. Describes Samson fire alarm systems for institutions, factories, etc. S. H. Couch Co., Inc., North Quincy, Mass.

**Watthour Meters.**—Bulletin GEA-2404A, 16 pp. Describes 2-element, single-disk watthour meters, their mountings, connection diagrams, etc. General Electric Co., Schenectady, N. Y.

**Underground Conduit.**—Bulletin 3751, 16 pp. Describes fibre conduit, standard and thin wall, together with fittings. Line Material Co., So. Milwaukee, Wis.

**Heating Units.**—Bulletin GED-650, 60 pp. Describes numerous small heating units and devices of all kinds for a wide variety of applications. General Electric Co., Schenectady, N. Y.

**Flexible Metal Tubing.**—Bulletin SS-3, 16 pp. Describes seamless flexible metal tubing, one of the 4 major styles of flexible metal hose made by this company. Illustrates a wide variety of installations where absolute tightness in conveying liquids or gases is essential. The American Brass Co., American Metal Hose Branch, Waterbury, Conn.

**Pulleys and Couplings.**—Bulletin, 4 pp. Describes a complete line of "V" grooved pulleys, variable speed and step-cone pulleys; flexible couplings. Congress Tool & Die Co., Inc., 9030 Lumpkin Ave., Detroit, Mich.

**Flow Meters.**—Catalog, 40 pp. Describes electrical and mechanical flow meters for recording, integrating, controlling and indicating the flow of steam, liquids, or gases. Details of the new electric flow meter and its operation, using Bristol's metameter principle of telemetering, are included. The Bristol Co., Waterbury, Conn.

**Service Cables.**—Bulletin C-31, 20 pp. Describes various types of service cables, illustrating uses and installations permitted by the National Electric Code. Typical applications and specifications are included. Anaconda Cable and Wire Co., 25 Broadway, New York City.

**Lightning Protective Equipment.**—Bulletin GEA-1743B, 12 pp. Describes lightning protective equipment for a-c rotating machines insuring protection against traveling-wave voltages due to lightning. The protective arrangement covers the combined use of arresters and capacitors. General Electric Co., Schenectady, N. Y.

**Motors.**—Bulletin 305. Describes Reliance disc-brake motors,—combined units for power applications requiring quick, accurate, automatic stops or the holding of a load. Typical applications are small cranes, hoists, and auxiliary movements on machine tools. They frequently eliminate the need for clutches and permit direct connection of motors. Reliance Electric & Engineering Co., 1086 Ivanhoe Rd., Cleveland, O.

**Arc Welders.**—Bulletin "The Arc-Welding of Tomorrow." Describes the advantages gained by the use of the internally stabilized arc of the "Smootharc Welder." Photographs illustrate the applications of many of the models, from the vertical 75- and 100-ampere types to the 200-, 300-, 400- and 600-ampere horizontal types. Stationary and portable-trailer models are also shown. Harnischfeger Corp., 4200 W. National Ave., Milwaukee, Wis.

**Transformers.**—Bulletin 340, 8 pp. Describes power and distribution transformers, illustrating various types of large equipment, single phase and three phase, used for power transmission, electric arc furnaces, railway systems, or other industrial purposes. Brief mention is made of a few of the important developments and improvements, such as uni-row radiators, straight line tap-changers, circular coils, etc. Pennsylvania Transformer Co., 1701 Island Ave., N. S., Pittsburgh, Pa.

**Voltage Regulators.**—Bulletin 5601, 8 pp., Electronic Automatic Alternator Voltage Regulator, Type EF. Describes and illustrates this type of regulator which can be used with any known method of excitation. It explains in detail the operation of this comparatively new method of automatic voltage regulation. Bulletin 5602, 8 pp. Describes a similar regulator designed for only one scheme of excitation, i. e., one regulator for each exciter. Ward Leonard Electric Co., Mt. Vernon, N. Y.

Entered as second class matter at the Post Office, Easton, Pa., April 20, 1932, under the Act of Congress March 3, 1879. Accepted for mailing at special postage rates provided for in Section 1103, Act of October 3, 1917, authorized on August 3, 1918. ¶ Publication Office: 20th & Northampton Streets, Easton, Pa. Editorial and Advertising Offices at the headquarters of the Institute, 33 West 39th Street, New York

### The Cover

**Construction view of Coulee Dam, feature item of the inspection trip program of the AIEE 1937 Pacific Coast convention (see news section)**

# High Lights

**Pacific Coast Convention.** An all-day inspection trip to the Grand Coulee project on the Columbia River is one feature that has been included on the program of the Institute's 1937 Pacific Coast convention to be held in Spokane, Wash., August 30–September 3, in the heart of the Pacific Northwest. Other attractions include a high-class technical program, a joint session with the Institute of Radio Engineers, the usual sports competitions, and special entertainment (*pages 910–12*).

**Huge Telescope Being Welded.** Framework for the 200-inch telescope now being built in a new observatory on Mt. Palomar, Calif., will consist of electric-arc-welded units bolted together at the site. Astronomers estimate that this new instrument will penetrate the universe to a distance of a billion light-years (*pages 783–6*).

**Charles Le Geyt Fortescue.** An appreciation of this noted electric-power-transmission engineer (who died December 4, 1936), prepared by one who was associated with him for many years, outlines his many contributions to the electrical industry (*pages 781–3*).

**Electrical Computer.** A search for a simple computing device to simplify and expedite the calculations involved in the design of the overhead catenary for an extensive railroad electrification led to the development of an electrical computer, the circuit of which represents an exact analogy of the mechanical system embodied in the messenger cable of a catenary span (*pages 787–90*).

**Summer Convention.** As this issue goes to press, the Institute's 1937 summer convention is being held in Milwaukee, Wis. At the opening session, election of 2 noted engineers as AIEE Honorary Members was announced, and new officers to serve the Institute during the ensuing year were named (*pages 913–14*).

**Letters to the Editor.** Readers of ELECTRICAL ENGINEERING continue to express themselves informally on a variety of subjects through the "Letters To The Editor" columns (*pages 917–18*).

**Saturated Synchronous Machines.** Effects of saturation in salient-pole and cylindrical-rotor synchronous machines operating under steady load may be analyzed by a method based upon the 2-reaction theory, with good agreement between calculated and test results; torque angle is obtained by using saturated quadrature synchronous reactance rather than unsaturated reactance (*pages 858–63*).

**Ignitors.** A rod of high-resistivity material is used in ignitron tubes to initiate the discharge by the formation of an arc between the rod and the mercury-pool cathode in which the rod is immersed. Current required by the ignitor should be as small as possible; shaping the rod to a point and slotting it greatly increase its effectiveness (*pages 810–12*).

**Distance Relays.** Distance-measuring and directional elements are used in various relay combinations to provide fault protection in power systems; the performance of distance relays may be determined from the effective impedance presented to the element, which may be expressed in terms of certain fundamental quantities and thus reduce to a minimum the labor involved in the calculations for any specific situation (*pages 833–44*).

**Photoelectric Hysteresigraph.** Initial magnetization curves or any desired symmetrical or unsymmetrical hysteresis loops may be recorded graphically on the fluorescent screen of a d-c instrument which depends for its operation on a photoelectric fluxmeter (*pages 805–09*).

**Directors' Report.** The annual report to the membership of the Institute's board of directors summarizes activities and the work of national committees during the year. Membership statistics and financial statements are included (*pages 791–804*).

**Potier Reactance.** Calculation of Potier reactance, which is a combination of reactance, change of saturation, and change of flux form, is possible by means of 3 approximate empirical methods given in this issue. The probable accuracy of the methods for typical machines is shown (*pages 813–18*).

**Oil-Impregnated Paper.** Extended tests indicate that there is no correlation between dielectric loss and electrical life of oil-impregnated paper insulation, and that gas-free specimens are superior to any specimens saturated with gas at pressures up to 200 pounds per square inch (*pages 845–9*).

**Relay Operation.** When synchronous machines hunt or fall out of step with one another an oscillating interchange of power may cause relays to operate unnecessarily. Some remedies for such incorrect relay operation have been suggested (*pages 823–32*).

**The Perfect Reading Page.** Is ELECTRICAL ENGINEERING's "easy reading" page really easier to read? This question is answered in part by a writer thoroughly qualified to draw conclusions on the subject (*pages 779–81*).

**Distortion of Traveling Waves.** The shape of a lightning wave traveling on a transmission line is altered by corona at normal operating frequency. How to predict the distortion is described in a paper in this issue (*pages 850–6*).

**Lightning Arresters.** A new station type of autovalve lightning arrester is described in a paper in this issue (*pages 819–22*).

# DISCUSSIONS

Appearing in this issue are discussions of the following papers:

## Communication

Currents and Potentials Along Leaky Ground-Return Conductors—Sunde 887
Inductive Co-ordination of Common-Neutral Power-Distribution Systems and Telephone Circuits—Coleman and Davis 889
Calorimetric Measurement of Dielectric Losses in Solids—Race and Leonard 890

## Electric Welding

The Resistance Welding Circuit—Pfeiffer . . . 864

## Electrical Machinery

Proposed Transformer Standards—Clem . . . . 868
A New Electrostatic Precipitator—Penney . . . 869
Negative-Sequence Reactance of Synchronous Machines—Thomas 903
Two-Reaction Theory of Synchronous Machines—Crary 905
Synchronous Machine With Solid Cylindrical Rotor—Concordia and Poritsky 906
Contributions to Synchronous-Machine Theory—Langsdorf 907

## Electronics

Electronic Transient Visualizers—Reich . . . . 873
An Electronic Regulator for D-C Generators—Gulliksen 875
Sealed-Off Ignitrons for Welding Control—Packard and Hutchings 875
Amplification Loci of Resistance-Capacitance Coupled Amplifiers—Seletzky 877

## Instruments and Measurements

Watt-Hour Meter Bearings—Kinnard and Goss 871
Development of a Modern Watt-Hour Meter—Kinnard and Trekell 879
Impulse-Generator Voltage Charts for Selecting Circuit Constants—Thomason 881
Short-Time Spark-Over of Gaps—Hagenguth . . 882

## Power Transmission and Distribution

Studies of Stability of Cable Insulation—Halperin and Betzer 871
Automatic Boosters on Distribution Circuits—Olmsted 893
Trends in Distribution Overcurrent Protection—Lincks and Benner 895
Pole Flexibility as a Factor in Line Design—Seelye and Zucker 900
A Review of Overhead Secondary Distribution—Holben 902

## Branch Activity—*A Message From the President*

ON August 1, 1936, there was no phase of the Institute work of which I knew so little as I did about the work of the Student Branches. Today there is no phase in which I am more interested, or which I feel is better conducted. A successful Branch must overcome some natural handicaps. If limited to the 2 upper classes, the membership must be completely replaced every 2 years. There are many claims on the students' time. The potential members have had little experience in organization affairs. Active membership is of such short duration that there is little opportunity for the development of leaders. In a Section the average chairman comes to office with several years' experience in Section and committee work, but the Branch chairman seldom has more than one year's training in Branch activity. In the Sections, past-chairmen are a source of inspiration, counsel, and guidance, while in the Branches, the past-chairmen are lost through graduation.

Why, then, is the Branch movement so successful? From my observation, it is because of 3 factors: the enthusiasm of youth; the desire to make use of every agency in acquiring an engineering training; the advice and guidance from the counselors.

From my visits to Branches and Branch conventions come several ideas as to how Branch activity is being successfully carried on. I believe that these ideas are worthy of record, and hope that the future will see many additions to the record. The Student Branch should be organized on the following fundamental principles.

It is an honor and a duty to be a member; a privilege to attend the meetings. The officers should be selected from the most capable and distinguished members, for certainly capable, enthusiastic officers are essential for a successful Branch. The meetings must be worth while. At the close of the meeting, each one attending must feel that he has gained professionally by being present. Discussion of the subject presented should be stimulated and encouraged, for often it is the most valuable part of the meeting. It should be understood that the meetings are closed to nonmembers, excepting on specific invitation. The Branch officers should be responsible for, and carry on, the Branch activities, depending upon the counselor only for advice and guidance.

The program should be planned in advance and as a co-ordinated whole, for it is the most important of the Branch activities. Although programs should be broadened beyond the highly theoretical and basically technical, the Branch should always remember that it is an integral part of a national technical society. A meeting where engineering results are demonstrated with the aid of equipment is extremely interesting and very popular. Speakers should be sought from 3 sources: graduate engineers in industry; faculty members from the home and other colleges; and from the membership of the Branch. Exchange of faculty speakers between neighboring Branches produces good results.

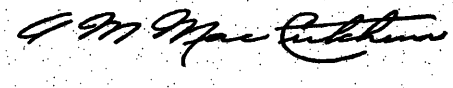
The year may be divided into 2 periods, providing 4 periods within a cycle of membership. Officers would then be elected twice each year, resulting in more opportunities for service and less time required from each officer. Rotation in office, with its advantages, is then possible. In one school where such a plan is followed, an observer from each of the freshman and sophomore classes is invited to attend the executive committee meetings, as well as the Branch meetings. These observers do not pay dues, are carefully selected by the Branch, and the selection is considered an honor. In this school, regular membership is open only to juniors and seniors. As each sophomore class becomes junior, there are 4 men who know something of the purposes, conduct, and activities of the Branch, and these men almost invariably join and take an active part in the Branch affairs.

Where several Branches are geographically close, joint activities are inspiring to each. During the last year, I saw 2 illustrations of the effectiveness of such a plan: at Pittsburgh in a joint afternoon session of the Branches from Carnegie Institute of Technology, the University of Pittsburgh, and the University of West Virginia; in North Carolina between Duke University, the University of North Carolina, and the North Carolina State College. Such joint activities provide training in co-operation, and offer the stimulation of competition.

Co-operation from a neighboring Section is of great assistance. Although the primary responsibility rests on the Section, the Branch should be very receptive. Many Sections offer a reduced price to Branch members if they attend a Section dinner. In the West, each of a group of interested Section members has pledged himself to entertain once each year a Branch member as his guest at a Section dinner.

Light refreshments following a Branch meeting offer the opportunity for, and stimulate, sociability—a good quality which many engineers lack. The cost may be kept so low as not to be a burden on the treasury, and yet the purpose accomplished.

At one university I visited, an Engineer's Lounging Room was provided and furnished through the co-operation of the university authorities and the other engineering society branches.



One of the most interesting and stimulating functions at the District meeting held in Dallas was the luncheon of the Branch chairmen, secretaries, and counselors. The counselor participated only by introducing the Branch chairman, who told of the plans for the future and the accomplishments of the past. Each of the 13 Branches was represented, and the 13 chairmen limited their remarks to a total of 45 minutes, each one telling something of interest to all.

In one of the schools, I found an engineering society to which all upper classmen were eligible. No junior or senior was denied the advantage and opportunity of an organized technical activity. This university engineering society was divided into groups, corresponding to the national professional engineering societies. Within the general society was developed the professional consciousness so desirable, and joint meetings were held treating economic and social responsibilities of the engineer. Once each year a purely social meeting was held. At this university, one evening a month was designated as Engineers' Night, and the other student organizations studiously avoided any conflicting activities. On Engineers' Night there was held either a joint meeting with all members of the engineering society free to participate, or simultaneous group meetings, with each devoted to a subject peculiarly interesting to that group. Contact with the national engineering society was maintained through the corresponding branch. With such an organization, possibly 4 evenings a year might be devoted to joint meetings and the presentation of general subjects, and 5 evenings devoted to parallel group meetings, featuring the presentation of specialized technical subjects. A joint meeting, with its consequently larger audience, is particularly suitable for an address by an outside engineer, or by a professor from the same or another technical school. Under this type of organization, I suggest the following as a typical Branch program.

| *No.* | *Class* | *Speaker* | *Type of Subject* |
|---|---|---|---|
| 1. | Joint | Professor | "The Problems of a Student Engineer" |
| 2. | Branch | Outside Engineer | "What My Company Expects of a Young Engineer" |
| 3. | Joint | Social | "Skits of the Anvil or Gridiron Variety" |
| 4. | Branch | Student | "Description of an Interesting Engineering Test or Problem" |
| 5. | Branch | Student | "Paper on Some Phase of Electronics" |
| 6. | Joint | Outside Engineer | "The Engineer's Opportunities and Responsibilities" |
| 7. | Branch | Graduate Student | "Presentation of a Research Problem" |
| 8. | Branch | Outside Engineer | "Description of Interesting Installation, Application or Research Problem" |
| 9. | Joint | Students | "Several Demonstrations" |

As you study this program, you will note that no student is asked to prepare a paper before the fourth meeting, by which time the interst in the engineering society and Branch activities would have been stimulated by 2 good lectures and one social meeting. The closing meeting would be devoted to several technical demonstrations presented by the various divisions. To this unusually interesting meeting all of the sophomores and freshmen might be invited. The program would have been built up to a fine climax, and the enthusiasm and interest of this last meeting would assure a successful following year for each division.

In the training of the young engineer, the American Institute of Electrical Engineers and the other professional societies are privileged to play an important part. Of this they should be deeply conscious and should meet fully their obligations and embrace their opportunities. The student engineer, in relation to his group and his college, is quite analogous to the graduate engineer in his relation to society. There is a growing feeling that the graduate engineer has not always fully met his responsibilities and risen to his opportunities; that he has not always recognized his social and economic responsibilities. Many engineers have failed to realize that the best idea is of little value unless it is so convincingly presented to others that they accept it and assist in its execution. A compromise plan which is accepted and produces results is far better than the most brilliant individual plan which is neither accepted nor adopted. All engineers need training in the convincing expression of their thought. They should listen to the ideas of others and endeavor to see their viewpoints; should judicially weigh all expressed thoughts as evidence, and select that which is sound for combination with their own views; and should be able to express convincingly a logical conclusion. The development of a unified professional consciousness is of great importance, for then the profession may better serve humanity. Contact between older and younger engineers is stimulating to both. Each has much of value to the other—knowledge, experience, professional standing, and resources on the one side; youth, eagerness, enthusiasm, and a fresh viewpoint on the other. The branch of a national engineering society is a medium through which these needs of a student engineer should be met.

# The Perfect Reading Page

By MATTHEW LUCKIESH
MEMBER AIEE

**With the January 1937 issue, ELECTRICAL ENGINEERING presented to its readers the "easy reading" page. This article presents a discussion of the factors that would influence the production of a perfect reading page, and an opinion, founded upon scientific research, concerning this "easy reading" page as an approximation of the theoretical ideal.**

DIFFERENCES of opinion cease to exist when adequate knowledge is available. Although this ideal stage has not been reached for the perfect reading page, great advancement has been made recently in the science of seeing. So long as opinions are based merely upon the science of vision, they must remain opinions because the basis is inadequate. Seeing is an activity of human beings; vision is merely an ability of eyes and the visual sense. Seeing involves the end products of human efficiency, behavior, and welfare.* It considers human beings as seeing machines and relegates eyes or the visual sense to the status of a part of the machine. Abuse of eyes is one of the consequences of unnaturally close and prolonged visual tasks imposed by civilization; however, much control can be exercised over certain factors, such as printing and lighting, to reduce the severity of visual tasks and the unnecessary waste of human resources.

The visibility of objects depends primarily upon

1. Size of the critical details.
2. Contrast between the object and background.
3. Brightness of the object and background, which depends upon the reflection factor and intensity of illumination.
4. Time available for recognizing the object.

In general, the theoretically ideal printed page results from

1. Large type of the most legible style.
2. Paper of high reflection factor and dull surface. If it is tinted, it should be optically and aesthetically satisfactory.
3. High level of illumination comparable to that in the shade of a tree or porch.
4. Time usually is not of great importance, if other factors are satisfactory.

Before considering the ideal printed page from a practical viewpoint, the process of reading should be considered. The focus of the eyes passes along the printed line in a series of leaps. Inasmuch as the movement of the eyes does not produce any apparent blurring, the eyes are assumed to be in some manner anesthetized during rapid motion. If one sees only when the eyes are at rest, the duration of the fixational pause is important. This has been found to vary chiefly between 0.07 and 0.30 second. These values are of importance in considering cases in which split seconds are important, but are merely of passing interest for the present.

Reading is done by swallows, as in drinking water. Words, or even groups of them, are seen at each pause. The number of stops made in reading a line depends upon visibility, familiarity, practice, and intelligence; consequently, the distinguishing of a critical detail, such as the space between the dot and the body of the letter *i*, may appear to be of little or no importance. Details remain of utmost fundamental importance, however, as typographical errors adequately testify. These details seem to dwindle in importance only through extensive practice in reading; in fact, seeing is very largely learning. Human beings learned to see things out in space before thinking became a conscious act.

## Components of the Perfect Reading Page

A scientific analysis of visibility and the results of seeing show that the fundamental factors already listed are the basis of ease of seeing and, therefore, of the perfect reading page.

By omitting some of the tedious steps in considering type size, 12-point type may be concluded to be quite satisfactory for continued reading. Newspapers commonly are set in 8-point type, with parts of them in 6-point type. These small sizes, combined with paper of poor quality and generally meager intensities of illumination, make newspaper reading a severe visual task. The effect of type style on legibility is a complex matter, but long experience has evolved satisfactory styles devoid of needless details and with an openness necessary for good legibility. Obviously, the size of type determines the amount of matter that can be printed upon a page. This is an important consideration for publications such as newspapers, but such economy in space should not be carried too far in journals, and particularly in books.

The contrast between the print and the page depends upon the blackness of the ink and the reflection factor of the paper. Perfect black on perfect white does not exist. This would be 100 per cent contrast as computed on the basis of the ratio

$$100 \times \frac{\text{Background brightness—Object brightness}}{\text{Background brightness}}$$

An article written especially for ELECTRICAL ENGINEERING.

MATTHEW LUCKIESH is director of the lighting research laboratory General Electric Company, Cleveland, Ohio. Doctor Luckiesh received the degrees of bachelor of science in electrical engineering (1909) and doctor of engineering (1935) at Purdue University; electrical engineer (1912) and doctor of science (1926) at Iowa State College; and master of science (1911) at the State University of Iowa. He has been associated with the Nela Park research laboratories of the General Electric Company since 1910, having served successively as physicist, director of applied science, and director of lighting research. Doctor Luckiesh has received several honors for his work in color and lighting research, and has written many books and technical papers.

* SEEING—A PARTNERSHIP OF LIGHTING AND VISION (a book), M. Luckiesh and Frank K. Moss. Williams and Wilkins Company, Baltimore, Md., 1931.

Usually the nearest approach is a contrast of about 97 per cent. For a telephone directory the contrast between the print and paper commonly is about 80 per cent, and for the better examples of newsprint about 85 per cent.

Any color, even a light tint, added to white paper decreases the contrast slightly; however, the extent to which this decrease causes a decrease in visibility should be considered in weighing this against other considerations. There can be no justification for the use of highly colored paper for pages that must be read for extended periods; furthermore, from purely the optics of the eye, blue, violet, purple, and pink papers are inadvisable. Normal eyes cannot focus blue light at the usual reading distance. Adequate experiments have shown that elimination of the blue and violet components of light does not decrease visibility appreciably, because the resultant loss of light is compensated by increased definition of the image. For this reason alone, a yellowish tint is better than any other.

The loss in contrast is very slight in a white paper tinted yellow, and is less in ordinary artificial light than in daylight. Although contrast is very important in the visibility of objects, it is of only slight importance in the range of high contrasts; therefore, any other small advantage gained by the use of a paper of yellowish tint overcomes the loss caused by the slight decrease in contrast.

The reflection factor of a paper having a slight yellowish tint is a few per cent less than it would be if the tint were eliminated, thus reducing the brightness of the paper under a given intensity of illumination by an amount exactly proportional to the reduction in reflection factor. An appreciable change in visibility requires such a large change in brightness, however, that the reduction caused by a slightly lowered reflection factor is negligible, particularly when the intensity of illumination is sufficient for ease of seeing.

The perfect reading page, so far as the reader is concerned, depends upon lighting as well as upon the paper or printing. Glossy paper may reflect bright, imperfect images into the eye; dull paper is ideal, but if half tones must be considered, the practical ideal may be different. Dull papers nevertheless have been developed for halftone printing without too much compromise between the reader, printer, and paper manufacturer.

Ease of reading printed matter depends upon visibility, but manifests itself remotely from this. The writer and his colleague, Frank K. Moss, have measured successfully the nervous muscular tension indicated by the finger tips for a large number of subjects over a range of illumination intensities of from one to 100 foot-candles. One foot-candle, which is the illumination one foot from a candle, is a common illumination indoors. The general average in the indoor world is less than 5 foot-candles where reading is done. Near a window in the daytime there is commonly an illumination of several hundred foot-candles.

Experiments have indicated that while the subjects read a book printed in 12-point type on excellent dull, white paper, the ease of reading continues to increase up to at least 1,000 foot-candles. No one is conscious of this nervous muscular tension, except in special cases of difficult visual work; but it results from all visual work and represents waste of human resources. The 12-point type could be read at one foot-candle.

This and many other researches prove that ease of reading cannot be judged by visibility, and the mere possibility of seeing provides no reason for believing that further improvement in seeing is of no value. This new knowledge arose directly from an expansion of the concept of vision into one of seeing, and from a consideration of human seeing machines, instead of merely eyes.

Whether refinements of this new technique could show appreciable difference in the ease of seeing objects against a yellowish tint, as compared with a white one, is at present unknown; however, some other reasons for using a slightly yellowish paper seem to be adequate. It does not decrease visibility appreciably because of its slightly lower reflection factor and the consequent slightly lower contrast; moreover, its color is in the right direction from the viewpoint of chromatic aberration of the eye.

Aside from the foregoing considerations, the aesthetic or, more broadly, psychological effects are important. From an aesthetic point of view the author prefers a slightly yellowish tint, and many other persons have expressed a similar preference. Psychologically, the subtle warmth of the yellowish tint has something in its favor. White has much virtue in its place and, in fact, is symbolic of virtue; but white has disappeared from many places in which it dominated until a few years ago. Modern hospitals have eliminated it to a great extent, and modern kitchens and bathrooms have little of it. The decorative schemes of hospitals, kitchens, and bathrooms consequently have reverted to their proper function—to please aesthetically and psychologically.

## Electrical Engineering's "Easy Reading" Page

The reflection factors of the paper formerly used in ELECTRICAL ENGINEERING and of the present sepia-tinted paper are 76 and 73 per cent, respectively, for ordinary tungsten-filament light. The difference is slightly greater for daylight. Assuming the same quality of ink and printing, this difference is not sufficient to produce an appreciable difference in contrast. In fact, measurements made with the Luckiesh-Moss visibility meter of the visibility of print of the same size of type on the former and present papers revealed no significant difference; therefore, the change has been made with no appreciable sacrifice in measurable factors. In other words, whatever the gain (or loss) may be in the aesthetic comfort and possibly in physical comfort is achieved without other sacrifices. The appraisal of the factors that cannot be measured at present must be left to the readers. Their present, or initial, reactions will be interesting to compare with their reactions a few months hence. Certainly there is a striking difference in the appearance of the 2 papers, considering the slight difference in brightness or reflection factor. Many white papers have reflection

factors of from 80 to 85 per cent, and there would be an appreciable difference in the visibility of a given black print on them and on this sepia-tinted paper, which has a reflection factor of 73 per cent. The present discussion, however, refers to the paper formerly used and not to any other so-called white paper. Incidentally, all these measurements were made with papers backed up by several thicknesses, thus simulating actual reading conditions for a book or magazine.

Regardless of initial reactions to a yellowish-tinted paper, one should first give consideration to the general reaction against white. As to the influence of aesthetic and psychological effects upon the efficiency and behavior of human beings there can be no doubt on the part of those who understand that human beings are seeing machines. Feelings are just as real as any reality, and one can be just as unconscious of them as of other results of seeing, such as nervous muscular tension. To recapitulate, there is some scientific evidence, however slight, in favor of a paper of yellowish tint, and from the aesthetic and psychological viewpoints also it may have something in its favor. At any rate, knowledge springs both from controlled researches and mass experience. The present attempt to produce a perfect reading page provides opportunities for demonstrating or acquiring knowledge along these 2 general lines.

# Charles Le Geyt Fortescue

## and His Contributions to the Electrical Industry

By C. A. POWEL
MEMBER AIEE

CHARLES LE GEYT FORTESCUE will long be remembered as an engineer well-known for his technical achievements and well-loved for his qualities as a man. Some of his accomplishments have been so outstanding that it seems worth while calling attention to their value and to the extent to which they have been useful in extending human knowledge and lightening the labor of other engineers in his own and succeeding generations.

In the appreciation of the present generation of electrical engineers, Doctor Fortescue will be known for 3 principal fields of work. These probably would be his development of the method of symmetrical co-ordinates used for the solution of unbalanced polyphase circuits; his analysis of the factors affecting stability of transmission systems; and his philosophy of lightning protection and his contribution to the theory of direct strokes. A group of engineers a little earlier in time probably would credit him with his work in rationalizing the design of transformers; with his studies of dielectric phenomena which led to the adoption of the sphere gap as a standard of high voltage measurement; and with his work on the development of line insulators on the so-called "faradoid" principle.

These and many similar accomplishments indicate that his interests lay principally in the transmission of power and its related problems, a field which has expanded enormously since he entered the profession.

Fortescue was born at York Factory, Manitoba, Canada, November 11, 1876, where his father was chief factor of the Hudson Bay Company. He came of an old Devonshire family that as far back as the fifteenth century became prominent in literature. Educated at Dawlish, Devon, England, and at Queens University, Kingston, Ontario, Canada, he was Queens' first graduate in electrical engineering, and it used to be remarked that "they started with a good one." In recognition of his outstanding contributions to electrical engineering, his alma mater awarded him, in 1929, an honorary degree of doctor of laws. On graduation in 1898 he joined the Westinghouse Electric & Manufacturing Company at East Pittsburgh, Pa., where he remained throughout his professional career.

Doctor Fortescue became an Associate member of the AIEE in 1903 and was transferred to the grade of Fellow in 1921. He served on the following Institute committees: power transmission and distribution, 1925–29 and 1932–36; telegraphy and telephony (now communication) 1914–17; electrophysics, 1916–17, 1920, 1922–24, 1927–31. He was the author or co-author of 23 technical papers and numerous discussions published in the AIEE TRANSACTIONS over a period of 27 years.

Starting as an apprentice in the Westinghouse shop, he

Written especially for ELECTRICAL ENGINEERING.

C. A. POWEL is manager of the central station engineering department of the Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa., and was associated with Doctor Fortescue for many years. He is a director of the AIEE and has been a member of the Institute's committee on power generation since 1933; he was chairman of the AIEE Pittsburgh Section, 1935–36.

was quickly noticed by B. G. Lamme, who happened to be in need of a young assistant to devise new designs and new methods of building armature coils. The problem of meshing together the ends of armature coils—primarily a problem in 3-dimension geometry—was a fertile field in which the mathematically minded young engineer had full scope for imagination and for adapting theoretical schemes to practical necessities. His success in working out original short-cut methods of designing coils with short ends, requiring very little clearance, marked him as having ingenuity to an unusual degree, and he was transferred to the transformer department to see what could be done to rationalize the design of transformers, which at that time, as Fortescue himself used to say, "was more of an art than a science." His success in this work perhaps is best demonstrated by the section prepared by him for the "Standard Handbook for Electrical Engineers" which follows closely the principles developed by him in the years spent on this work.

About 1909 Fortescue became imbued with the importance of the dielectric field in transformers. He claimed that the so-called creepage effect was not a characteristic of the insulation surface itself but of the dielectric field in which the surface lay. Assisted by S. W. Farnsworth, development work was undertaken to prove or disprove this idea and to lay out a high-voltage transformer design in which the dielectric field was taken into account. This resulted in 2 very noteworthy papers published in the AIEE TRANSACTIONS of 1913:

AIR AS AN INSULATOR WHEN IN THE PRESENCE OF INSULATING BODIES OF HIGHER SPECIFIC INDUCTIVE CAPACITY by C. L. Fortescue and S. W. Farnsworth, pages 893–906.

THE APPLICATION OF A THEOREM OF ELECTROSTATICS TO INSULATION PROBLEMS by C. L. Fortescue, pages 907–25.

An important result of this research was the proposal that the sphere gap should be used as a standard for measuring high voltages. This was done in 2 papers, also published in 1913 in the AIEE TRANSACTIONS:

THE SPHERE SPARK GAP by S. W. Farnsworth and C. L. Fortescue, pages 733–7.

CALIBRATION OF THE SPHERE GAP VOLTMETER by L. W. Chubb and C. L. Fortescue, pages 739–48.

This proposal was accepted and today has become standard practice throughout the world.

About this time Fortescue turned his attention to railway electrification and the related power-supply problems. For heavy traction, the transmission lines and the trolley-rail circuits with their interconnecting transformers constituted a network of considerable complexity; and since there was then practically no literature on networks, he applied himself to their solution and formulated a number of network theorems. One of these was the theorem of equivalent loads by which a load at any point on a railroad could be replaced by 2 loads at adjacent substations inversely proportional to the impedance of the trolley-track circuit from the 2 substations to the actual load point. Another was that of superimposed solutions, which permits the determination of voltage drop to a given point by adding the separately computed voltage drops to that point due to loads at each of many load points. In the same way, the current in any branch of the network may be determined by adding the separately determined currents in that branch due to each particular load. These theorems are rigorously correct; they serve to reduce a complicated network to a very simple one, thus permitting one to make calculations in a very few hours that formerly would have required days.

Fortescue was active on the various a-c railway electrifications, including particularly those of the New York, New Haven and Hartford, Norfolk and Western, and Pennsylvania railroads, and did much to rationalize the design of railway power-supply systems and to set the reactance proportions which obtain at the present time. He gave attention to the problems of inductive co-ordination with communication and railway-signal circuits, and in connection with the latter he contributed the resonant impedance bond. He proposed several new schemes of phase balancing and phase conversion, and among others the series type of phase balancer which was the first scheme to provide balancing action without automatic devices such as voltage regulators.

It was while working on these unbalanced railway-supply circuits that Fortescue conceived the possibility of a mathematical analysis that led to the invention of symmetrical co-ordinates. In simple mathematical terms it consists of a system of generalized Lagrangian co-ordinates especially suitable to all types of polyphase problems. His paper

METHOD OF SYMMETRICAL CO-ORDINATES APPLIED TO THE SOLUTION OF POLYPHASE NETWORKS, AIEE TRANSACTIONS, volume 37, 1918, pages 1027–1115

is one of the milestones of the industry. This mathematical tool is now established in all countries as the only effective method of analyzing general polyphase network problems. For his development of this theory Doctor Fortescue received the Elliott Cresson Gold Medal of the Franklin Institute.

With the advent of the interconnection of power systems during and following the World War, Fortescue began to interest himself in the problems of the maintenance of synchronism over long transmission lines. Here again in his search for methods of simplifying the calculations he and his associates broke new ground by bringing out the so-called power-angle diagram which today is the form generally used for expressing stability.

Following the establishment of these interconnecting transmission lines, their principal drawback was found to be their susceptibility to outage due to lightning. This led Fortescue to turn his attention to the problem of methods of protection against lightning. In 1923, J. F. Peters, now consulting engineer of the Westinghouse company, brought out the klydonograph which was the first instrument suitable for field studies of lightning surges. With this device studies were made under the direction of Doctor Fortescue in co-operation with power companies, and the results of these gave a great deal of information regarding lightning surges which previously had been unsuspected. Thus encouraged, Fortescue undertook a further series of tests using the Norinder type of oscillograph,

the results of which confirmed the ideas Fortescue had been building up, and in a paper

THEORETICAL AND FIELD INVESTIGATIONS OF LIGHTNING, AIEE TRANSACTIONS, volume 48, 1929, pages 449–68

he promulgated his idea that induced strokes of lightning were not in general harmful to transmission lines and that protection against direct strokes was quite feasible.

Doctor Fortescue was a prolific inventor, the recipient of some 185 patents. Perhaps his outstanding characteristic as an inventor was his fondness for generalized theorization, which led him away from beaten paths and produced many inventions of fundamental and outstanding character, leaving to others the task of perfecting details as to methods for carrying them out. Among the important Fortescue patents might be mentioned those on the design of transformer windings to distribute properly the electrostatic stress through the insulation; thermoelectric protection of distribution transformers against burnouts and secondary short circuits; the high-voltage condenser-type bushing; shunt and series phase-balancers for railway systems; high-speed d-c circuit breakers with impulse tripping for d-c railways; the application of the "faradoid" principle to porcelain insulator design whereby the insulator surfaces were shaped to conform to the electrostatic field about the insulator; control grids for vapor-filled converters; and interphase transformers for vapor-filled converters.

His technical achievements, great as they were, did not account for his great popularity. He was human, sometimes beautifully inconsistent in little things. On a fishing trip he was complaining about lack of regulation in the United States which permitted any number of fishermen on a given stream. "Now in England," he said, "a stream like this would be fished by but one man who had bought the fishing rights on the stream." "Of course," rejoined another of the party, "you assume that you would be that one man."

He often worked on "hunches," but with the unerring instinct of genius. He had a feeling of what the answer to a problem should be and backed his "hunches" with logic. It is sometimes much easier to solve a problem backwards by assuming an answer.

His company always was sought. Aside from his wide technical interests, his reading and contemplations covered the arts and social sciences. An interesting conversationalist, "Forty," as he was familiarly known, always had a fresh and original point of view. He thoroughly enjoyed a story, both in the hearing and the telling. A favorite with old and young, his association with young engineers seemed to affect him as Ponce's waters and accounted for the enthusiasm that was so characteristically "Forty," even during the debility occasioned by his last illness.

His influence was felt in every group with which he worked. Doctor Joseph Slepian, now consulting research engineer of the Westinghouse company, has said that he received more inspiration from his contact with Fortescue than with any other man in the company. Working with a group, his personality was impressed both upon his work and upon his associates, frequently to the extent that a group's labor came to be associated only with the name of Fortescue. Outside engineers also sought his advice and counsel. His integrity and honest judgment enhanced still further his technical recommendations.

# 200-Inch Telescope Being Welded Electrically

## Mounting structure for the 200-inch telescope being built on Mt. Palomar, in Southern California, will consist of electric-arc-welded units

A BILLION light-years is the distance to which scientists and astronomers estimate that they will be able to explore the universe when the new 200-inch reflecting-type telescope, largest in the world, is completed on Mt. Palomar, Calif. This is twice the range of the next largest telescope in existence, the 100-inch instrument at Mt. Wilson, Calif. (A light-year is the distance traversed by light in a year and is approximately $6\times10^{12}$ miles.) Mt. Palomar, which is about 90 miles from Los Angeles, was selected because of its ideal weather conditions and its isolation. In addition to a new observatory to house the huge telescope, the project includes construction of a new 20-mile road, a new community for the operating staff, several smaller domes, power plant, radio station, million-gallon water reservoir, and an airplane landing field. Headquarters of the observatory will be on the campus of the California Institute of Technology, Pasadena, which institution will supervise its operation.

Originally conceived by Doctor George Ellery Hale in 1918, immediately following completion of the 100-inch Mt. Wilson telescope, actual work on the project began in 1928 when a grant of $6,000,000 was made by the Rockefeller Foundation. It is expected to be completed by 1940. The structure for supporting the telescope is being built in the South Philadelphia Works of the Westinghouse Electric and Manufacturing Company. It consists of

Prepared especially for ELECTRICAL ENGINEERING from information supplied by the Westinghouse Electric & Manufacturing Company, South Philadelphia (Pa.) Works, and particularly that compiled by J. Ormondroyd, experimental division engineer (now with University of Michigan, Ann Arbor) and Norman L. Mochel, metallurgical engineer.

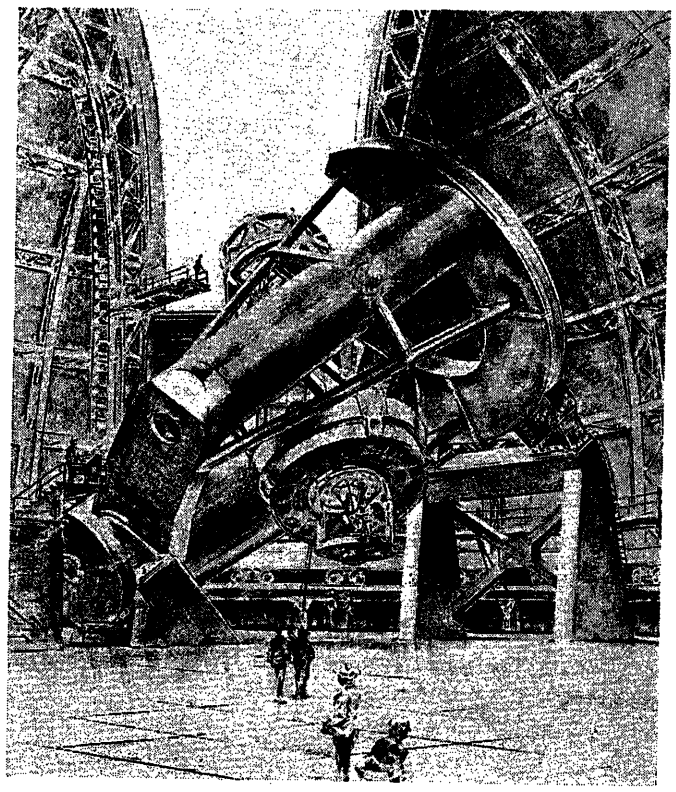


**Figure 1. Artist's conception of the 200-inch Mt. Palomar telescope as it will appear when completed**

several electric-arc-welded units which will be shipped by water to the Pacific Coast and thence by special trucks to the Mt. Palomar site, and which will be bolted together there. The 200-inch glass mirror, which will be the last unit to be installed in the telescope, is now being ground in the optical shop of the California Institute of Technology.

The magnitude of the 200-inch telescope perhaps can be understood best by comparing it with the 100-inch Mt. Wilson telescope (see table I). Its over-all height will be approximately 75 feet. The method of controlling the instrument has not been determined but, undoubtedly it will be electrical. Some conception of the control problem may be gained when it is realized that most of the observations to be made by the telescope will be upon photographic plates and that some exposures will require many hours each. The control mechanism must keep the telescope focused accurately throughout the entire period of exposure.

## Mounting Will Consist of 2 Main Parts

The mounting for the telescope will consist of 2 parts: a tube, and a cradle or yoke which will carry the tube (see figures 1 and 2). The tube, which will serve as the supporting structure for the principal optical elements, will rotate about 2 ball-bearing trunnions supported in the horseshoe-shaped yoke. Its range of rotation will be from the southern horizon to the north celestial pole. The axis around which it will rotate relative to the supporting cradle is known as the declination axis.

The yoke will turn about an axis that is perpendicular to the declination axis. This axis, lying in the meridian (north-south) plane, will be placed at an angle to the horizontal equal to the latitude of the observatory, which will make the axis parallel to the polar axis of the earth, and will point it toward the celestial pole. For this reason, this axis is called the polar axis of the telescope. The yoke will rotate 105 degrees to either side of the meridian plane.

These 2 rotations around the polar and declination axes will permit the telescope to be held on any celestial object within its range. Continuous rotation about the polar axis at the rotational speed of the earth, but in the opposite direction, will keep the tube oriented at a fixed angle relative to the "fixed stars."

The polar-axis bearings, which support the yoke, will be unique in telescope design. To insure smoothness of rotation, the whole million-pound telescope will be floated on oil under high pressure, at both the north and south ends. At the north end the "horseshoe" will be supported on 4 pads. In the surface of each pad will be 4 symmetrically spaced recesses with central oil inlets. Oil flowing through these inlets at a pressure of from 250 to 300 pounds per square inch will support the telescope. Oil will flow continuously through a gap of from 0.003 to 0.005 inch between the pad surface and the outer periphery of the "horseshoe." At the south end, the single bearing will be a ball and socket 8 feet in diameter with oil inlets so spaced that the radial and thrust loads of the telescope will be supported with the ball held about 0.005 inch away from the socket.

The total viscous friction torque of these 2 bearings at the operating speed of one revolution per day will be of the order of 50 foot-pounds. This figure becomes remarkable only when it is realized that conventional roller and ball bearing supports would lead to a friction torque of 30,000 foot-pounds, 600 times the oil-pad friction torque. The smallness of this friction is emphasized by the fact the telescope can be kept rotating at one revolution per day by the amazingly small output of about 1/160,000 horsepower. For quick setting, however, a driving motor of at least $^1/_2$ horsepower will be required.

**Table I. Comparison of 200-Inch Mt. Palomar and 100-Inch Mt. Wilson Telescopes**

| Item | Mt. Palomar | Mt. Wilson |
|---|---|---|
| Type of telescope | Reflecting | Reflecting |
| Diameter of mirror, inches | 200 | 100 |
| Approximate weight, pounds | 1,000,000 | 125,000 |
| Approximate cost, dollars | 6,000,000 | Less than 1,000,000 |
| Fabrication of structure | Welded | Riveted |
| Focal length of mirror, inches | 666 | 500 |
| Relative aperture | 3.33 | 5 |
| Yoke bearings | Oil pad | Mercury float |
| Maximum range, light-years | *1,000,000,000 | 500,000,000 |

*Estimated.

## Arc Welding Being Employed Throughout

The decision to employ arc welding so extensively in the construction of the tube and mounting of the 200-inch telescope is another outstanding example of the engineer's confidence in the welding art. There is nothing of an experimental nature, however, in the adoption of welded construction for the various members of the telescope. Other structures of comparable size and complexity, and of like value and importance, have been fabricated successfully by this method.

Steel plates, bars, structural shapes, and a few steel forgings are being welded together to form the member parts of the telescope. The size and shape of these member parts naturally reflect the general design, but have also been influenced by such practical considerations as the availability of material, machining facilities, transportation, and the necessity for minimizing internal stresses and resulting distortions.

It must be understood that the various member parts are being prepared by machining for bolting together at Mt. Palomar. Frequent references to all-welded construction may have given the erroneous impression that member parts were to be joined on location by welding. It is true that in many large structures, member parts have been and are being joined by welding on location. In such structures, however, the construction and intended service invariably are such as to tolerate distortions that may take place during welding or during the useful life of the structures, or in which the presence of variable and unknown degrees of internal stress are of little concern. Obviously such conditions could not be tolerated in the 200-inch telescope.

In any discussion of welding, one is naturally interested in the materials that must submit to welding. Again one encounters an erroneous impression—that a telescope must be constructed largely of special alloys that have low expansivity. Although it is true that some materials of this type are being used in connection with the mirror and other optical parts, most of the material being used for the tube and mounting is quite ordinary mild carbon steel. All the materials being welded are of standard commercial grades—an important practical consideration.

All plates, bars, and structural shapes have been rolled by one supplier from specially selected heats, to give the greatest possible uniformity of composition. Plates less than $1^1/_2$ inches thick were made of the usual flange quality of steel plate, similar to that covered by ASTM Specification *A*-70. All such steel for the tube was made from a single heat, specially melted for the purpose. Plates $1^1/_2$ inches thick and more were rolled from silicon-killed steel poured into hot-top ingots, to guarantee soundness of section. This steel is similar to grade *A*, ASTM Specification *A*-150. Two carbon-molybdenum steel forgings are being

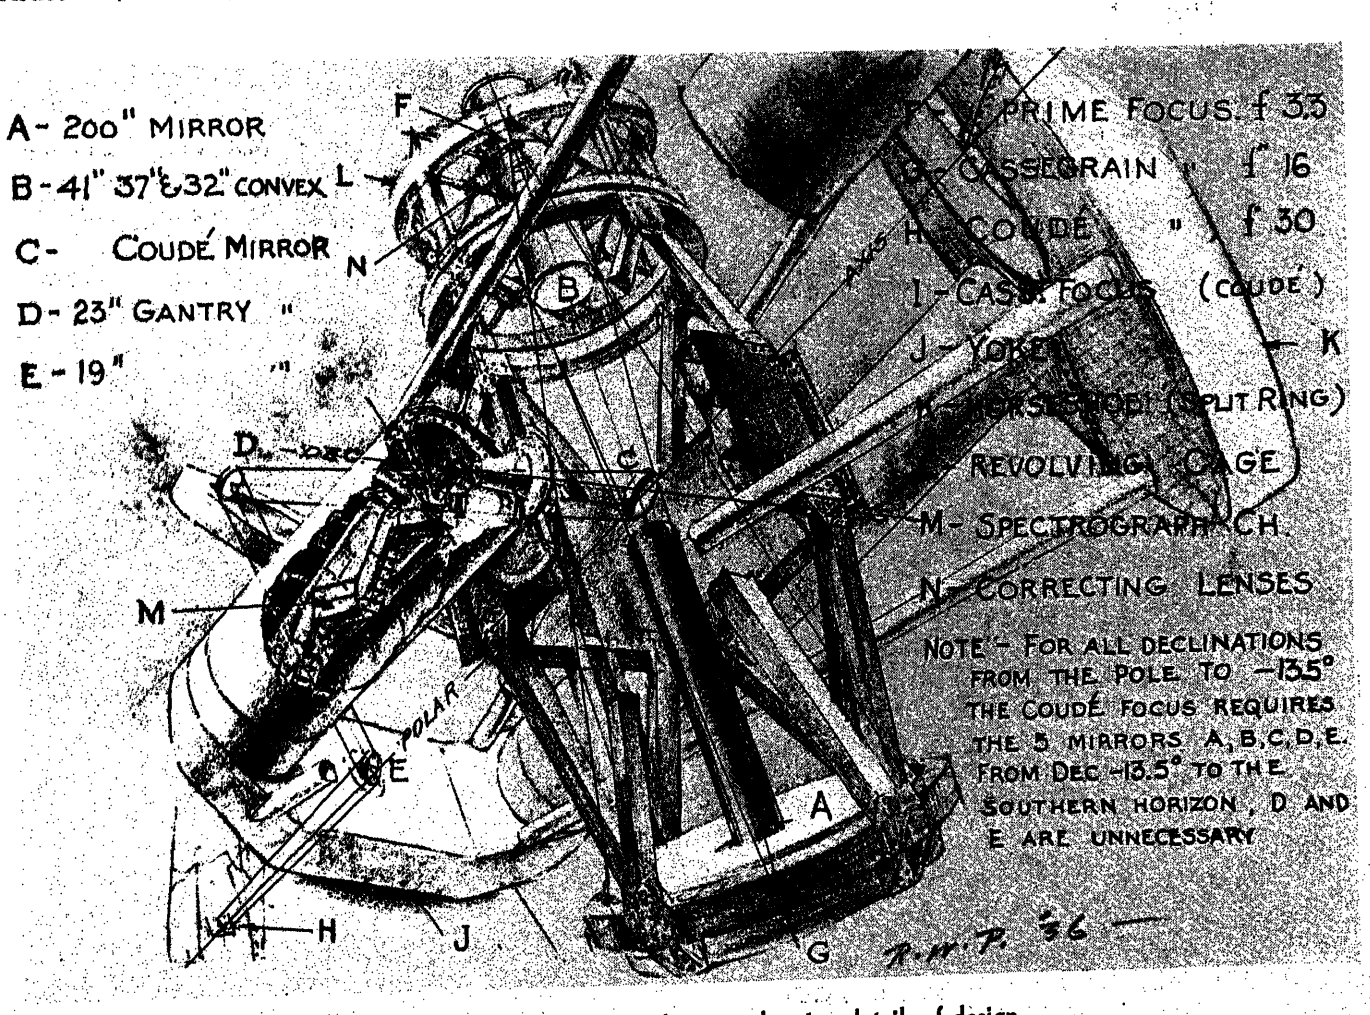

Figure 2. Diagram of telescope showing details of design

used in fabricating the declination bearing housing.

Arc welding only is being employed, and heavily coated electrodes of the mineral-coating or slag-producing type are being used. These are of but 2 makes, both of the highest quality available. It is well recognized today that electrodes can be devised that will meet best some given condition of deposition. Full advantage of this has been taken and 3 kinds of electrodes, as regards position of deposition, have been used. One was used for all down-hand butt welds; another for all down-hand or horizontal fillet welds; and yet another for welds that of necessity had to be made in a vertical position. Overhead welding has been avoided. The electrodes are of such nature that they are equally satisfactory with either d-c or a-c welding apparatus. Both are being used throughout; a-c welding was found to be especially useful for welding into corners.

All welding on the tube parts and to date on the "horseshoe" has been manual welding. The 2 declination-bearing housings were produced using automatic welding for the longitudinal and external circumferential welds.

Figure 3 shows a stage in the fabrication of the prime-focus cage. The lower main ring of the cage was formed on the floor plate and the uprights, formed elsewhere as detail parts, were assembled as shown. The ring is approximately 22 feet in outside diameter and the cage is roughly 12 feet long with the top ring in place. The gauge for controlling the proper radius and for accurately locating the pieces of tubing that are in evidence, may be noted. The simple method for supporting and clamping the ring both inside and out is shown. The use of intermittent welding may be noted in most of the parts.

Figure 4 shows work in progress in the fabrication of one of the end sections of the "horseshoe." This "horseshoe" has an outside diameter of approximately 46 feet. The plates used to form the inner and outer bands were preformed, and are $4^1/_2$ inches thick and 60 inches wide. One side plate was formed first. This plate was then clamped down and the inner and outer bands moved into position and clamped around the outside. Clamping blocks were welded to the bands as shown. The internal plates and reinforcing members were fitted in place and secured by tack welding. After properly fitting the cellular or box-like structures that fasten to the outer band and fixing the various component parts by welding a bar across them, they were removed from the main part and welded under the most ideal conditions on the floor. This had a double advantage: It permitted turning them in any position to get the best welding, and it avoided undue heating and stressing of the main members by the considerable amount of welding necessary. There are 5 of these sub-assemblies, 2 of which are shown in place in figure 4.

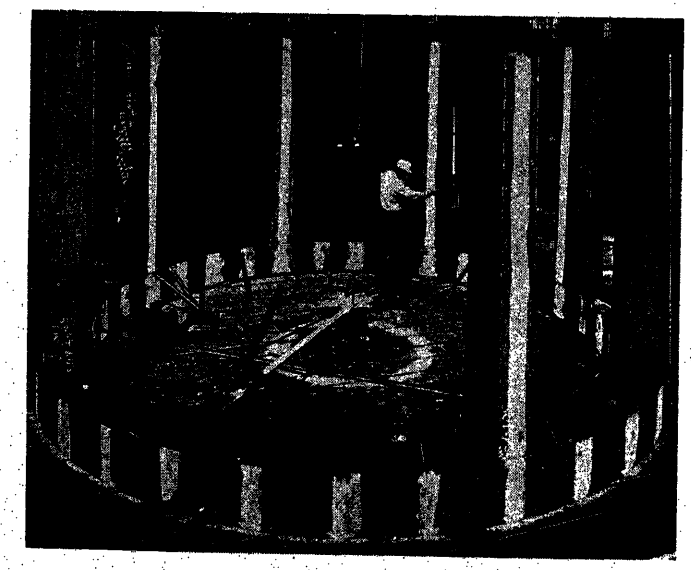

**Figure 3. Fabrication of bottom ring and uprights of prime-focus cage. Note that clamping blocks, struts, and stays are attached exactly where wanted by welding; they are readily removed later**

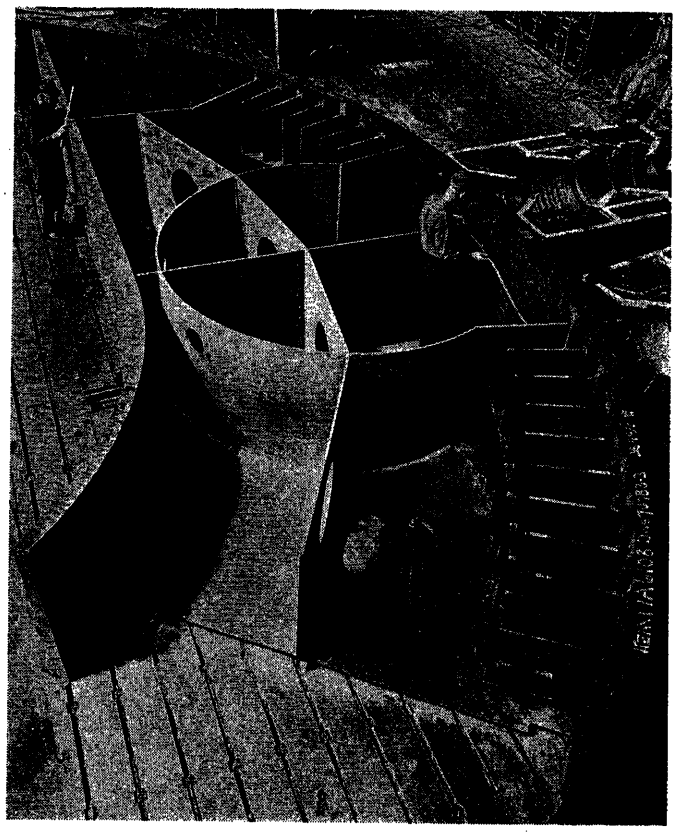

**Figure 4. Early stage in fabrication of one section of the yoke "horseshoe"**

All the telescope parts are being carefully annealed to relieve internal stresses. A double annealing cycle is being used: first heating to from 1,150 to 1,200 degrees Fahrenheit, holding for a period of 3 hours for the first one inch of thickness or fraction thereof, followed by a slow cooling in the furnace until the temperature has fallen below 600 degrees Fahrenheit; and then repeating this cycle in its entirety and cooling below 300 degrees Fahrenheit before the furnace doors are opened.

As an example of the accuracy with which the parts were held to size throughout welding and annealing, when the prime-focus cage was placed on the boring mill to face the lower end where it bolts to the top ring of the tube, the departure from roundness was not greater than $^1/_{16}$ inch.

# Electrical Computer Eliminates Calculations

**Based upon an exact electrical analogy of a mechanical system, a specially constructed electrical computer eliminated many laborious calculations in designing the overhead catenary system for an extensive railroad electrification**

By FRED H. HEDIN
ASSOCIATE AIEE

MANY engineering applications involve the solution of numerous laborious and repeated calculations of a similar nature. The design of the overhead catenary for an extensive railroad electrification, which is typical of such applications, involves the determination of the shape of a messenger cable for thousands of spans that differ only in length and in the location and values of the supported loads. During the design of a recent railroad electrification, a squad of from 15 to 20 men were continuously employed by the engineers on such calculations for a period of about 2 years. Both the volume and required accuracy of these calculations led to a search for some simple computing device whereby the most monotonous part of the calculations might be eliminated and the progress of the work expedited. The purpose of this article is to describe the computer which was developed for this purpose.

## The Problem

As is well known, the contact wire of a catenary system is supported directly or indirectly by means of hangers from a messenger cable, which in turn is supported at intervals of from 200 to 300 feet on structures transverse to the tracks. For the modern high-speed electrification, where heavy currents are collected at speeds of the order of 90 miles per hour by means of the sliding contact of a pantagraph, it is of paramount importance that the riding contact wire be in nearly a horizontal plane, or if a change in elevation is necessary, that the change be smooth and gradual.

On tangent track, with no special work such as crossovers or turnouts, the computation of the shape of the loaded messenger, for the purpose of selecting hanger lengths to give a smooth-riding contact wire, is comparatively simple. Tables or templates are used, as the load is distributed uniformly and there is practically no error in the assumption that the messenger takes a parabolic shape.

However, at interlocking points and yards, the problem is much more difficult. The intersection of the catenary from different tracks, as well as the design of air breaks for sectionalizing purposes, requires that the contact wire be raised or lowered with respect to its normal riding datum, with resultant changes in messenger loading (since the contact wire is itself under high tension). Also the concentrated loads of sectionalizing insulators, which may amount to several hundred pounds, must be carried. The resultant shape of the messenger, under the various concentrated and distributed loads that may exist in a span, is no longer a smooth and simple mathematical curve and must be calculated by the laborious step-by-step moment method. The various spans usually have different loadings because of physical obstructions in locating structures and variations in existing track layout.

Not only are the computations laborious and monotonous, but they consume much time because of the added necessity for checking. It is difficult and very expensive to make field correction, because of the flexible nature of the catenary and because the installation may be made under an extreme temperature condition, which affects the messenger shape.

A typical span, selected from thousands of similar ones, is shown in figure 1(*a*). The messenger loading and shear diagrams also are shown in figure 1(*b* and *c*).

The problem therefore was essentially this: Given a flexible cable, strung at known tension, over a known span, between fixed supports, and subject to known vertical loads, at known points in the span; to develop a simple and accurate device to determine, quickly and automatically, the reactions at the supports and the complete shape of the cable. Further, the device must be equipped to handle variations in the given factors of tension and span length, as well as direction, location, and number of vertical loads.

## Evolution of the Circuit

During the course of the search for a fundamental basis for such a computing device, the following analogy was visualized, more or less accidentally: First, referring to figure 2 (*a*), consider the simple case of a messenger of span $L$ and given horizontal tension $T$, subjected to a single concentrated load $W$ at any point in the span. Then the part of the load $W$ carried at each messenger support (reactions), and the shear in the messenger is as shown. Then, consider the electrical analogy as shown in the simple circuit figure 2 (*b*). A resistor of any length, and of any uniform resistance per unit of length, has a current $I$ supplied to it at the same relative point in its length as the mechanical load is in the messenger span.

Written especially for ELECTRICAL ENGINEERING.

FRED H. HEDIN is with Municipal Civil Service Commission, New York, N. Y., as examiner, electric railroad.

If the 2 ends of the resistor (or current divider) are tied together to a common return circuit, then the division of the current is as shown.

By comparison of (*a*) and (*b*) of figure 2, it is at once apparent that a useful analogy exists. The mechanical load $W$ seems to divide and "flow" to each messenger support, exactly as though the messenger were a uniform resistance connected as shown in (*b*). Therefore, it can readily be seen that if a constant value of pounds per ampere is assumed, and if an ammeter is calibrated directly in pounds on that basis and connected as $A_3$ in figure 2 (*c*) and 2 similarly calibrated ammeters are inserted in the circuit as $A_1$ and $A_2$, and if the input (or "load") current is regulated by resistance $R$ so that $A_3$ reads $W$ pounds; then $A_1$ and $A_2$ will read, directly in pounds, the reactions $R_1$ and $R_2$.

This analogy was based upon the simplest kind of a span with only one concentrated load. The question that now naturally arises is whether the division will be made correctly should additional currents be supplied simultaneously to other points of the resistance divider, to represent other concentrated loads on the messenger. The messenger itself acts to distribute the various concentrated loads to each support exactly as though each load were acting alone on the messenger, the summation of each individual load's reaction being the total reaction at that support. It can be demonstrated by rigid proof that the electrical circuit as shown acts in an identical manner. This proof is somewhat involved for the purpose of this article, but it can be visualized partially by noting that, although there are various $IR$ drops in various parts of the resistance divider due to the application of several "loads," nevertheless, if any point in the divider is considered as a point of application for still another "load," the total potential drop from the proposed point of application to either end of the divider tube is the same. Thus the existence of other "loads" on the resistance divider does not affect the correct distribution of a proposed additional "load" and only serves to require a little more "push" to get the load into the divider. This extra "push" is provided by cutting out a slight amount of additional resistance in the load-applying circuit. Since this resistance always is regulated to produce the correct "load" reading on the ammeter in its circuit, the final position of this uncalibrated load-regulating resistance is not important.

Another interesting fact revealed by comparing (*a*) and (*b*) of figure 2 is that the current distribution in the divider is identical with the shear diagram for the messenger. The current even reverses its direction at the same point as the shear passes through zero. This analogy is true for any number of applied loads on the messenger if corresponding "load" currents are supplied to the resistance divider.

From the foregoing facts, one more step now is possible. In a messenger span under given tension, the sag at various points is proportional to the total moment at these points. The moment involves load and length (moment arm). Similarly, the voltage drop from any point on the resistance divider to either end is dependent on the current (load) and resistance (length) of the section. Therefore it might be surmised that a definite relation exists between the sag at a given point on the messenger and the voltage drop from the end of the properly loaded resistance divider to a corresponding point on the divider. If this is investigated mathematically, the following formula results:

$$V = wpkT \times \text{sag in feet}$$

where

$p$ is the relation between the length of the span and the length of the resistance divider in feet.
$k$ is the amperes per pound used to calibrate the load and reaction meters.
$w$ is the ohms per foot of the resistance divider.
$T$ is the messenger tension.

The constants $w$ and $k$ may be incorporated in the calibration of the volmteter; the factors $p$ and $T$, which are constant for a given problem but may vary in different problems, are calibrated into the voltmeter for the maximum span length and minimum tension (i.e., maximum sag) that are likely to occur. Then the voltmeter reading is reduced by a variable series resistor, calibrated in the ratio of tension to span length, for computing other problems involving greater messenger tension or shorter span, or both. Thus, the voltmeter will read the sag directly in feet if one end is permanently connected to the ends of the resistance divider and the other end arranged to contact the divider at any point where the corresponding messenger sag is desired.

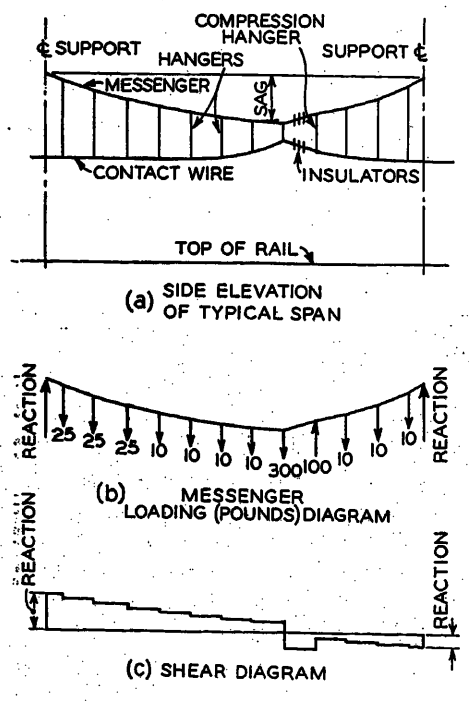

**Figure 1. Typical catenary span to be solved on computer, showing construction, messenger loading, and shear diagrams**

## Construction of Computer

A computer was designed and constructed according to the described electromechanical analogy. The complete wiring diagram is shown in figure 3, and the completed computer is shown in figures 4 and 5.

A choice of design constants was available, and the

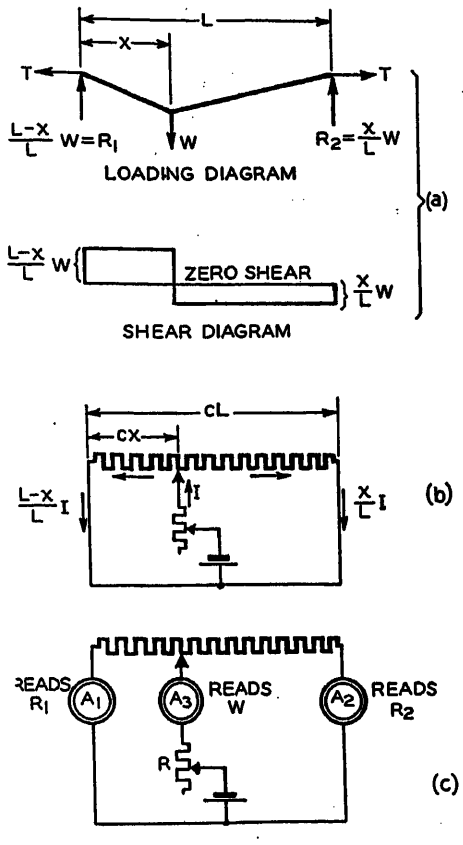

**Figure 2. Elementary analogy between a loaded cable and the simple electrical circuit shown**

design was evolved from the usual balance of one against the other. A special effort was made to locate controls and meters so as to give a visual picture of the loaded messenger, for ease in manipulation.

The main problem was to secure extremely sensitive meters. The voltmeter must have unusually high resistance because its current requirement acts as a "load" on the divider. Any resistance in the reaction ammeters causes, in effect, an extension of the length of the divider resistance. The divider scale is extended beyond the actual ends of the divider to eliminate any such error, but any appreciable extension of this scale would result in a "blind spot" for the application of "loads" that are close to the messenger supports. Also the load current and divider resistance had to be kept as low as possible to avoid heating and to keep the size of the computer within reasonable bounds. Special meters having cobalt steel magnets to give very high sensitivity were needed to obtain close accuracy in the solution of this problem.

As shown in figure 3, sliding contacts were used for applying the "load" currents to the divider. Although in general sliding connections are not satisfactory for good contact, it should be noted that, because of the inherent features of the circuit, no error is produced if the contact resistance varies slightly from day to day as the correct current still is supplied by the "load" circuit since it is read directly on the ammeter.

It should be noted also that, although the computer could be designed so that the divider scale is calibrated directly in feet of span, this would require that the connection to one end of the divider be a sliding connection. As any change in contact resistance of this slider would materially affect the proper division of current and would not be readily apparent, it was decided to incorporate the span length factor into the voltmeter multiplier circuit.

## Operation and Results

A systematic method of operating the computer was developed. Standard data forms were printed and given to the men laying out the catenary design. This form was provided with a tabular arrangement for listing in order: (1) the value and direction (up or down) of the messenger loads, starting from the left support; (2) the respective distances of these loads from the left support in per cent of the total span; (3) the total load carried by the messenger; and (4) the ratio of tension to span length. For use of the computing-machine operator, space was provided for listing: (1) the sag at each load point, and (2) and (3) the reactions $R_1$ and $R_2$. A separate sheet was used for each span and labeled with the numbers assigned

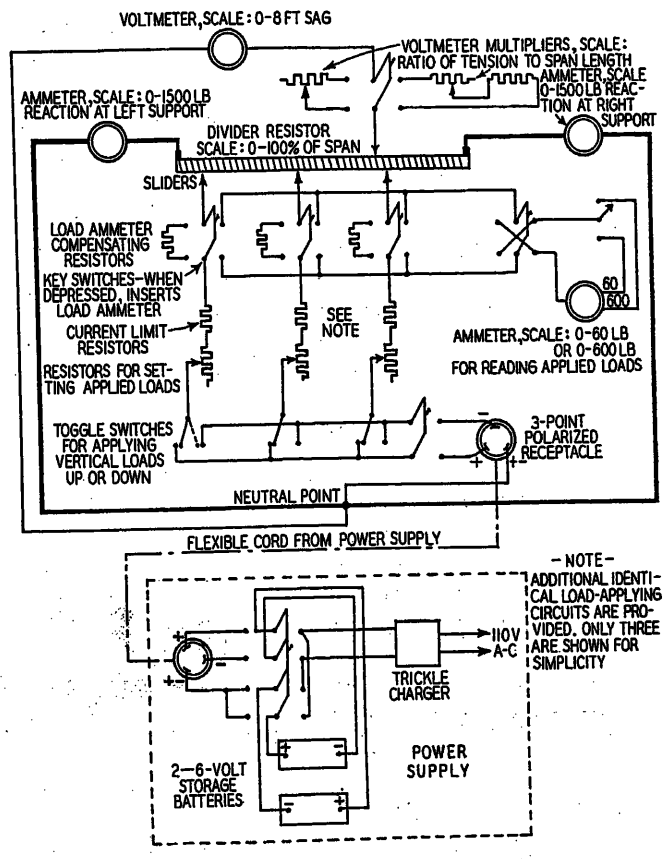

**Figure 3. Wiring diagram for the computer as built, showing the added arrangements for ease in operation**

to the particular messenger and structures involved. At various times, these sheets were collected from all the designers and given to the computing machine operator. He then set up the problems on the machine and completed the data sheets from the meter readings. The completed sheets were returned to the designers and the data used to calculate hangers.

The computing-machine operator's procedure, for a

given span, is as follows (see figures 3 and 4): With the data sheet as a guide, the operator sets the load sliders, in order from left to right at their given percentage locations on the divider scale. Then the toggle switches for the directions of the various loads are set, starting from left to right, from the data sheet (the loads are usually downward). The extreme left load ammeter key then is depressed, inserting the load ammeter in the extreme left slider circuit, and the corresponding load regulating resistor is adjusted until the load ammeter reads the given messenger load nearest the left support. The load ammeter key then is released and returns to its normal position, leaving the first load set and the ammeter available for setting the next load. The load is set for the next slider location in the same way, and the procedure is repeated for all the required load circuits. The divider now is completely "loaded."

Without further manipulation, the reactions may be read, immediately, on their respective meters and noted on the data sheet. The 2 reactions as read on the meters are added, and their sum should exactly equal the total messenger load given on the data sheet. This is practical proof that no mistake has been made in setting the various loads. Although it is possible that compensating errors may give the same result, the chance of such errors is so remote that results may be considered entirely satisfactory.

Without changing the load setup, the next step is to set the voltmeter multiplier scale on the tension-to-span ratio given on the data sheet. Then the sags, which determine the shape of the messenger, are read directly (in feet) from the sag voltmeter by successively moving its slider to the load locations on the divider scale. The sag at any other point in the span may be read by moving the voltmeter slider to the corresponding point on the divider scale. The controls then are brought to zero, and the computer is ready for another problem.

The computer requires very little intelligence to operate and no mechanical or electrical knowledge. It is practically foolproof, and the operator can use it continuously for long periods without going "stale" as he may with continuous mathematical calculations.

Results obtained with the computer have been very satisfactory. Accuracy has been of the order of $1/4$ per cent, which is equal or better than that obtained by slide rule.

The most important gain has been in saving time. A careful check has shown that the computations for a span are completed in an average time of 5 minutes on the computer and are self-checking; the same computation, done "by hand" requires approximately 40 minutes including checking time by a higher-salaried designer. One computer and one operator can handle these computations for a large squad of designers.

## Other Problems Can Be Solved

The most common practice at present is to use stranded cables between guyed columns as supporting structures for the catenary, instead of beams or trusses. The only difference between the solution for the shape of these messengers and the longitudinal messengers, is that the former is designed for constant sag for different spans rather than constant tension. The shape of these cross-span messengers also is solved on this computer as built, with only a slightly different manipulation of the tension-to-span ratio multiplier.

Many other mechanical problems may be solved on slightly different computers involving essentially the same circuit and analogy. It illustrates one more surprisingly exact analogy between electrical and mechanical laws.

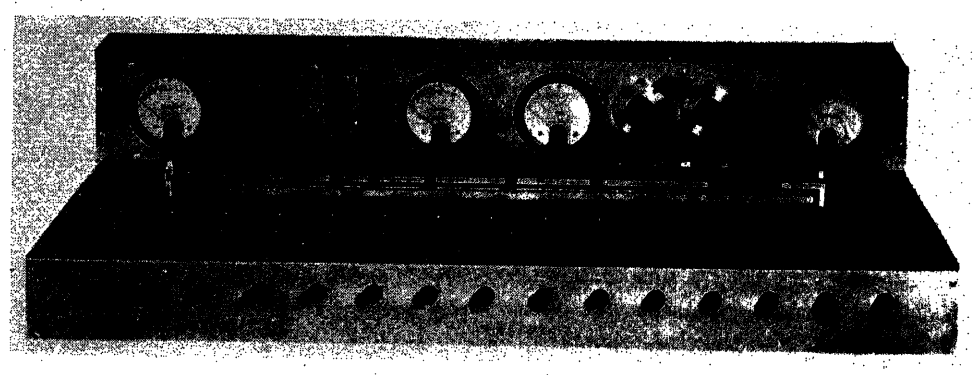

Figure 4 (above). Front and top view of the computer as built, showing compactness and logical location of apparatus for ease in visualizing problem

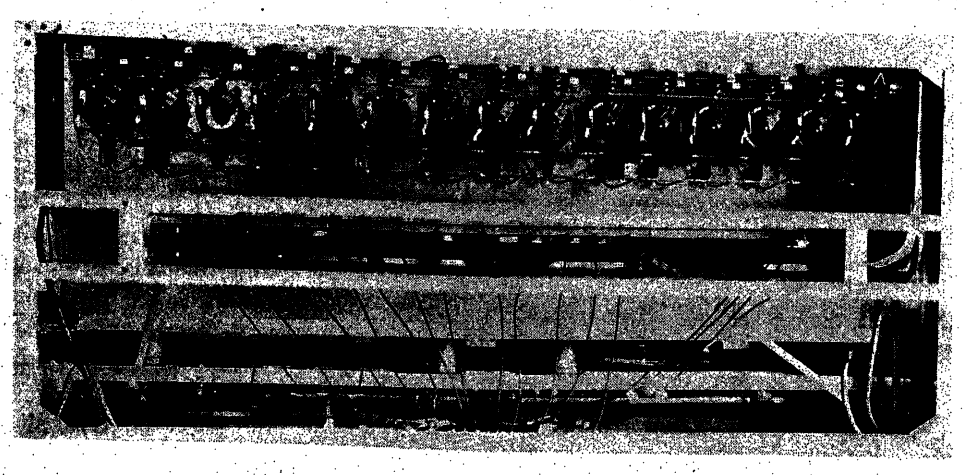

Figure 5 (left). Bottom view of finished computer, showing compact arrangement of wiring and equipment

# Report of the Board of Directors

THE BOARD OF DIRECTORS of the American Institute of Electrical Engineers presents herewith to the membership its fifty-third annual report, for the fiscal year ending April 30, 1937. A general balance sheet showing the condition of the Institute's finances on April 30, 1937, together with other detailed financial statements, is included herein. This report contains a brief summary of the principal activities of the Institute during the year, more detailed information having been published from month to month in ELECTRICAL ENGINEERING.

## Board of Directors' Meetings

During the year, the board of directors held 5 meetings, 4 in New York City, and 1 at Pasadena, Calif. The executive committee meetings in December and March were held in place of regular meetings of the board. Information regarding many of the more important activities of the Institute which have been under consideration by the board of directors and the committees is published each month in the section of ELECTRICAL ENGINEERING devoted to "News of Institute and Related Activities."

## President's Visits

President MacCutcheon attended the winter convention and the South West District meeting. He also visited many Sections, and a considerable number of educational institutions in their vicinities. In several cases, he addressed assemblies of engineering students, while in other cases he spoke at meetings of the AIEE Student Branches.

The places visited are listed below:

**Alabama**
- Alabama Section, Birmingham
- Alabama Polytechnic Institute, Auburn
- University of Alabama, Tuscaloosa

**California**
- Los Angeles Section
- San Francisco Section
- University of California, Berkeley

**Colorado**
- Denver Section
- University of Colorado, Boulder

**Connecticut**
- Connecticut Section and Yale University, New Haven

**District of Columbia**
- American Engineering Council, Washington

**Florida**
- Florida Section, Jacksonville, Gainesville, and Miami
- University of Florida, Gainesville

**Georgia**
- Atlanta Section
- Georgia School of Technology, Atlanta

**Idaho**
- University of Idaho, Moscow

**Illinois**
- Chicago Section

**Maryland**
- Baltimore Section and student convention

**Massachusetts**
- Boston Section
- Lynn Section
- Springfield Section
- Worcester Section
- Worcester Polytechnic Institute, Worcester

**Michigan**
- Detroit-Ann Arbor Section

**Minnesota**
- Minnesota Section, Minneapolis

**Missouri**
- Kansas City Section
- St. Louis Section

**Montana**
- Montana Section
- Montana State College, Bozeman

**New York**
- New York Section
- Winter Convention, New York City
- Board of Directors Meetings, etc.

**North Carolina**
- North Carolina Section, Raleigh
- Duke University, Durham
- North Carolina State College, Raleigh

**Ohio**
- Akron Section
- Columbus Section

**Oklahoma**
- Oklahoma City Section

**Oregon**
- Portland Section

**Pennsylvania**
- Erie Section
- Philadelphia Section
- Pittsburgh Section
- Sharon Section

**Rhode Island**
- Providence Section and Brown University

**South Carolina**
- Columbia
- Clemson Agricultural College, Clemson

**South Dakota**
- District No. 6 Conference on Student Activities, Brookings

**Tennessee**
- East Tennessee Section, Knoxville and Chattanooga

**Texas**
- South West District meeting, Dallas
- Houston Section and Rice Institute

**Utah**
- Utah Section, Salt Lake City
- University of Utah

**Virginia**
- Virginia Section, Richmond

**Washington**
- Seattle Section
- Spokane Section
- State College of Washington, Pullman

**Wisconsin**
- Madison and Milwaukee Sections in Milwaukee
- Summer convention committee, Milwaukee

**Canada**
- Toronto (Ont.) Section
- Vancouver (B. C.) Section

During May and June, President MacCutcheon will visit the Cincinnati, Ithaca, Lehigh Valley, Cleveland, and Rochester Sections, and Massachusetts Institute of Technology Branch, and will attend the North Eastern District meeting, Buffalo, N. Y., and the summer convention, Milwaukee, Wis.

## National Conventions

Two national conventions were held during the year, and a brief report on each follows:

*Summer Convention.* The fifty-second summer convention was held at Pasadena, Calif., June 22–26, 1936, combined with the twenty-fourth Pacific Coast convention. Forty-two technical papers were presented at 9 sessions, and 10 student papers at 2 additional sessions. Six technical conferences were held. Other parts of the convention were the annual business meeting of the Institute, conference of officers, delegates, and members, an address by Doctor R. A. Millikan, golf and tennis tournaments, president's reception and dance, banquet, and ladies' events. The Lamme Medal for 1935 was presented to Doctor Vannevar Bush, of Cambridge, Mass. The registration was 715.

*Annual Meeting.* The annual business meeting of the Institute was held on Monday morning June 22, as part of the opening session of the summer convention. The annual report of the board of directors for the fiscal year ending April 30, 1936, was presented in abstract, the committee of tellers reported upon the election of officers for the administrative year beginning August 1, 1936, and a financial report was presented by National Treasurer W. I. Slichter. President-Elect MacCutcheon responded to the announcement of his election with a brief address.

*Winter Convention.* The twenty-fifth winter convention, held in New York City, January 25–29, 1937, was

opened by a brief general session including an address of welcome by C. R. Beardsley, chairman of the winter convention committee, an address by President MacCutcheon, and a brief announcement regarding the technical sessions by H. S. Osborne, chairman of the technical program committee. President MacCutcheon announced the award of the Alfred Noble Prize for 1936 to Abe Tilles, instructor in electrical engineering at the University of California. During the 13 sessions held, 56 papers were presented. At an evening session, the Edison Medal was presented to Doctor Alex Dow, and John C. Parker, vice-president, Consolidated Edison Company of New York, Inc., gave a lecture on "Power and People." Numerous inspection trips aroused keen interest. The registration was 1,165.

## District Meetings

Two District meetings were held during the year and brief reports follow.

*North Eastern District Meeting.* Held in New Haven, Conn., May 6–9, 1936, with a registration of more than 300 members, students, and guests. The program consisted of 11 technical papers, 4 special addresses, 9 student papers, inspection trips, and entertainment events.

*South West District Meeting.* The sixth South West District meeting was held in Dallas, Texas, October 26–28, 1936. Thirteen technical papers and several special addresses were presented at 5 technical sessions, and 9 student papers at 2 student sessions. A special address was given by Doctor Matthew Luckiesh at a luncheon meeting held jointly with the Dallas Electric Club. There were also numerous inspection trips and entertainment events. The total registration was 533, including 179 students.

## Sections

The activities of the Sections during the past year were outstanding in several respects, particularly with respect to the unusually large total number of meetings held, and the extensive efforts to determine and arrange for meetings of types of special interest to the members.

Seven or more meetings were held by each of 46 Sections, and only 4 Sections held fewer than 4 meetings. There was a great increase in interest in technical groups, special technical meetings, technical lectures, technical committees, discussion groups, and other arrangements desired by Section members. Twenty Sections conducted meetings of these special types in addition to the regular Section meetings. Six Sections offered courses of instruction on engineering subjects. Several Sections held local group meetings at points distant from regular meeting places.

Interest of the Sections in student activities was shown by the holding of the usual joint meetings with Branches, the sponsoring of student conventions, etc.

The East Tennessee Section was organized on September 2, 1936, under authority granted by the board of directors on May 25, 1936, including as its territory approximately the eastern half of the state. Dinner meetings were held in Knoxville and Chattanooga on September 18 and 19, respectively, with excellent attendance and much enthusiasm.

The final report of the special committee to revise Section territories, appointed by action of the board of directors in 1935 to develop plans for extending Section territories and the formation of new Sections to include in so far as practicable all parts of the United States, was presented at the meeting of the board of directors held on January 27, 1937, and the actions recommended were approved, the changes in territories to become effective August 1, 1937. The changes will bring within Section territories nearly one-half of the few hundred members now outside.

Detailed information on these activities may be found in the annual report on Section and Branch activities in the June issue of ELECTRICAL ENGINEERING, pages 762–5.

## Student Activities

Under authority granted by the board of directors at its meeting held on January 26, 1937, the Columbia University Branch was organized on February 19, and the Tulane University Branch was organized on March 1, bringing the total number to 119.

The total number of meetings reported exceeds that for any previous year, and the total number of talks by students is practically equal to the largest number previously reported. However, a considerable number of Branches reported less than a normal number of meetings and no talks by students.

Students have shown an increasing interest in the opportunities to take active parts in the technical programs of national conventions and District meetings. One student technical session was included as part of the North Eastern District meeting in New Haven, 2 such sessions were held during the combined summer and Pacific Coast conventions in Pasadena, and 2 such sessions were held as parts of the South West District meeting in Dallas. The quality of the content and the presentation of the student papers inspired many favorable comments by Institute members.

The terms of enrollment of 1,253 students expired on April 30, 1937, and 674, or about 54 per cent, applied for admission as Associates. The percentage during the past few years has been approximately 50.

**Table I. Section and Branch Statistics**

| | For Fiscal Year Ending | | | |
|---|---|---|---|---|
| | April 30, 1931 | April 30, 1933 | April 30, 1935 | April 30, 1937 |
| **Sections** | | | | |
| Number of Sections | 59 | 60 | 61 | 62 |
| Number of Section meetings held | 491 | 498 | 521 | 621 |
| Total attendance | 108,523 | 73,806 | 73,381 | 74,950 |
| **Branches** | | | | |
| Number of Branches | 109 | 111 | 117 | 119 |
| Number of Branch meetings held | 1,137 | 1,026 | 986 | 1,363 |
| Total attendance | 51,807 | 59,439 | 36,629 | 46,121 |

More detailed information on these activities appears in the annual report on Section and Branch activities in the June issue of ELECTRICAL ENGINEERING, pages 762–5.

## Section and Branch Statistics

Data on the Sections and Branches are given in table I.

## Technical Program Committee

The work of the technical program committee may be considered under 3 general topics: arranging for technical programs under the present established procedures; studying alternative arrangements as to program building and publication of papers to determine whether any constructive recommendations can be made; and in co-operation with other committees making arrangements for general meetings at Institute conventions.

### ARRANGEMENTS FOR TECHNICAL SESSIONS

Under the present unified publication policy, all papers for national conventions (except special addresses) and all approved discussions are published in ELECTRICAL ENGINEERING. The space allotted to the technical program committee for the current year (1,115 pages) is approximately $^2/_3$ the space used by the committee 6 years ago. Under these conditions it is naturally impossible to meet all of the desires of the technical committees for sessions and for presentation of papers. For the summer convention, 18 technical sessions were proposed, 10 scheduled, and 8 postponed or rejected. Twenty-eight per cent of the papers submitted are rejected or withdrawn because of abbreviation or other modifications required for acceptance. Other papers, the number of which, of course, is not known, are not offered to the Institute because of these conditions.

During the past 12 months, there have been 2 national conventions (the summer convention and Pacific Coast convention being consolidated into one) and 2 District meetings. At these 4 meetings, 122 papers have been presented. Every effort has been made by the technical program committee to have the meetings at the national conventions and, in co-operation with the District committees, the District meetings as well, cover the wide range of interests of the Institute membership. In general, the papers have been of high grade, upholding the tradition of the Institute as to the high quality of the material presented at its meetings. The committee has continued to encourage the conference type of session at which papers and discussions are presented without publication. Ten such conference sessions were held during the 2 national conventions.

### ALTERNATIVE ARRANGEMENTS FOR TECHNICAL PROGRAMS

The field of Institute activities, namely, "the advancement of the theory and practice of electrical engineering and of the allied arts and sciences" is diverse and rapidly expanding. In spite of the very considerable provision made by the Institute for the publication and presentation of papers, it is natural that the programs should still be possible of improvement. Some members of the Institute feel that more time and space should be given in Institute programs to subjects of broad general interest including questions in which engineering and social science are jointly involved. On the other hand, many members would like more opportunity for a discussion at Institute meetings of specialized technical subjects on the frontier of immediate technological advance.

It may be questioned whether a mere extension of the program with present procedures as to publication and presentation is the best way to take care of this constant trend toward expansion. Furthermore, the unified publication policy which has served the Institute admirably during the period of depression has certain disadvantages both from the standpoint of program making and of publication. It requires relatively long intervals between the preparation and presentation of papers and involves the distribution in printed form to all members of the Institute of all technical papers, many of which are of interest to only a small proportion of the members.

With these facts in mind, the technical program committee has appointed a subcommittee which is actively studying the whole problem of procedures relating to Institute meetings. It is hoped that based upon these studies the technical program committee will, before the expiration of its term, be able to make specific recommendations for the consideration of next year's committee.

### GENERAL MEETINGS

In response to may suggestions regarding the desirability of having as a part of Institute conventions meetings of broad general interest, arrangements have been made for such a meeting at the summer convention in Milwaukee. The first part of the meeting will consist of an address on the subject "The Engineer in a Changing World," by Doctor Ralph E. Flanders, who is an authoritative speaker on the relations between engineering and economic problems. The second part of the meeting will include a general discussion by the members of the Institute on the subject "How Can Institute Programs Be Made of Greatest Value to the Membership?"

Arrangements for this general session have been made by a special committee consisting of the chairmen of many of the principal committees of the Institute. Based upon the results of this meeting, the special committee will make recommendations to the board of directors regarding the advisability of having similar meetings at future Institute conventions.

## Publication Committee

Throughout the year effort has been made to improve the usefulness of ELECTRICAL ENGINEERING to the membership by including more articles of a general interest type.

The initial budget included an extra appropriation specifically for this purpose, so that the publication of highly technical papers would not have to be curtailed to permit the publication of general interest articles. At the January meeting of the board of directors, a further

specific appropriation was granted to cover the publication of general interest articles.

In requesting this latter appropriation, the publication committee defined the scope of general interest articles as follows:

Timely review articles on various phases of electrical engineering, feature articles by men prominent in the Institute or in other fields of scientific and engineering endeavor, reprints of important electrical engineering papers originally published in English abroad, reprints of important papers published in this country in other fields of engineering, and appropriate general articles on economics and the status of the engineer written by outstanding men; also at times interpretive abstracts of important and highly technical papers published in full elsewhere in ELECTRICAL ENGINEERING; possibly also some English translations of important electrical engineering papers published originally in a foreign language.

Starting with the January issue ELECTRICAL ENGINEERING acquired "The Easy-Reading Page." Based on scientific studies and in the interests of reader comfort, the typography, the paper, and the ink have been selected to provide a nonglare easy-reading page. Many letters have been received commenting favorably on this change.

In general, the unified publication plan adopted by the board of directors in August 1933 has been followed.

## Membership Committee

The work of the membership committee has followed along much the same lines as it has for the past 2 or 3 years. Probably the most important change has been the increased responsibility given to the District vice-chairmen of the committee in connection with the Section membership committees in each District. The vice-chairmen have done an excellent job, and together with the very good co-operation given them by the Section committees, have made possible a report that shows marked improvement in the Institute's membership analysis. The entire membership has again given the committees much assistance this year by suggesting that certain nonmembers be approached. A new pamphlet was prepared, published, and, though written for membership work mainly, it was placed in the hands of every member of the Institute. It is titled, "Membership in the American Institute of Electrical Engineers."

The changes that have occurred in the Institute's membership totals during the year are given in table II. The most interesting figures are those that give the change in total enrollment. There is shown a gain of 708 which is more than twice the gain reported a year ago, the first year of increase since the business depression. There was a good increase in the number of "new members qualified," and the decrease of the members "dropped" column is encouraging. The number dropped this year is 526 compared with 797 last year.

The number of applications received increased again, as shown in table III, by about 11 per cent. The increase of some 13 per cent in Student applications for transfer, and the increase in applications for Student membership, as well as in the total Student enrollment (see table IV) are all very encouraging.

Table V shows a steady decrease in delinquent reinstatements for the past 2 years. This is as it should be since the total number of delinquents has been reduced considerably over the past 2 years. There are 1,869 owing dues on April 30, 1937, as recorded in table VI. The same figure last year was 2,154. The figure of 460

**Table II. Membership Statistics for the Fiscal Year Ending April 30, 1937**

| | Honorary | Fellow | 6-Year Member | Associate | Associate | Total |
|---|---|---|---|---|---|---|
| Membership on April 30, 1936 | 11 | 699 | 3,912 | 5,679 | 4,299 | 14,600 |
| **Additions** | | | | | | |
| Transferred | 1 | 27 | 182 | 571 | | |
| New members qualified | | 6 | 150 | 40 | 1,285 | |
| Former members reinstated | | 2 | 17 | 37 | 42 | |
| | 12 | 734 | 4,261 | 6,327 | 5,626 | 16,960 |
| **Deductions** | | | | | | |
| Died | 2 | 19 | 26 | 32 | 4 | |
| Resigned | | 2 | 34 | 135 | 91 | |
| Transferred | | 1 | 24 | 165 | 591 | |
| Dropped | | 3 | 59 | 204 | 260 | |
| Membership on April 30, 1937 | 10 | 709 | 4,118 | 5,791 | 4,680 | 15,308 |

**Table III. Number of Applications Received From Enrolled Students and From All Others**

| Year Ending | From Students | From All Others | Total |
|---|---|---|---|
| April 30, 1937 | 716 | 1,040 | 1,756 |
| April 30, 1936 | 631 | 946 | 1,577 |
| April 30, 1935 | 575 | 715 | 1,290 |
| April 30, 1934 | 467 | 496 | 963 |
| April 30, 1933 | 674 | 305 | 979 |

**Table IV. Number of Enrolled Students**

| | |
|---|---|
| April 30, 1937 | 4,503 (2,249) |
| April 30, 1936 | 4,049 (1,991) |
| April 30, 1935 | 3,806 (1,983) |
| April 30, 1934 | 3,186 (1,548) |
| April 30, 1933 | 3,260 (1,494) |

Following the number of Students reported for April 30 of each year is indicated within parentheses the number of new applications received during that year; the difference between this number and the reported total, of course, reflects the number of renewals of Student enrollment for the corresponding period.

**Table V. Number of Members in Section Territory Reinstated**

| | |
|---|---|
| August 1, 1936, to April 30, 1937 | 460 |
| Year beginning August 1, 1935 | 663 |
| Year beginning August 1, 1934 | 831 |
| Year beginning August 1, 1933 | 741 |
| Year beginning August 1, 1932 | 277 |

**Table VI. Membership of the Institute, April 30, 1937**

Of the 15,308 members reported for April 30, 1937, 13,439 are fully paid to April 30, 1937. The balance of 1,869 are divided into the following groups:

| | |
|---|---|
| 1. Members owing dues to April 30, 1936. Total number of members who have not acted upon resolution of board of directors adopted in January 1937 providing an extension of time for payment of these dues | 505 |
| 2. Members owing dues to April 30, 1937 | 1,364 |

(During the period May 1 to 25, 1937, 311 members have paid dues to April 30, 1937, reducing the total to 1,053).

### Table VII. Memberships Fully Paid

| | Membership as of April 30 | Number of Members Fully Paid as of April 30 | Per Cent Fully Paid |
|---|---|---|---|
| 1937 | 15,308 | 13,439 | 87.8 |
| 1936 | 14,600 | 12,446 | 85.2 |
| 1935 | 14,260 | 11,512 | 80.5 |
| 1927 (year of maximum membership) | 18,344 | 16,247 | 88.5 |

### Table VIII. Record of AIEE Membership

| Total Membership May 1 | | Total Membership May 1 | | Total Membership May 1 | | Total Membership May 1 | |
|---|---|---|---|---|---|---|---|
| 1884 | 71 | 1899 | 1,133 | 1913 | 7,654 | 1927 | 18,344 |
| 1885 | 209 | 1900 | 1,183 | 1914 | 7,876 | 1928 | 18,265 |
| 1886 | 250 | 1901 | 1,260 | 1915 | 8,054 | 1929 | 18,133 |
| 1887 | 314 | 1902 | 1,540 | 1916 | 8,202 | 1930 | 18,003 |
| 1889 | 333 | 1903 | 2,229 | 1917 | 8,710 | 1931 | 18,334 |
| 1890 | 427 | 1904 | 3,027 | 1918 | 9,282 | 1932 | 17,550 |
| 1891 | 541 | 1905 | 3,460 | 1919 | 10,352 | 1933 | 17,019 |
| 1892 | 615 | 1906 | 3,870 | 1920 | 11,345 | 1934 | 15,200 |
| 1893 | 673 | 1907 | 4,521 | 1921 | 13,215 | 1935 | 14,269 |
| 1894 | 800 | 1908 | 5,674 | 1922 | 14,263 | 1936 | 14,600 |
| 1895 | 944 | 1909 | 6,400 | 1923 | 15,208 | 1937 | 15,308 |
| 1896 | 1,035 | 1910 | 6,681 | 1924 | 16,455 | | |
| 1897 | 1,073 | 1911 | 7,117 | 1925 | 17,319 | | |
| 1898 | 1,098 | 1912 | 7,459 | 1926 | 18,158 | | |

in table V is not directly comparable with the others since it represents only a 9-month period, but the same figure for the same period last year was 608, which indicates a definite trend.

Table VII shows the percentage of fully paid membership to be within less than 1 per cent of the highest figure ever recorded. An increase of 2.6 per cent over last year should give additional encouragement to the members.

Table VIII gives an interesting record of the Institute's growth since its founding in 1884.

## Deaths

The following deaths occurred during the year:

*Honorary Members:* Elihu Thomson, Edward Weston.

*Fellows:* James R. C. Armstrong, Charles L. Fortescue, William D. Gherky, Stephen Q. Hayes, Halbert P. Hill, William B. Jackson, Samuel M. Kintner, Frank A. Laws, Edward B. Meyer, D. McFarlan Moore, George R. Murphy, Louis C. Nichols, Louis F. Reinhard, Albert S. Richey, Robert A. Ross, Frederick A. Scheffler, George C. Shaad, Arthur Williams, Fremont Wilson.

*Members:* Clinton J. Axtell, Allan Cunningham, Frederick S. Cutting, William A. E. Doying, Albert G. T. Goodwin, William K. Hale, Charles E. Hebbert, William A. Hillebrand, Joseph D. Israel, Hamilton McR. Jones, Philip A. Lang, Adolf J. Lobeck, Meldon H. Merrill, Elam Miller, Henry A. Morss, Robert E. Orr, Hugh Pattison, Albert T. Perkins, Arthur J. Ralph, Crandall Z. Rosencrans, Lester R. Sailer, John A. Sirnit, Guy S. Turner, William S. Twining, William F. White, Russell A. Yerxa.

*Associates:* Eugene L. Alexander, Alfred Alsaker, James D. Andrew, Walter E. Bare, Frederick H. Barrington, Irving F. Day, Burton L. Delack, William H. Dieringer, John C. Dolph, Francis E. Donohoe, William G. Ely, Paul Engleheart, William H. R. Fraser, Harry W. Fuller, Nicholas S. Hill, John Jenkinson, Ed. C. Jerman, David H. Kelly, Edgar Knowlton, Edward F. Lawton, Robert Lundell, Frank G. McRae, Julius Meyer, Jesse B. Millard, Thomas E. Penard, John W. Purcell, John A. Rockwood, A. W. Russell, Charles J. Russell, Thomas Spencer, Harry B. Thayer, Carroll Thomas, Earle Lamar Tyler, Hugo Vecera, Francis R. Welles, Charles V. Woodward.

## Board of Examiners

The board of examiners held 10 meetings during the past year, averaging about $2^1/_2$ hours each, and considered 3,787 cases, divided as shown in table IX.

## Standards Committee

The activities of the standards committee for the past year reflect the general upturn in the engineering field with increased interest in standardization activities. The AIEE committees, as well as the sectional committees under the American Standards Association, have been extremely active. Much of this activity has had to do with needed revisions and suggested further development of existing standards.

For instance, the AIEE committee on applications to marine work is preparing an extensive revision of Standard No. 45, "Recommended Practise for Electrical Installations on Shipboard" (Marine Rules). These rules have been in general use without change since 1930. The committee on protective devices submitted to the standards committee 2 reports, one dealing with a proposed revision of "Oil Circuit Breaker Standards," No. 19, now before a sectional committee working under ASA procedure, and the other a new project, "Fuses Above 600 Volts." Both were ordered printed and circulated in report form.

The AIEE committee on instruments and measurements presented a report giving latest revised data on sphere-gap spark-over voltages. This was published by order of the standards committee in ELECTRICAL ENGINEERING so that it might become generally available. Eventually, these data will be included in a general revision, now being developed by the same committee, of Standard No. 4, "Measurement of Test Voltages in Dielectric Tests."

Renewed activities in the development of the test code

### Table IX. Applications for Admission and Transfer

| | | |
|---|---|---|
| **Applications for Admission** | | |
| Recommended for grade of Associate | 1,077 | |
| Re-elected to the grade of Associate | 112 | |
| Not recommended | 3 | 1,192 |
| Recommended for grade of Member | 113 | |
| Re-elected to the grade of Member | 20 | |
| Not recommended | 38 | 171 |
| Recommended for grade of Fellow | 3 | |
| Re-elected to the grade of Fellow | 1 | |
| Not recommended | | 4 |
| **Applications for Transfer** | | |
| Recommended for grade of Member | 167 | |
| Not recommended | 27 | 194 |
| Recommended for grade of Fellow | 24 | |
| Not recommended | 2 | 26 |
| **Students** | | |
| Recommended for enrollment as Students | | 2,200 |
| Total | | 3,787 |

series have also taken place during the past year. An informal session was held during last winter's convention for the discussion of the codes. As a result a revised edition of both the synchronous and the induction machines codes will be issued, and a new code added to the series on d-c machines. The standards committee delegated to the committee on instruments and measurements the development of a code for measurements. Likewise the subcommittee on sound has offered for approval a "Code for Apparatus Noise Measurement."

Many of the ASA sectional committees on which the Institute has representation have been similarly increasingly active. The sectional committee on transformers is about to issue a very complete report on transformers. This will embody not only the revised and enlarged standards themselves, but will include as appendices, the test code and guides for operation of transformers. The sectional committee covering graphical symbols, letter symbols, and abbreviations, has been completely reorganized and is now revising the standards developed by its predecessor. The sectional committee on insulated wires and cables is about ready to issue a series of both revised standards and new ones. These represent only a few of the active sectional committees.

The Institute's co-operation through the standards committee was sought in several general fields. An appointment was made of a representative on a research committee on grounding to study the whole situation. Representation was also had on a committee on radio-electrical co-ordination, a field whose scope and possibilities will require much careful co-operative study and co-ordination work. The most recent development was the committee on international standardization of photometric units to which appointment was made on invitation of the National Bureau of Standards.

It might be well to point out in closing that there seems to be a general tendency under ASA procedure for sectional committees to issue reports in which are combined not only standards, but much related material. This is of particular interest from a historical viewpoint. When development was proposed by the Institute of codes and operating recommendations in particular much opposition was incurred and argument offered opposing such activity. Finally, approval was obtained on the basis that such reports when issued must be entirely distinct from the accepted standards. Evidently, a better understanding of the subject matter has eliminated opposition to such projects.

## U.S. National Committee of the IEC

The past year has been an active one for the International Electrotechnical Commission for a year in which no plenary meeting has been held. The commission has been saddened by the deaths of two of its honorary presidents, Professor Elihu Thomson and Professor Paul Janet of France. The loss sustained by these 2 deaths will not be easily forgotten.

Meetings of advisory committees as follows were held during the year: storage batteries—number 21, aluminum—number 7, radio communication—number 12, electrical installations on shipboard—number 18, and international electrotechnical vocabulary—number 1. In addition, the international special committee on radio interference held a meeting.

President Burke has continued to devote his attention to the financial affairs of the commission, so that the commission ended its fiscal year on January 1 in the most favorable financial position which it has enjoyed for a number of years.

Meetings of the following advisory committees will be held in Paris June 17–23, 1937:

Rating of electrical machinery, transformer section only—number 2

Standard voltages and currents and high voltage insulators—number 8

Electric traction equipment—number 9

Electrical measuring instruments—number 13

It is expected that the U.S. national committee will be represented at these meetings by a good delegation, which will be headed by President Sharp. In addition, there will be held in Paris, June 30 to July 3, an international conference on acoustics. The purpose of this meeting will be to make plans as to the handling of a comprehensive program of standardization in the acoustic field. The conference will be held under the auspices of the IEC, but it is not yet certain as to how the international acoustical work will be set up. The work originally was proposed to the IEC by the international consultative committee on telephony (CCIF), and it is now contemplated that the work will include definitions, units, notations, graphical symbols, methods of measurement and measuring apparatus, including noise meters, electrotechnical acoustics, recording transmission and reproduction of sound (except telephony), architectural acoustics, noise abatement, etc. Acoustical work in the United States is well advanced, 3 important standards in the field having been approved as American standards. The sectional committee in charge of the work is a most authoritative and representative body. The U.S. national committee is accordingly in an excellent position to take care of this work on behalf of American industry. The U.S. national committee will be represented at the meetings by President Sharp, Doctor Harvey Fletcher, and probably others.

The following reports of progress in specific technical projects will be of interest:

INTERNATIONAL ELECTROTECHNICAL VOCABULARY—NUMBER 1

This work was undertaken by the IEC soon after its formation in 1904. It has now progressed to the point where it is planned to publish the first edition during 1937. The vocabulary will contain over 2,000 scientific and industrial terms used in the various branches of electrotechnics. The terms are given in both English and French, and translations of the title are given in German, Italian, Spanish, and Esperanto.

The whole work is divided into 14 sections, the first of which covers fundamental and general definitions. The others more specifically deal with: machines and transformers; switchgear and control gear; apparatus for scientific and industrial measurements; generation, transmission, distribution; electrical traction; power applications; thermic applications; lighting; electrochemistry; telegraphy, telephony; radiology; electrobiology.

While the committee developing this "International Vocabulary" appreciates that it does not constitute a complete unification of electrotechnical nomenclature, it believes that through periodic review and revision based on the constructive criticism of electricians of the world, it should become increasingly valuable to engineers.

As the edition will be limited, copies should be reserved at once by writing to the U.S. national committee of the International Electrotechnical Commission at 29 West 39th Street, New York. The price of the "Vocabulary" will be about $2.50.

STEAM TURBINES—NUMBER 5

The secretariat for this project is held by the U.S. national committee, and during the year they prepared an appendix to IEC Publication No. 46, "Rules for Acceptance Tests for Steam Turbines —Supplementary Notes to Section 4, Instruments and Methods of Measurement," which was sent to the central office during the year for circulation for final approval under the 6-months rule. Active work is now going forward on expanding the rules to cover non-condensing back pressure extraction and mixed pressure turbines.

INSULATING OILS—NUMBER 10

The U.S. national committee appointed a representative on an international subcommittee to draw up an ideal testing procedure for determining the sludging properties of insulating oil. This work is going forward.

TERMINAL MARKINGS—NUMBER 16

During the year the American standard on rotation, connections and terminal markings for electric power apparatus was approved and printed. This document has been transmitted to the central office to become the American part of the international specifications for terminal markings.

SWITCHGEAR—NUMBER 17

During the year the draft IEC specification for a-c circuit breakers was studied by the U.S. national committee, and approved for service as an international standard. It is expected that the revised edition will be published shortly. During the year IEC Publication No. 54 ("IEC recommendations for standard direction of motion of operating devices and for indicating lamps for circuit breakers") appeared in printed form.

ELECTRIC CABLES—NUMBER 20

During the year IEC specifications for tests on impregnated-paper-insulated lead-covered cables having voltages from 10 kv to 66 kv were considered and discussed. The U.S. national committee had technical objections to these rules, and voted against their issuance. However, these objections were withdrawn with the understanding that an immediate revision of the rules would be undertaken.

The next plenary meeting of the International Electrotechnical Commission is scheduled to be held in England, June 1938.

## Committee on Safety Codes

The committee submitted proposals for expanding the scope of its activities in order that it might study technical and engineering problems in connection with the safer use of electricity. The present by-laws limit the committee to matters connected with safety codes which for years have been handled by other organizations. After consideration by the Institute policy committee and the board, no formal action was taken on the proposal for enlarged scope. However, the board is interested in the possibility that the Institute within its proper scope may make further contributions to the cause of safety and has invited the committee on safety codes to make further suggestions to this end. The committee is preparing to comply with the board's invitation in the immediate future.

The chairman of the committee on safety codes, as the AIEE representative, attended the annual meeting of the electrical committee of the National Fire Protection Association. At this meeting the biennial revision of the national electrical code was made.

The chairman represents the Institute on the committee on low voltage hazards of the National Safety Council but was called upon for no action during the past year.

The chairman attended the annual meeting of the National Fire Waste Council in Washington. Little of electrical engineering interest is considered at these meetings.

## Co-ordination Committee

The committee followed the established practice of requesting District and Section officers to submit by January 1 applications for the authorization of any national conventions and District meetings desired in their respective Districts during the calendar year 1938, and a recommended schedule of such meetings has been presented to the board of directors and approved.

## Institute Policy Committee

The Institute policy committee has considered and reported upon 2 broad questions referred to it by the board of directors.

The first of these was the question of the possible enlargement of the scope of the committee on safety codes. A report was submitted to the board of directors generally endorsing the proposal and suggesting a review with specific suggestions from the committee itself.

The committee has also reported to the board of directors on the recommendation of the committee on research that the Institute contribute financially to the support of such researches as the Institute may recommend, under its sponsorship, to the Engineering Foundation. An extensive study was made of this question, and a report was submitted to the board of directors indicating a divided opinion within the committee, and the consequent inability to make a recommendation either for or against the proposal.

Two resolutions submitted to the board of directors, one proposing the establishment of the office of executive vice-president, and the other proposing an additional man, for further development of the work of the Institute committees, to be added to the staff of the national secretary, have been referred to this committee and are now under examination.

## Special Committee to Consider Dues of Associates and Related Matters

A final report of this committee was presented to the board of directors recommending no changes in the present

rules and dues. This was received and approved and the committee discharged.

## Committee on Code of Principles of Professional Conduct

During the year a number of points were raised by nonmembers of the committee and these points were presented by letter to the committee members. In no case has any member of the committee urged that any change be made in the present code of principles of professional conduct.

## Committee on Constitution and By-Laws

This committee had no meetings, as no matters had been referred to it until in the latter part of the year, when it was requested to consider several proposed amendments to the constitution and by-laws of the Institute.

## Committee on Economic Status of the Engineer

The committee has conducted a somewhat limited but pertinent study of the economic status of the engineer as it affects his ability to earn an income commensurate with his needs and his value to the welfare of mankind. This study has disclosed much information in reports made by various organizations interested in education. It is hoped a further study of these data will confirm the impression that in general engineers have "weathered" the depression pretty well.

This committee recommends activity on the part of engineers in seeking channels other than the AIEE through which they may take active part in educating the public regarding affairs of significance to our economic welfare which involve engineering works. For further information on this point, attention is called to the papers obtained by the special committee on Institute activities which will be presented and discussed at the summer convention.

## Committee on Award of Institute Prizes

Five national prizes and 13 District prizes for Institute papers presented in 1935 were awarded to the authors. These awards were announced in the 1936 issues of ELECTRICAL ENGINEERING for June and July.

The committee has made a careful study of a number of suggestions for changes in the rules for the award of Institute prizes. As a result they have recommended certain changes which have been adopted by the board of directors. These changes provide that in the future the national prize for Branch papers shall be based upon the college year, i.e., July 1 to June 30 inclusive, rather than the calendar year as at present. They also provide for a District prize for graduate student papers. A revised issue of the rules for the award of prizes including these changes is now being printed.

## Committee on Award of Columbia University Scholarships

By arrangement with Columbia University, this committee of the AIEE has the privilege of awarding each year a scholarship in electrical engineering for each class, the amount covering the annual tuition fees of $380.

As a result of improving business conditions, no definite application for the scholarship for the academic year 1936–37 was received.

## Edison Medal

The Edison Medal, which is awarded by a committee composed of 24 members of the Institute, was, for 1936, awarded to Doctor Alex Dow for "outstanding leadership in the development of the central station industry and its service to the public," and was presented on January 27, 1937, during the winter convention. The medal may be awarded annually "for meritorious achievement in electrical science, electrical engineering, or the electrical arts."

## John Fritz Medal

The John Fritz Medal board of award, composed of representatives of the national societies of civil, mining, mechanical, and electrical engineers, awarded the thirty-third medal (for 1937) to Arthur Newell Talbot, professor emeritus of engineering, University of Illinois, who was cited as "moulder of men, eminent consultant on engineering projects, leader of research, and outstanding educator in civil engineering."

## Lamme Medal

The Lamme Medal committee awarded the medal for 1936 to Doctor Frank Conrad "for his pioneering and basic developments in the fields of electric metering and protective systems." Arrangements are being made for the presentation of the medal at the annual summer convention at Milwaukee, Wis., June 21–25, 1937. The medal may be awarded annually to a member of the AIEE "who has shown meritorious achievement in the development of electrical apparatus or machinery."

## Alfred Noble Prize

This prize, established in 1929, consists of a certificate and a cash award of $500 from the income from a fund contributed by engineers and others to perpetuate the name and achievements of Alfred Noble, past-president of the ASCE and of the Western Society of Engineers. It may be made to a member of any of the co-operating societies, ASCE, AIME, ASME, AIEE, or WSE, for a technical paper of particular merit accepted by the publication committee of any of these societies, provided the author, at the time of such acceptance, is not over 30 years of age. The award for 1936 was presented to Abe Tilles, instructor in electrical engineering at the University of California, Berkeley.

## Washington Award

The Washington Award for 1937 was bestowed upon Doctor Frederick Gardner Cottrell, "for his social vision in dedicating to the perpetuation of research the rewards of his achievements in science and engineering," and was presented to him on February 23, 1937. This award may be made annually to an engineer by the commission of award composed of 9 representatives of the Western Society of Engineers and 2 each of the American Society of Civil Engineers, American Institute of Mining and Metallurgical Engineers, American Society of Mechanical Engineers, and AIEE.

## Iwadare Foundation Committee

The fifth lecturer to visit Japan was Doctor Edwin H. Colpitts, who has just retired from his position as executive vice-president of Bell Telephone Laboratories, Inc. Doctor Colpitts sailed from San Francisco on March 4 last and planned to be in Japan throughout the month of April. He gave 3 different lectures: "Organized Scientific Research in Bell Telephone Laboratories," "Recent Trends in Toll Transmission in the United States," and "Scientific Research Applied to the Telephone Transmitter and Receiver."

## Employment Service

The Institute co-operates with the national societies of civil, mining, and mechanical engineers in operation of the Engineering Societies Employment Service with its main office in the Engineering Societies Building, New York. Offices are operated in Chicago and San Francisco also. In addition to the societies named, others co-operate in certain of the offices as follows: New York—Society of Naval Architects and Marine Engineers; Chicago—Western Society of Engineers; San Francisco—California Section of the American Chemical Society; and the Engineers' Club of San Francisco.

The service is supported by the joint contributions of the societies and their individual members who are benefited. In addition to the publication of the employment service announcements monthly in ELECTRICAL ENGINEERING, weekly subscription bulletins are issued for those seeking positions.

An analysis of this employment service as reported to the national societies is given in table X.

## American Engineering Council

The American Engineering Council has continued its activities in the wide range of affairs which are found within the scope of its objectives: "to further the public welfare wherever technical and engineering knowledge and experience are involved, and to consider and act upon matters of common concern to the engineering and allied technical professions," and within the interests of its many member-bodies.

The work of Council has, during the past year, been carried on by 4 groups of committees:

1. Public affairs
2. Engineering-economics
3. United action of member organizations
4. AEC operating

Some of the principal actions taken by the assembly at its annual meeting held January 15 and 16, 1937, provide for:

1. Efforts to encourage the completion of the basic mapping program of the United States.
2. Continued support of efforts which will bring about ultimate unification of engineering in public works activities.
3. Support of the proposed plan for a single court of patent appeals, and opposition to the various proposals which would restrict the freedom of owners of patents.
4. Initiative to be taken by Council in the formation of co-operative relations between its staff and committees and representative groups in economics and social science to enable the engineering profession to make its proper contributions to the consideration and solution of problems in these broader fields.
5. Study by the executive committee of the possibility of developing and carrying out a broad educational program to encourage rural electrification.

A conference of secretaries of engineering societies was held under the sponsorship of Council on January 14, and was attended by secretaries of about 30 national, state, and local organizations.

A committee of Council has continued to confer with representatives of the Bureau of Labor Statistics regarding the contents of the report upon the 1935 survey of the engineering profession. Three articles have been published. A detailed report of the survey will be published later by the bureau.

Council appointed an advisory committee to co-operate with the Lewis Historical Publishing Company in connection with preparations for a new edition of "Who's Who in Engineering."

More detailed information regarding the work of Council has been published frequently in ELECTRICAL ENGINEERING.

**Table X. Analysis of Employment Service**

| Month | Men Registered | | | | Men Placed | | | |
|---|---|---|---|---|---|---|---|---|
| | New York | Chicago | San Francisco | Total | New York | Chicago | San Francisco | Total |
| 1936 | | | | | | | | |
| May | 186 | 61 | 71 | 318 | 46 | 31 | 32 | 109 |
| June | 228 | 113 | 73 | 414 | 48 | 23 | 22 | 93 |
| July | 154 | 60 | 66 | 280 | 47 | 41 | 35 | 123 |
| August | 114 | 35 | 58 | 207 | 51 | 39 | 33 | 123 |
| September | 125 | 82 | 57 | 264 | 60 | 36 | 26 | 122 |
| October | 125 | 49 | 67 | 241 | 51 | 30 | 27 | 108 |
| November | 128 | 37 | 39 | 204 | 57 | 36 | 27 | 120 |
| December | 115 | 65 | 44 | 224 | 64 | 36 | 24 | 124 |
| 1937 | | | | | | | | |
| January | 197 | 48 | 69 | 314 | 72 | 36 | 32 | 140 |

| March | 346 | 107 | 109 | 562 | 65 | 33 | 41 | 139 |
| April | 475 | 94 | 78 | 647 | 54 | 40 | 25 | 119 |
| Total | 2,475 | 834 | 793 | 4,102 | 665 | 417 | 350 | 1,432 |

## United Engineering Trustees, Inc.

This organization, as an agency of the founder societies, made further improvements in the Engineering Societies Building, including the redecoration of the rooms occupied by the library and improvements in elevator equipment and service, and presented a plan for resuming payments to the depreciation and renewal fund of the building. Much consideration has been given to investment problems in order to secure the maximum income consistent with safety of principal.

The UET continued as treasurer of the Engineers' Council for Professional Development.

An abstract of the annual report of the United Engineering Trustees, Inc., was published in ELECTRICAL ENGINEERING for December, 1936, pages 1400–01.

## Engineering Foundation

The Engineering Foundation suffered a serious loss in the death of its director, Doctor Alfred D. Flinn, on March 14, 1937.

During 1936, the Foundation supplied financial support for many research projects sponsored by the founder societies, notably the following: ASCE—earths and foundations; AIME—alloys of iron and barodynamic studies; ASME—cottonseed processing, cutting fluids, critical pressure steam boilers, fluid meters, boiler feed water, strength of gear teeth, "Cutting of Metals" handbook; AIEE—welding with pure iron electrodes (terminated on September 30, 1936) and comprehensive program under supervision of the welding research committee sponsored by the AIEE and the American Welding Society, with the co-operation of industries.

The Foundation also assisted in studies of the plastic flow of concrete at the University of California, and the plasticity of metals at the University of Pittsburgh.

It continued to assist the Engineers' Council for Professional Development and the Personnel Research Federation.

An abstract of the annual report of the Engineering Foundation was published in the December 1936 issue of ELECTRICAL ENGINEERING, pages 1401–02.

## Engineering Societies Library

The Engineering Societies Library, which was formed by combining the separate libraries of the 4 national societies of civil, mining and metallurgical, mechanical, and electrical engineers, and the preparation of a composite card catalog, has been expanded as a single engineering library, which probably constitutes the best collection of this type of literature in the country.

On September 30, 1936, the library had 138,742 volumes, 7,246 maps, and 4,298 bibliographies. Books, pamphlets, and maps totaling 12,148 were received during the year ending at that time. Current issues of 1,358 periodicals were received. Work progressed rapidly on a classified index to periodicals, and the index now contains more than 150,000 references to articles published since 1927.

Special services rendered by the library include: photoprints, searches, abstracts, translations, bibliographies, book loans by mail, etc.

An abstract of the annual report of the library was published on page 1402 of ELECTRICAL ENGINEERING for December 1936.

## Engineers' Council for Professional Development

This council, which was formally organized in 1932 for the enhancement of the professional status of the engineer, includes 3 representatives of each of the 7 participating organizations: the national societies of chemical, civil, electrical, mechanical, and mining and metallurgical engineers, the Society for the Promotion of Engineering Education, and the National Council of State Boards of Engineering Examiners.

The principal activities of ECPD include the guidance of young individuals thinking of entering the engineering field, the accrediting of engineering schools, encouragement and assistance to individuals continuing their engineering and cultural training during several years after graduation, and the establishment of suitable standards for indicating the attainment of the status of an engineer.

Actions were taken, at the annual meeting in October 1936, upon curricula of 39 institutions in regions I and II, and a list of accredited curricula in those regions was issued soon afterward. Actions upon curricula of a few additional institutions were taken on April 23, 1937. Consideration of engineering curricula throughout the remainder of the country is proceeding rapidly in preparation for actions at the annual meeting in October 1937.

The committe on professional training selected a few cities in which conditions seemed especially favorable for the establishment of operating programs for assisting junior engineers in their self-development. Excellent progress was made in Providence through the leadership of the Providence Engineering Society.

Detailed information regarding the recommendations submitted by ECPD to the participating organizations and other features of its activities were published during the year in numerous issues of ELECTRICAL ENGINEERING.

## Representatives

The Institute has continued its representation upon many joint committees and national bodies, with which it co-operates in a wide range of activities of interest and importance to engineers and others.

A complete list of representatives was published in the

September 1936 issue of ELECTRICAL ENGINEERING and in the 1937 Year Book.

## Finance Committee

The committee, as usual, recommended a detailed budget to the board of directors, passed upon the expenditures for various purposes, made recommendations regarding delinquent members, and performed the other duties prescribed for it in the constitution and by-laws.

Haskins and Sells, certified public accountants, have audited the books, and their report follows.

Respectfully submitted for the board of directors.

H. H. HENLINE,
*National Secretary*

May 24, 1937

HASKINS & SELLS
CERTIFIED PUBLIC ACCOUNTANTS

22 EAST 40TH STREET
NEW YORK

May 21, 1937

American Institute of Electrical Engineers,
33 West 39th Street,
New York.

Dear Sirs:

We have made an examination of your balance sheet as of April 30, 1937, and of your recorded cash receipts and disbursements for the year ended that date. In connection therewith, we examined or tested your accounting records and other supporting evidence in a manner and to the extent which we considered appropriate in view of your system of internal accounting control. We present the following financial statements:

Balance Sheet, April 30, 1937 (Exhibit A).
Property and Restricted Funds Securities, Less Reserve for Bonds of Doubtful Value (Schedule 1).

Statement of Recorded Cash Receipts and Disbursements of General Fund for the Year Ended April 30, 1937 (Exhibit B).

Statement of Recorded Cash Receipts and Disbursements of Property and Restricted Funds for the Year Ended April 30, 1937 (Exhibit C).

In accordance with the terms of our engagement, members and other debtors were not requested to confirm to us the amounts receivable from them at April 30, 1937, and, in accordance with the usual practice of the Institute, no provision has been made for dues which may prove to be uncollectible.

In our opinion, based upon such examination and subject to the foregoing, the accompanying Exhibit A fairly presents your financial condition at April 30, 1937, and the accompanying Exhibits B and C set forth your recorded cash receipts and your disbursements of funds, as indicated, for the year ended that date.

Yours truly,

HASKINS & SELLS

---

## AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS

# A New Photoelectric Hysteresigraph

By R. F. EDGAR
ASSOCIATE AIEE

## Introduction

GRAPHICAL RECORDING of hysteresis loops or magnetization curves by means of a hysteresigraph is in many instances a much more convenient way of obtaining desired magnetic data than is the usual ballistic method. Unsymmetrical hysteresis loops, for example, may require considerable laborious procedure if obtained in the usual manner, but are easily recorded by some types of hysteresigraphs. The photoelectric hysteresigraph described herein is an instrument which readily records initial magnetization curves or any desired symmetrical or unsymmetrical hysteresis loops.

Several different forms of hysteresigraphs have been described. They are of 2 general types, depending upon whether the test specimen is magnetized by alternating current or by direct current. An a-c hysteresigraph may employ a cathode-ray oscillograph arranged in such a manner that the horizontal deflection of the electron beam is made proportional to magnetizing force while the vertical deflection is made proportional to induction.[1] Other types of a-c hysteresigraphs also have been described.[2,3] Eddy currents within the specimen tend to distort the shape of the recorded hysteresis loop, making laminated specimens necessary. A–c hysteresigraphs record only cyclic loops. Usually symmetrical loops are recorded, but minor or unsymmetrical loops may be obtained if the power supply furnishing the magnetizing current can be arranged to introduce current of suitable harmonic frequency superimposed upon the fundamental component of the magnetizing current. A-c hysteresigraphs appear to have been applied principally to testing sheet materials of low loss and high permeability.

An early form of cathode-ray tube hysteresigraph,[4] and a magnetic curve tracer described by Ewing,[5] may be used to obtain either cyclic a-c loops or d-c loops formed by slowly varying the magnetizing current through the desired cycles. In these devices part of the magnetic circuit is through air, and the strength of the magnetic field in the air path is measured as an indication of the induction in the specimen while the magnetizing current is taken as a measure of magnetizing force. Introduction of an air gap in the magnetic circuit, however, tends to prevent uniform magnetization of the specimen with resulting errors in the measurement of both induction and magnetizing force. A recent magnetic curve tracer [6] obtains d-c loops and is applicable to the testing of specimens in a closed magnetic circuit. It employs a search coil interlinking the specimen and a fluxmeter having its restoring torque automatically counterbalanced throughout its range of deflection so that it is accurately responsive to slow flux changes.

D-c hysteresigraphs do not require laminated specimens because the desired cycle of magnetization may be carried out so slowly that eddy currents do not become large enough to affect the results even if solid specimens are used. Initial magnetization curves and unsymmetrical hysteresis loops, as well as symmetrical hysteresis loops may be obtained. Besides being applicable to the testing of electrical sheet steels the d-c hysteresigraph may also be used in testing magnet materials, specimens of which are commonly solid rather than laminated.

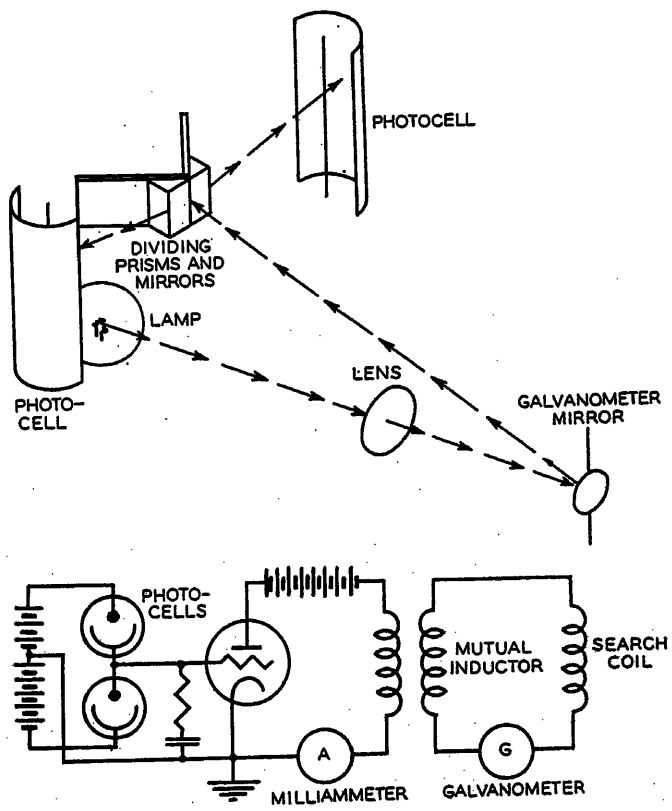

**Figure 1. Optical system and electrical circuit for photoelectric fluxmeter**

## Description

The hysteresigraph described herein is a d-c instrument which may be used to test either laminated or solid specimens in ring or bar form. For bar specimens it is connected to a permeameter in the same manner as the common ballistic galvanometer equipment. When used with the saturation permeameter [7] measurements may be made to a mag-

A paper recommended for publication by the AIEE committee on instruments and measurements. Manuscript submitted March 25, 1937; released for publication May 3, 1937.

R. F. EDGAR is employed in the general engineering laboratory of the General Electric Company, Schenectady, N. Y.

1. For all numbered references, see list at end of paper.

netizing force of 3,000 oersteds or higher. The equipment is sturdy and does not employ any delicate instruments which require careful handling, fine adjustment, or special mounting.

## The Photoelectric Fluxmeter

The heart of the instrument is a photoelectric fluxmeter[8] which is responsive to slow changes in flux linking a search coil, and provides an indication which remains constant without drift as long as the flux linking the search coil remains constant. Elementary diagrams of the fluxmeter are shown in figure 1. A galvanometer and search coil are used, and in series with them is connected the secondary coil of a mutual inductor. By means of an optical system and 2 photoelectric cells connected in a vacuum-tube circuit the galvanometer deflection is maintained at zero, the current in the primary coil of the mutual inductor being automatically varied so as to induce a voltage in the secondary coil equal and opposite to any voltage which may be induced in the search coil by a change of flux interlinking it. The change of interlinkage in the secondary coil caused by the change in primary current is then equal and opposite to the change of interlinkage in the search coil. The variation in primary current is, therefore, a measure of the flux variation in the search coil. Since the galvanometer remains at the zero position its suspension torque does not act to cause drift, and the primary current varies only when the flux linkage in the search coil varies.

The optical system and electrical circuit is adapted from the photoelectric recorder.[9] The beam from the galvanometer mirror is focused upon a set of mirrors and prisms which divides it into 2 parts and reflects each part into a photocell. Deflection of the galvanometer causes the light in one cell to increase and that in the other to diminish. The 2 photocells are connected in series with a voltage source, and to the grid of a vacuum tube in such a way that any unbalance of the divided light beam between the 2 cells causes a change in the grid voltage with a resultant change in plate current. The plate current, supplied by a second voltage source, flows in the primary coil of the above-mentioned mutual inductor. The direction of current flow is such that any change caused by a deflection of the galvanometer light beam causes a change of flux linking the secondary coil of the mutual inductor, tending to correct the galvanometer deflection and restore the orginal light balance.

A slight deflection of the galvanometer is evidently necessary to initiate the corrective change of plate current. This, however, is very small, and the final position when a new balance is restored is almost exactly the same as the original position. The photocells are of the vacuum type and are operated at a high voltage so that the current through them depends upon the light falling upon them and is nearly independent of voltage variation. The current for any constant value of grid voltage must be the same in both photocells, since they are in series, and any difference in current would necessarily alter the charge on the grid capacitor and change the grid voltage. The light division between the 2 cells must, therefore, be the same also, which means that the final position of the galvanometer beam must be the same for all steady values of flux linking the search coil. This was demonstrated in the development of the apparatus by setting up in place of the galvanometer a pivoted rod carrying a galvanometer mirror and having an arm 50 centimeters long projecting at right angles. The outer end of the arm was held lightly against the screw of a rigidly mounted micrometer. Turning the micrometer screw caused the end of the arm to move, rotating the mirror as it would rotate if mounted in the usual manner in a galvanometer. It was found that a motion at the outer end of the arm of 0.001 centimeter was sufficient to change the plate current of the tube from one extreme to the other. This corresponds to a light beam deflection of 0.0008 centimeter at the dividing prisms, and would be equivalent to a deflection of 0.004 centimeter on a scale set up at the customary meter distance.

Angular movement of the galvanometer coil equivalent to 0.001 centimeter deflection at the end of a 50 centimeter arm causes an interlinkage change in the galvanometer coil of about 30 maxwell-turns with the coil and field strength employed. In practice the galvanometer is used without any external shunt or series resistance, but is connected directly to the search coil and mutual inductor secondary winding. Since the total number of interlinkages in a circuit tends to remain constant, the difference between the change of flux linkages in the secondary coil of the mutual inductor and that in the search coil is about equal to that in the galvanometer coil. This difference is, therefore, about 30 maxwell-turns for a full-range change in the search coil. With the tube used in this test, the full-range change of plate current was

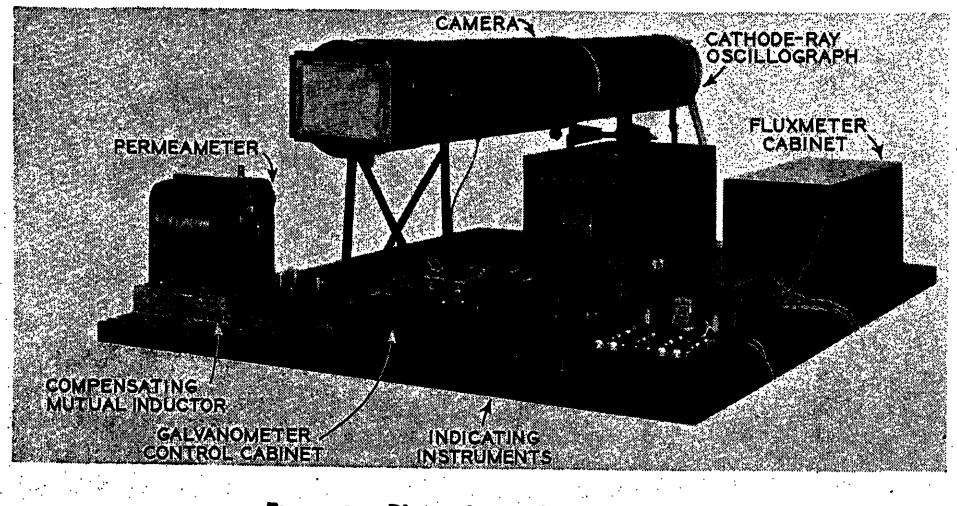

**Figure 2. Photoelectric hysteresigraph**

about 27 milliamperes. A mutual inductor of $10^7$ secondary maxwell-turns per primary ampere is used, so that full-range change of flux linkages was about 270,000 maxwell-turns. The difference between the actual change of interlinkage in the search coil and that indicated by the change in plate current through the primary winding of the mutual inductor is then about 0.0011 per cent. The tube has since been changed to a type which permits a larger change of plate current and has a higher mutual conductance so that the present figure is somewhat less.

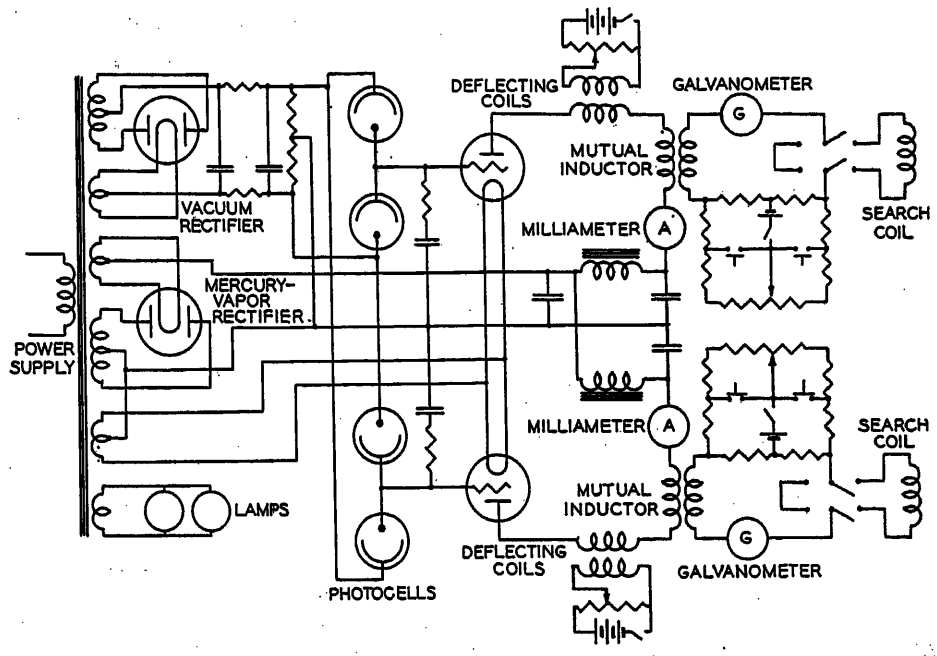

**Figure 3. Photoelectric hysteresigraph circuit diagram**

The amount of deflection during the flux change depends upon the rapidity of the flux change, the constants of the grid and plate circuits, and the characteristics of the galvanometer and its circuit. When the apparatus is used merely as an indicating fluxmeter this deflection is not important, since it returns to the small equilibrium value when the instrument indication becomes steady and can be read. It is necessary only that the deflection be small enough so that there is not sufficient suspension restoring torque to cause measurable drift during the flux change.

For use in automatic curve tracing, however, it is necessary that the current in the primary coil of the mutual inductor shall change accurately in agreement with the changing of interlinkages in the search coil. There must be no measurable lag between them. The galvanometer coil must have sufficiently low inertia to quickly begin to deflect and initiate a corrective change in the plate current when there is a change in interlinkages in the search coil. The capacitance in the grid circuit must be low enough so that the grid voltage quickly changes when there is an unbalance in the photocell circuit. The inductance in the plate circuit must be low enough to permit quick changes of plate current. It has been found that a portable reflecting galvanometer is entirely satisfactory, and no difficulty is experienced in making the constants of the circuits correct for accurate response to slow changes of interlinkage.

The accuracy of the measurement is not affected by small changes in supply voltage, vacuum-tube characteristics, photocell sensitivity, or light intensity. The optical system and photoelectric circuit are similar to those of the photoelectric recorder in being self-compensating for all normal changes in these variables.

The photoelectric fluxmeter is equivalent to a galvanometer of infinitely long period, in that it responds accurately to slow flux changes and its indication remains constant at any part of the range without drift. Moreover, the output of the instrument, instead of being merely deflection of a light beam on a scale, is in the form of electric current of sufficient power to operate sturdy and relatively insensitive indicating instruments or recording devices.

## The Hysteresigraph

The photoelectric hysteresigraph as illustrated in figure 2 consists of 2 such fluxmeters combined with a cathode-ray oscillograph. Magnetic deflection coils fitted to the oscillograph tube are connected in the plate circuits of the fluxmeters so that one fluxmeter causes vertical deflection of the electron beam and the other causes horizontal deflection. The search coil of the first fluxmeter is linked by the specimen under test and that of the second lies adjacent to the specimen but is not linked by it,[7] so that one fluxmeter measures induction changes and the other magnetizing force changes. Bar or strip specimens may be tested at high magnetizing force in the saturation permeameter. The hysteresigraph is adaptable to any type of permeameter in which the magnetizing force can be measured by means of a search coil as described, but which requires no varying compensating adjustment over the range of test. Ring specimens may be tested by using only one fluxmeter, a portion of the magnetizing current being passed directly through the horizontal deflection coils.

The circuit diagram for the hysteresigraph is shown in figure 3. It is similar to that of figure 1, the batteries being replaced by rectified a-c power sources, and 2 complete fluxmeters being provided. A small dry cell with fixed and variable resistors in each galvanometer circuit provide a means of balancing out any small thermoelectric or other voltage which may be present. Push buttons in this circuit facilitate shifting the plate current at will so

that it can be set at any desired value for the beginning of a test, and switches enable the search coils to be inserted in or removed from the circuit.

Figure 4 shows the arrangement of galvanometers, photocells, optical system, and vacuum tubes for both fluxmeters in one cabinet. Transformers, capacitors, and wiring are mounted on the under side of the subbase. The galvanometers are of the portable type[10] having sturdy suspensions and require no careful leveling or delicate adjustment. Moving systems of relatively low resistance are used. Stops are provided limiting the deflection to a small angle and preventing the beam from being thrown entirely off the dividing mirrors at any time. The light beams are supplied by 32-candlepower 6-volt automobile headlight bulbs in ventilated housings, and convex lenses in adjustable tubes. The photocells and prisms are enclosed in housings which prevent entrance of stray light. Voltage is supplied to the photocells by a vacuum rectifier tube through a resistance-capacitance filter circuit. Power is supplied to the plate circuits by a mercury-vapor rectifier tube having a low voltage drop, and a filter circuit of inductance and capacitance.

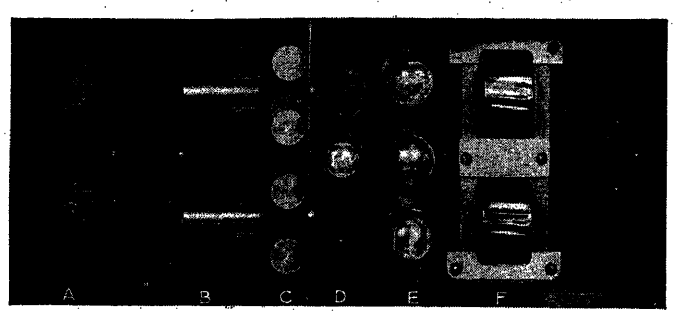

**Figure 4. Interior view of fluxmeter cabinet**

*A*—Galvanometers
*B*—Lens mountings
*C*—Photocell housings
*D*—Lamp housings and rectifier tube
*E*—Vacuum tubes and mercury-vapor rectifier
*F*—Filter reactors

Figure 5 shows the cabinet containing the 2 mutual inductors and the galvanometer control circuits. The 2 mutual inductors are each in 2 sections, astatic to uniform external fields, and are so mounted as to have no inductive coupling between them.

The cathode-ray oscillograph has a tube with a screen 7 inches in diameter, and is equipped with its own power supply. The magnetic deflection coils are located on 2 yokes of nickel-iron alloy having high permeability and low hysteresis, placed so as to produce magnetic fields at right angles to each other and to the electron beam. Two sets of coils are placed on each yoke, one being connected in the fluxmeter circuit and the other being connected to a battery and adjustable resistance. The second set is used to provide adjustment of the zero position of the electron beam.

A photographic record of the pattern traced on the fluorescent screen is made by means of the camera attached to the oscillograph. A piece of fiber tubing is fitted to the shield around the oscillograph tube. In the center is a lens equipped with a shutter and cable release, and at the end provision is made for exposing film or sensitized paper in 5-inch by 7-inch film holders. The shutter is normally used in the "bulb" position, and held open by means of the cable release while the record is being obtained.

A motor generator set has been provided to supply the magnetizing current for the specimen. Field control of the separately excited generator is used to obtain the desired maximum current. Reversing contactors included in the armature circuit of the generator permit a cyclic state of the sample to be obtained quickly, if desired, before tracing the loop. The magnetizing current is varied through the desired cycle by means of 2 rheostats having the resistance elements connected in parallel across the power supply line from the generator and the sliders connected to the magnetizing coil. The sliders are mechanically coupled together in such a way that moving them from one extreme to the other causes the magnetizing current to vary from a maximum value through zero to an equal and opposite maximum value. Not only symmetrical cycles, but any desired unsymmetrical and complicated cycle can be easily obtained.

When specimens are tested in the saturation permeameter a compensating variable mutual inductor may be used to compensate for any desired portion of the area of the potential coil measuring induction. By properly adjusting this inductor the space inside the coil but outside the specimen may be compensated for so that total induction in the sample is recorded. If desired, the entire area of the potential coil may be compensated for, so that intrinsic induction in the specimen is recorded. The primary coil is connected in series with the magnetizing coil of the permeameter, and the secondary coil is connected in series with the search coil measuring induction. The magnetizing force in the saturation permeameter is very

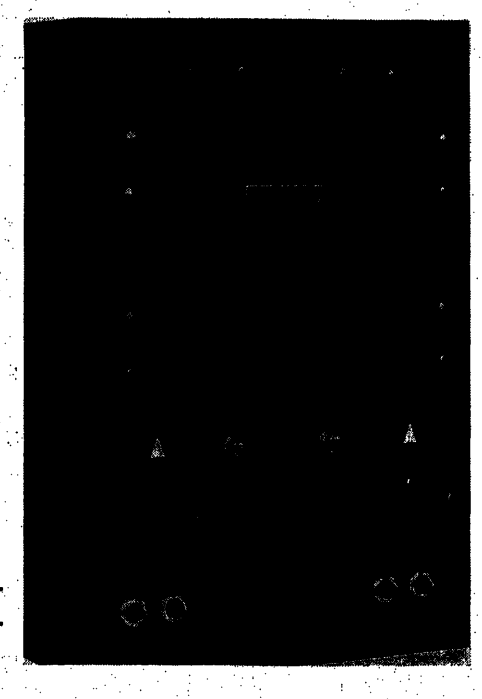

**Figure 5. Galvanometer control cabinet**

nearly proportional to the magnetizing current, so that by means of the compensating inductor a component of flux linkages proportional to the magnetizing force is introduced into the circuit containing the induction search coil. Since the flux linkages in this search coil due to space outside the specimen, or that due to the difference between total and intrinsic induction in the specimen, is proportional to magnetizing force, these flux linkages can be compensated by means of the compensating inductor.

## Records

Samples of records obtained with this equipment are shown in figures 6 and 7. Figure 6 shows portions of symmetrical hysteresis loops for 3 magnet materials. Figure 7 shows the upper portion of a loop having several minor loops traced in the second quadrant.

The co-ordinate lines are put in after the loop has been traced by switching the search coils out of the circuit, setting the plate current for one fluxmeter successively at values representing desired values of induction and varying the other through its entire range, then setting the plate current for the other fluxmeter successively at values representing desired values of magnetizing force and varying the former through its entire range. Values of plate

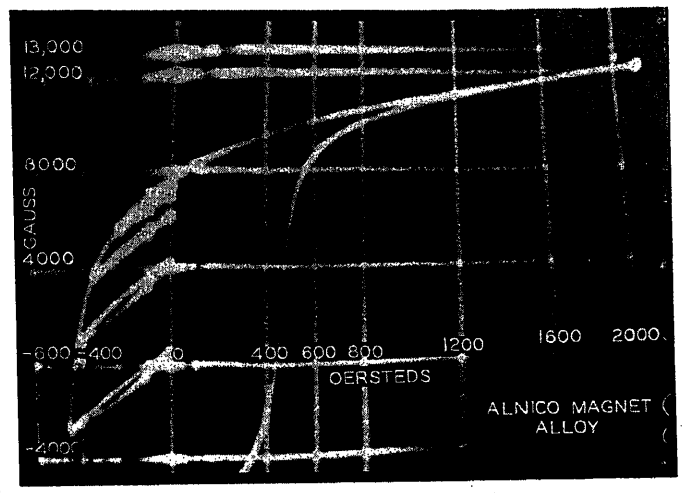

**Figure 7. Hysteresis loop for magnet material showing minor loops in the second quadrant**

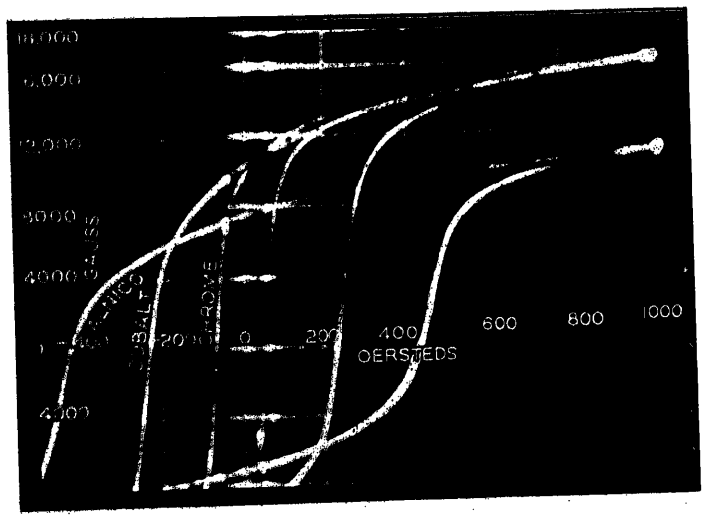

**Figure 6. Hysteresis loops for magnet materials**

current representing these quantities are calculated from a knowledge of the cross-sectional area of the sample, the number of turns and the areas of the search coils, and the mutual inductance of the inductors.

## Application

The hysteresigraph has been found particularly useful in the study of magnet materials, and in obtaining data for magnet design. Recent development of improved materials has brought about the use of permanent magnets in applications not previously considered practical, particularly in applications where the magnet may be subjected to varying external reluctance or strong demagnetizing magnetomotive force. For these applications the second quadrant of the symmetrical hysteresis loop alone is not sufficient for design calculations, but minor loops in this quadrant are also necessary. Figure 7 illustrates the type of data required.

Occasions frequently arise in which magnetic characteristics of a piece of equipment are desired for a particular type of unsymmetrical cycle. The hysteresigraph has been found to be a convenient instrument for obtaining such data.

## Conclusions

Development of the photoelectric fluxmeter and hysteresigraph was accomplished by combining only apparatus of known and tried characteristics to form a sturdy and accurate instrument simple to adjust and to operate. Testing of magnetic materials and of electrical equipment is facilitated, and magnet design data, not readily obtainable with other forms of testing equipment, are made available.

# Low-Current Ignitors

By A. H. TOEPFER
ASSOCIATE AIEE

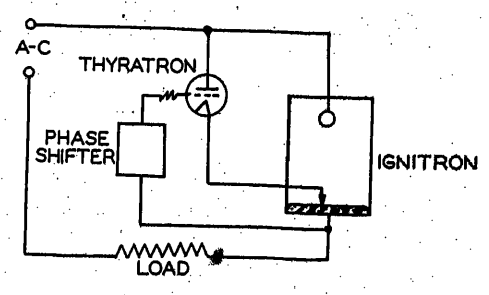
SLEPIAN AND LUDWIG'S discovery of the ignitron[1] principle of initiating the cathode spot of an arc has been followed by intensive investigation of the factors affecting the design and operation of the ignitron. Many of the design features of the ignitron follow conventional mercury-arc-rectifier practice. The distinguishing feature of the ignitron is the ignitor. An ignitor is an electrode of high resistivity material which is partially immersed in the cathode mercury. On sending a sufficiently large current through the ignitor into the mercury, a cathode spot forms upon the mercury at the ignitor mercury junction. The current to accomplish this varies in an inverse manner with the resistivity of the ignitor so that it is necessary to use relatively high resistivity material for practical ignitors. In practice the ignitor is connected to a suitable source of power with some means of switching so that the arc may be started at the proper time during the interval when the ignitron anode voltage is positive.

The most generally used circuit uses a thyratron for controlling the ignitor current as shown in figure 1.

When the grid control voltage of the thyratron and the anode voltage first become positive, the ignitor current flows and increases at a rate determined by the circuit until an arc starts in the ignitron. The current taken by the thyratron then drops to a low value depending on the relative arc drops of the thyratron and the ignitron and the resistance of the ignitor circuit. Generally this value is close to zero. The voltage across the ignitor at the same time drops to a few volts. Figure 2 shows approximately how the starting volts and amperes vary during operation.

The maximum instantaneous value of the current taken by the thyratron is many times larger than the average. It is necessary to use thyratrons with current ratings at least as large as the maximum current peaks required by the ignitors because their cathodes cannot repeatedly stand even momentary overloading without damage.

It is desirable to develop an ignitor requiring as little current as possible for several reasons. The smaller size thyratrons are cheaper than the larger, and usually the heating time of the smaller thermionic cathodes is shorter. If the starting current is reduced without changing the voltage, the load current is shifted from the ignitor circuit to the ignitron more readily at light loads. It is, therefore, more desirable to effect a reduction in starting current than to produce a cheaper thyratron to handle the ignitor load.



The theory advanced by Slepian and Ludwig[1] for the formation of the cathode spot at the ignitor mercury junction directs attention to the high current density and corresponding voltage gradient developed there, and points out the similarity between these conditions and the conditions existing at the last points of contact of separating electrodes. Other workers have used essentially the same picture.[2,3] Experience indicates that a material must satisfy the following conditions to be practically suitable for ignitors.

1. It must not be wet by mercury.
2. It must be workable.
3. It must not deteriorate in the arc.
4. It must have the proper electrical resistance.

The theory of Slepian and Ludwig suggests that the nature of the contact between the mercury and ignitor at the ignitor mercury junction is important. Hence, it is not surprising that if a material is wetted by the mercury during operation as an ignitor the starting current usually jumps to high values which may damage the thyratron. A convex meniscus seems to be necessary for low starting currents. If the material is wetted by the mercury a concave meniscus is obtained usually with large starting current. Also under these conditions the cathode spot tends to anchor at the ignitor instead of moving away from it in the usual way, and may damage it. This requirement eliminates many materials.

The substances which have been found to be useful ignitor materials are generally very hard in their crystalline form. Some of these materials are silicon carbide, boron carbide, and materials known under the trade names of Carborundum, Globar, and Silit. Shaping, mounting, and making electrical connection to these materials offers difficulties. Globar is easy to work when made up in high resistivity rods, but if processed to reduce the resistivity they become difficult to work because of increased hardness.

Figure 1

The need for working arises because it had been found desirable to shape ignitors to a point because this decreased the starting current. For example, comparing an ignitor made of quarter-inch rod and one made of the same material ground to a point, the latter required about one

A paper recommended for publication by the AIEE joint subcommittee on electronics. Manuscript submitted March 25, 1937; released for publication May 27, 1937.

A. H. TOEPFER is a research engineer with the Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

1. For all numbered references, see list at end of paper.

third of the current required by the rod at an increase in voltage of 20–25 per cent. The increase in voltage is due to the increase in the resistance of the ignitor due to reducing the section.

The cathode spot starts at the ignitor afresh each cycle and then does not have time to get very far away from it in the conducting period. Ignitrons also are usually built with the anode close to the cathode and often operate red hot. Hence, the ignitor frequently is required to run hot because it has little chance to dissipate heat through the ignitor lead or the mercury. Under these conditions the material must be stable. Materials have been found and are used that show no sign of deterioration, wear, or erosion after thousands of hours operation as ignitors. Some appear to have unlimited life.

The electrical characteristics depend on the resistivity and the geometric form of the ignitor. The geometric form and dimensions need to be a compromise between several conflicting conditions.

It is desirable to have the area of the ignitor actually under the mercury as small as possible, as this makes the ratio of the useful current which flows in the close vicinity of the junction, to the total current large. Also, it is desirable to make the length of the ignitor above the mercury as short as possible to reduce the voltage drop required to send the starting current through the length of the ignitor. The splashing of the mercury sets limits to what may be done in both of these directions. To avoid missing due to the ignitor losing contact with the mercury, it has been found necessary to use immersion depths of the order of a quarter of an inch. The distance from mercury to the conducting head, holder, or ignitor lead must be of the order of one half of an inch to prevent short circuiting of the ignitor by the splashing of the cathode mercury. Such short circuits may damage the cathode of the control tube if too much current passes through the circuit. Hence, we have the length fixed at $^3/_4$ of an inch plus the length of a head, or additional length to provide for some sort of mounting to make connection to the ignitor lead.

The thickness and shape are also reached by compromise between mechanical and electrical characteristics. The ignitor materials are brittle, therefore, they must be made in such diameters and shapes which will be strong enough to stand handling in assembly and the forces due to mercury when moving the ignitrons or during operation when some force is exerted by the mercury vapor and the motion of the mercury under the influence of the cathode spots. The shape generally used is approximately that of a cantilever beam of uniform strength. A typical ignitor is shown in figure 3. The tip diameter is of the order of 0.080 to 0.090 inch.

**Figure 4**

*W*—Width of slot

*D*—Depth of tip immersion

*S*—Surface tension of mercury = 0.0475 grams per millimeter

Pressure of immersed mercury = 0.0136 grams per square millimeter

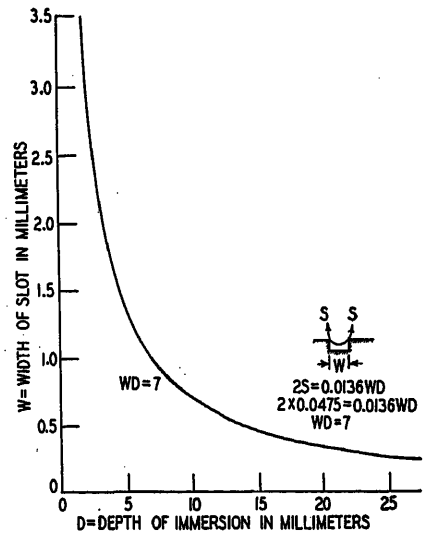


**Table I**

| Ignitor | Starting Amperes Before Slotting | Starting Amperes After Slotting | Starting Volts Before Slotting | Starting Volts After Slotting | Current Ratio After Slotting / Before Slotting |
|---|---|---|---|---|---|
| *PAN* 9 | 24 | 11 | 40 | 42 | 0.46 |
| *PAN* 14 | 20 | 7 | 50 | 50 | 0.35 |
| *PAL* 15 | 21 | 12 | 43 | 45 | 0.57 |
| *PAH* 20 | 18 | 9 | 38 | 40 | 0.50 |
| *PAH* 8 | 24 | 11 | 50 | 50 | 0.46 |
| *PAN* 19 | 14 | 7 | 75 | 80 | 0.50 |

The use of such a shape has a definite effect on the starting volts and amperes as mentioned before. For a definite size and shape of ignitor the starting voltage is directly and the starting current inversely proportional approximately to the resistivity of the material used. Thus increased resistivity generally means increased voltage and decreased current. The law has not been definitely established but examination of the characteristics of a large number of ignitors shows the trend toward such a law. The most desirable resistance to use is governed by the voltage and current limits that can be tolerated. The upper voltage limit is generally set at 100 volts for the present though it is desirable to have it as low as can be obtained. Many ignitors require less than this maximum limit. The current for an ignitor of a resistance that will give starting voltage of 100 volts would be more or less constant in value from one igniter to another if uniformly shaped ignitors were made of a material of a certain resistivity, but it happens that the problem of manufacturing ignitors is far from being as simple as that. The problem of wetting has driven the ignitor maker to treat ignitors, or make them of certain materials by processes that are

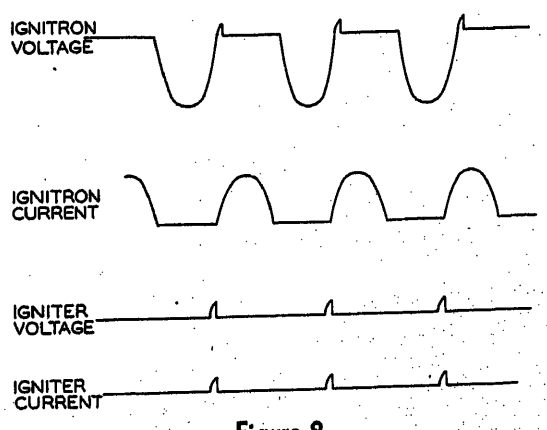

**Figure 2**

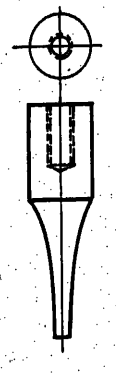

**Figure 3**

difficult to control and repeat exactly. Hence, the product varies in starting characteristics so an upper limit to the current required is set and the ignitors accepted if the current is less than 15 amperes and the voltage less than 100 volts.

The current is influenced a great deal by the surface of the part of the ignitor immersed in the cathode mercury. An ignitor with a smooth polished surface requires more current than one with a rough surface though the resistivities are the same. One may easily reduce the starting current, without affecting the voltage, by covering part of the immersed surface with insulation. However, fastening a suitable insulator on an ignitor is difficult and has been applied only in laboratory experiments.

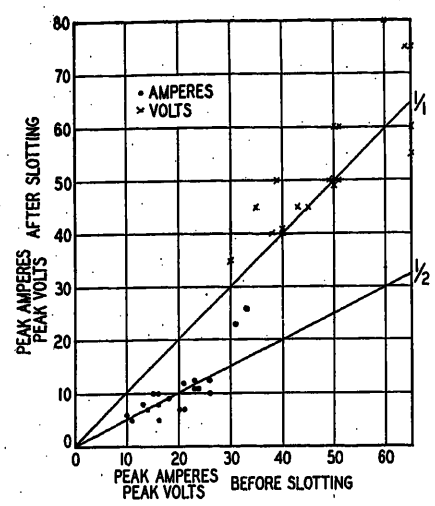

**Figure 5. Effects of slotting on starting volts and amperes**

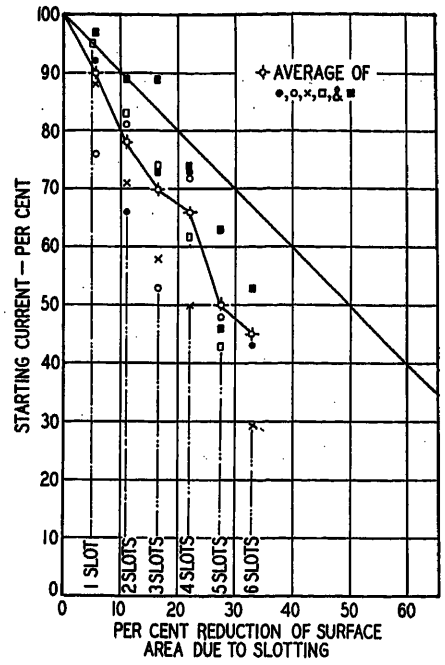

**Figure 6**

Slepian suggested a very effective method of reducing the surface area of the ignitor which could come in contact with the mercury and at the same time not appreciably increasing the resistance through the ignitor to the mercury junction. He estimated that the mercury would not enter slots of the order of one millimeter wide at ordinary ignitor immersion depths due to the high surface tension of the mercury. A simple experiment with 2 glass plates immersed in mercury proved the theory and calculations were made to show the relationship between the width of slot and depth of immersion when the surface tension forces just balance the static pressure. The results of these calculations are plotted in a curve, figure 4.

If the mercury level stayed always constant, the ideal slot would vary in width from tip to mercury surface. An ignitor with such slots has not been produced. It was convenient to take some of the present design of boron carbide ignitors which have a tip diameter of 0.080 or 0.090 inch and cut slots which were approximately 0.020 inch wide. Six slots were cut in each ignitor.

A few of the results are tabulated in table I.

A large number of ignitors were tested and the results spotted on figure 5. This shows the effect of slotting quite clearly. The slight increase in voltage may be due to the increase in resistance due to the cutting away of material. The current was reduced to nearly one half of the original. The picture figure 7 shows several slotted ignitors and an unslotted one for comparison.

It was observed that the current reduction was greater than the reduction in area. This was investigated by cutting one slot at a time and measuring the current after each slot was cut. The results are shown in figure 6, which shows starting current in per cent plotted against reduction of surface area in per cent.

An examination of the surface of the mercury at the slots and between slots showed that the line of contact of the mercury with the ignitor between slots was not a plane curve but was lower at the slots than between the slots. This fact coupled with a change in current distribution in the ignitor and mercury may account for the additional reduction in current.

The minimum current and voltage at which an ignitor will initiate an arc has not been determined. If the currents can be reduced sufficiently it becomes possible to use smaller and cheaper thyratrons and other means of supplying the ignitor current. Some ignitors do not suffer when back current passes through them so if the current requirement is reduced other methods of control become possible which, at present, are too costly or unwieldy to be useful.

# A New Photoelectric Hysteresigraph

By R. F. EDGAR
ASSOCIATE AIEE

## Introduction

GRAPHICAL RECORDING of hysteresis loops or magnetization curves by means of a hysteresigraph is in many instances a much more convenient way of obtaining desired magnetic data than is the usual ballistic method. Unsymmetrical hysteresis loops, for example, may require considerable laborious procedure if obtained in the usual manner, but are easily recorded by some types of hysteresigraphs. The photoelectric hysteresigraph described herein is an instrument which readily records initial magnetization curves or any desired symmetrical or unsymmetrical hysteresis loops.

Several different forms of hysteresigraphs have been described. They are of 2 general types, depending upon whether the test specimen is magnetized by alternating current or by direct current. An a-c hysteresigraph may employ a cathode-ray oscillograph arranged in such a manner that the horizontal deflection of the electron beam is made proportional to magnetizing force while the vertical deflection is made proportional to induction.[1] Other types of a-c hysteresigraphs also have been described.[2,3] Eddy currents within the specimen tend to distort the shape of the recorded hysteresis loop, making laminated specimens necessary. A–c hysteresigraphs record only cyclic loops. Usually symmetrical loops are recorded, but minor or unsymmetrical loops may be obtained if the power supply furnishing the magnetizing current can be arranged to introduce current of suitable harmonic frequency superimposed upon the fundamental component of the magnetizing current. A-c hysteresigraphs appear to have been applied principally to testing sheet materials of low loss and high permeability.

An early form of cathode-ray tube hysteresigraph,[4] and a magnetic curve tracer described by Ewing,[5] may be used to obtain either cyclic a-c loops or d-c loops formed by slowly varying the magnetizing current through the desired cycles. In these devices part of the magnetic circuit is through air, and the strength of the magnetic field in the air path is measured as an indication of the induction in the specimen while the magnetizing current is taken as a measure of magnetizing force. Introduction of an air gap in the magnetic circuit, however, tends to prevent uniform magnetization of the specimen with resulting errors in the measurement of both induction and magnetizing force. A recent magnetic curve tracer[6] obtains d-c loops and is applicable to the testing of specimens in a closed magnetic circuit. It employs a search coil interlinking the specimen and a fluxmeter having its restoring torque automatically counterbalanced throughout its range of deflection so that it is accurately responsive to slow flux changes.

D-c hysteresigraphs do not require laminated specimens because the desired cycle of magnetization may be carried out so slowly that eddy currents do not become large enough to affect the results even if solid specimens are used. Initial magnetization curves and unsymmetrical hysteresis loops, as well as symmetrical hysteresis loops may be obtained. Besides being applicable to the testing of electrical sheet steels the d-c hysteresigraph may also be used in testing magnet materials, specimens of which are commonly solid rather than laminated.

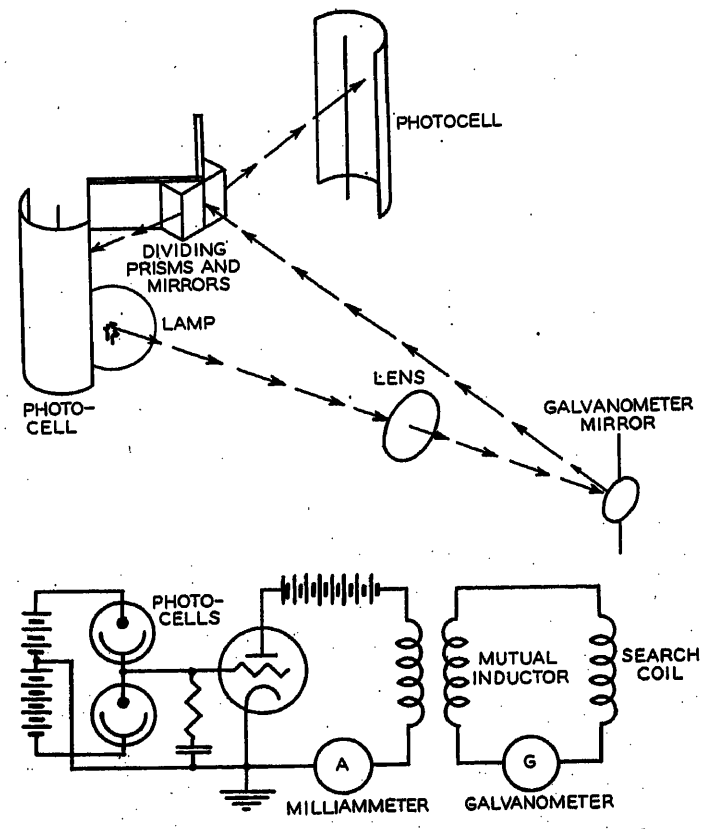

**Figure 1. Optical system and electrical circuit for photoelectric fluxmeter**

## Description

The hysteresigraph described herein is a d-c instrument which may be used to test either laminated or solid specimens in ring or bar form. For bar specimens it is connected to a permeameter in the same manner as the common ballistic galvanometer equipment. When used with the saturation permeameter[7] measurements may be made to a mag-

A paper recommended for publication by the AIEE committee on instruments and measurements. Manuscript submitted March 25, 1937; released for publication May 3, 1937.

R. F. EDGAR is employed in the general engineering laboratory of the General Electric Company, Schenectady, N. Y.

1. For all numbered references, see list at end of paper.

netizing force of 3,000 oersteds or higher. The equipment is sturdy and does not employ any delicate instruments which require careful handling, fine adjustment, or special mounting.

## The Photoelectric Fluxmeter

The heart of the instrument is a photoelectric fluxmeter[8] which is responsive to slow changes in flux linking a search coil, and provides an indication which remains constant without drift as long as the flux linking the search coil remains constant. Elementary diagrams of the fluxmeter are shown in figure 1. A galvanometer and search coil are used, and in series with them is connected the secondary coil of a mutual inductor. By means of an optical system and 2 photoelectric cells connected in a vacuum-tube circuit the galvanometer deflection is maintained at zero, the current in the primary coil of the mutual inductor being automatically varied so as to induce a voltage in the secondary coil equal and opposite to any voltage which may be induced in the search coil by a change of flux interlinking it. The change of interlinkage in the secondary coil caused by the change in primary current is then equal and opposite to the change of interlinkage in the search coil. The variation in primary current is, therefore, a measure of the flux variation in the search coil. Since the galvanometer remains at the zero position its suspension torque does not act to cause drift, and the primary current varies only when the flux linkage in the search coil varies.

The optical system and electrical circuit is adapted from the photoelectric recorder.[9] The beam from the galvanometer mirror is focused upon a set of mirrors and prisms which divides it into 2 parts and reflects each part into a photocell. Deflection of the galvanometer causes the light in one cell to increase and that in the other to diminish. The 2 photocells are connected in series with a voltage source, and to the grid of a vacuum tube in such a way that any unbalance of the divided light beam between the 2 cells causes a change in the grid voltage with a resultant change in plate current. The plate current, supplied by a second voltage source, flows in the primary coil of the above-mentioned mutual inductor. The direction of current flow is such that any change caused by a deflection of the galvanometer light beam causes a change of flux linking the secondary coil of the mutual inductor, tending to correct the galvanometer deflection and restore the orginal light balance.

A slight deflection of the galvanometer is evidently necessary to initiate the corrective change of plate current. This, however, is very small, and the final position when a new balance is restored is almost exactly the same as the original position. The photocells are of the vacuum type and are operated at a high voltage so that the current through them depends upon the light falling upon them and is nearly independent of voltage variation. The current for any constant value of grid voltage must be the same in both photocells, since they are in series, and any difference in current would necessarily alter the charge on the grid capacitor and change the grid voltage. The light division between the 2 cells must, therefore, be the same also, which means that the final position of the galvanometer beam must be the same for all steady values of flux linking the search coil. This was demonstrated in the development of the apparatus by setting up in place of the galvanometer a pivoted rod carrying a galvanometer mirror and having an arm 50 centimeters long projecting at right angles. The outer end of the arm was held lightly against the screw of a rigidly mounted micrometer. Turning the micrometer screw caused the end of the arm to move, rotating the mirror as it would rotate if mounted in the usual manner in a galvanometer. It was found that a motion at the outer end of the arm of 0.001 centimeter was sufficient to change the plate current of the tube from one extreme to the other. This corresponds to a light beam deflection of 0.0008 centimeter at the dividing prisms, and would be equivalent to a deflection of 0.004 centimeter on a scale set up at the customary meter distance.

Angular movement of the galvanometer coil equivalent to 0.001 centimeter deflection at the end of a 50 centimeter arm causes an interlinkage change in the galvanometer coil of about 30 maxwell-turns with the coil and field strength employed. In practice the galvanometer is used without any external shunt or series resistance, but is connected directly to the search coil and mutual inductor secondary winding. Since the total number of interlinkages in a circuit tends to remain constant, the difference between the change of flux linkages in the secondary coil of the mutual inductor and that in the search coil is about equal to that in the galvanometer coil. This difference is, therefore, about 30 maxwell-turns for a full-range change in the search coil. With the tube used in this test, the full-range change of plate current was

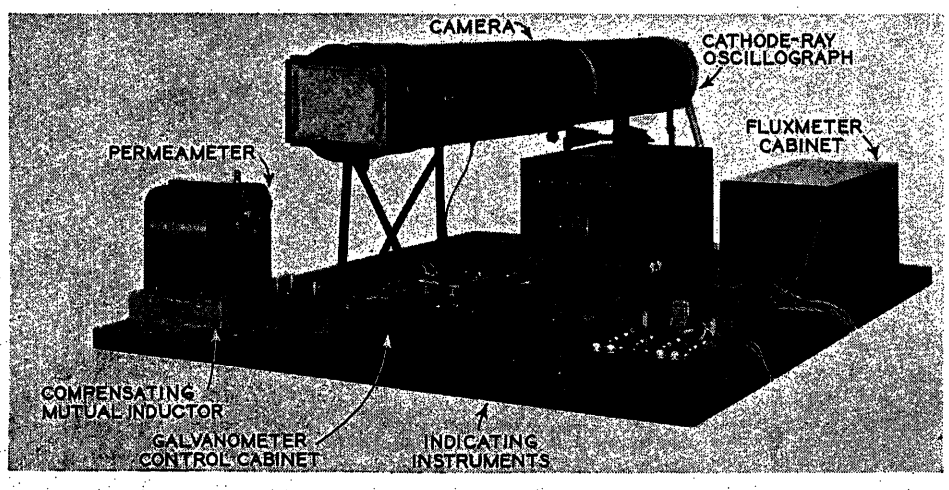

**Figure 2. Photoelectric hysteresigraph**

about 27 milliamperes. A mutual inductor of $10^7$ secondary maxwell-turns per primary ampere is used, so that full-range change of flux linkages was about 270,000 maxwell-turns. The difference between the actual change of interlinkage in the search coil and that indicated by the change in plate current through the primary winding of the mutual inductor is then about 0.0011 per cent. The tube has since been changed to a type which permits a larger change of plate current and has a higher mutual conductance so that the present figure is somewhat less.

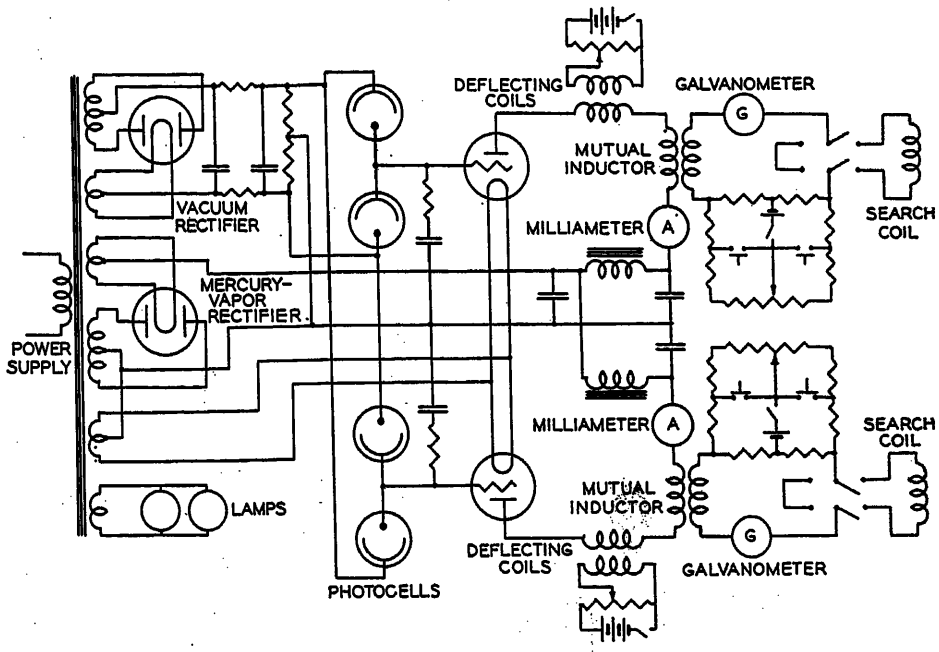

**Figure 3. Photoelectric hysteresigraph circuit diagram**

The amount of deflection during the flux change depends upon the rapidity of the flux change, the constants of the grid and plate circuits, and the characteristics of the galvanometer and its circuit. When the apparatus is used merely as an indicating fluxmeter this deflection is not important, since it returns to the small equilibrium value when the instrument indication becomes steady and can be read. It is necessary only that the deflection be small enough so that there is not sufficient suspension restoring torque to cause measurable drift during the flux change.

For use in automatic curve tracing, however, it is necessary that the current in the primary coil of the mutual inductor shall change accurately in agreement with the changing of interlinkages in the search coil. There must be no measurable lag between them. The galvanometer coil must have sufficiently low inertia to quickly begin to deflect and initiate a corrective change in the plate current when there is a change in interlinkages in the search coil. The capacitance in the grid circuit must be low enough so that the grid voltage quickly changes when there is an unbalance in the photocell circuit. The inductance in the plate circuit must be low enough to permit quick changes of plate current. It has been found that a portable reflecting galvanometer is entirely satisfactory, and no difficulty is experienced in making the constants of the circuits correct for accurate response to slow changes of interlinkage.

The accuracy of the measurement is not affected by small changes in supply voltage, vacuum-tube characteristics, photocell sensitivity, or light intensity. The optical system and photoelectric circuit are similar to those of the photoelectric recorder in being self-compensating for all normal changes in these variables.

The photoelectric fluxmeter is equivalent to a galvanometer of infinitely long period, in that it responds accurately to slow flux changes and its indication remains constant at any part of the range without drift. Moreover, the output of the instrument, instead of being merely deflection of a light beam on a scale, is in the form of electric current of sufficient power to operate sturdy and relatively insensitive indicating instruments or recording devices.

## The Hysteresigraph

The photoelectric hysteresigraph as illustrated in figure 2 consists of 2 such fluxmeters combined with a cathode-ray oscillograph. Magnetic deflection coils fitted to the oscillograph tube are connected in the plate circuits of the fluxmeters so that one fluxmeter causes vertical deflection of the electron beam and the other causes horizontal deflection. The search coil of the first fluxmeter is linked by the specimen under test and that of the second lies adjacent to the specimen but is not linked by it,[7] so that one fluxmeter measures induction changes and the other magnetizing force changes. Bar or strip specimens may be tested at high magnetizing force in the saturation permeameter. The hysteresigraph is adaptable to any type of permeameter in which the magnetizing force can be measured by means of a search coil as described, but which requires no varying compensating adjustment over the range of test. Ring specimens may be tested by using only one fluxmeter, a portion of the magnetizing current being passed directly through the horizontal deflection coils.

The circuit diagram for the hysteresigraph is shown in figure 3. It is similar to that of figure 1, the batteries being replaced by rectified a-c power sources, and 2 complete fluxmeters being provided. A small dry cell with fixed and variable resistors in each galvanometer circuit provide a means of balancing out any small thermoelectric or other voltage which may be present. Push buttons in this circuit facilitate shifting the plate current at will so

that it can be set at any desired value for the beginning of a test, and switches enable the search coils to be inserted in or removed from the circuit.

Figure 4 shows the arrangement of galvanometers, photocells, optical system, and vacuum tubes for both fluxmeters in one cabinet. Transformers, capacitors, and wiring are mounted on the under side of the subbase. The galvanometers are of the portable type[10] having sturdy suspensions and require no careful leveling or delicate adjustment. Moving systems of relatively low resistance are used. Stops are provided limiting the deflection to a small angle and preventing the beam from being thrown entirely off the dividing mirrors at any time. The light beams are supplied by 32-candlepower 6-volt automobile headlight bulbs in ventilated housings, and convex lenses in adjustable tubes. The photocells and prisms are enclosed in housings which prevent entrance of stray light. Voltage is supplied to the photocells by a vacuum rectifier tube through a resistance-capacitance filter circuit. Power is supplied to the plate circuits by a mercury-vapor rectifier tube having a low voltage drop, and a filter circuit of inductance and capacitance.

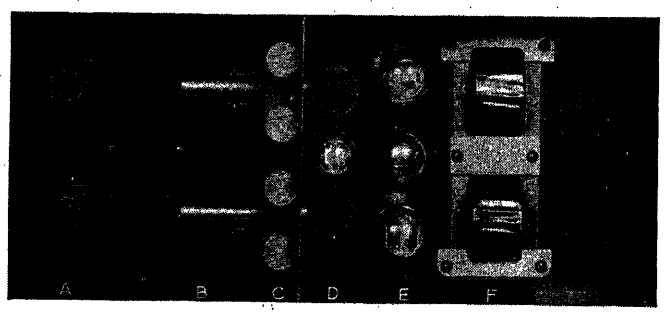

**Figure 4. Interior view of fluxmeter cabinet**

*A*—Galvanometers
*B*—Lens mountings
*C*—Photocell housings
*D*—Lamp housings and rectifier tube
*E*—Vacuum tubes and mercury-vapor rectifier
*F*—Filter reactors

Figure 5 shows the cabinet containing the 2 mutual inductors and the galvanometer control circuits. The 2 mutual inductors are each in 2 sections, astatic to uniform external fields, and are so mounted as to have no inductive coupling between them.

The cathode-ray oscillograph has a tube with a screen 7 inches in diameter, and is equipped with its own power supply. The magnetic deflection coils are located on 2 yokes of nickel-iron alloy having high permeability and low hysteresis, placed so as to produce magnetic fields at right angles to each other and to the electron beam. Two sets of coils are placed on each yoke, one being connected in the fluxmeter circuit and the other being connected to a battery and adjustable resistance. The second set is used to provide adjustment of the zero position of the electron beam.

A photographic record of the pattern traced on the fluorescent screen is made by means of the camera attached to the oscillograph. A piece of fiber tubing is fitted to the shield around the oscillograph tube. In the center is a lens equipped with a shutter and cable release, and at the end provision is made for exposing film or sensitized paper in 5-inch by 7-inch film holders. The shutter is normally used in the "bulb" position, and held open by means of the cable release while the record is being obtained.

A motor generator set has been provided to supply the magnetizing current for the specimen. Field control of the separately excited generator is used to obtain the desired maximum current. Reversing contactors included in the armature circuit of the generator permit a cyclic state of the sample to be obtained quickly, if desired, before tracing the loop. The magnetizing current is varied through the desired cycle by means of 2 rheostats having the resistance elements connected in parallel across the power supply line from the generator and the sliders connected to the magnetizing coil. The sliders are mechanically coupled together in such a way that moving them from one extreme to the other causes the magnetizing current to vary from a maximum value through zero to an equal and opposite maximum value. Not only symmetrical cycles, but any desired unsymmetrical and complicated cycle can be easily obtained.

When specimens are tested in the saturation permeameter a compensating variable mutual inductor may be used to compensate for any desired portion of the area of the potential coil measuring induction. By properly adjusting this inductor the space inside the coil but outside the specimen may be compensated for so that total induction in the sample is recorded. If desired, the entire area of the potential coil may be compensated for, so that intrinsic induction in the specimen is recorded. The primary coil is connected in series with the magnetizing coil of the permeameter, and the secondary coil is connected in series with the search coil measuring induction. The magnetizing force in the saturation permeameter is very

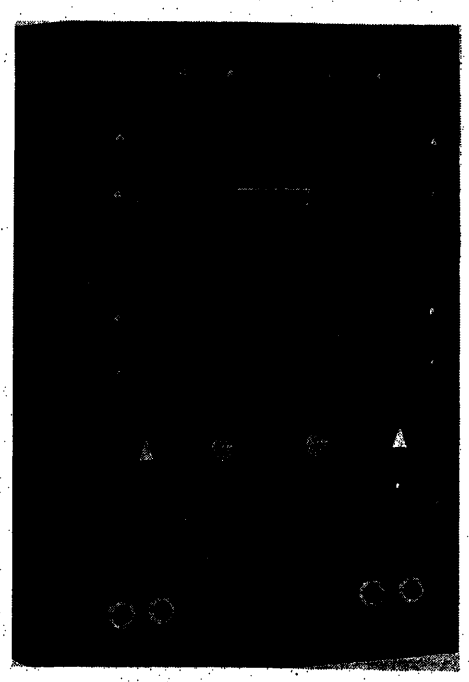

**Figure 5. Galvanometer control cabinet**

nearly proportional to the magnetizing current, so that by means of the compensating inductor a component of flux linkages proportional to the magnetizing force is introduced into the circuit containing the induction search coil. Since the flux linkages in this search coil due to space outside the specimen, or that due to the difference between total and intrinsic induction in the specimen, is proportional to magnetizing force, these flux linkages can be compensated by means of the compensating inductor.

## Records

Samples of records obtained with this equipment are shown in figures 6 and 7. Figure 6 shows portions of symmetrical hysteresis loops for 3 magnet materials. Figure 7 shows the upper portion of a loop having several minor loops traced in the second quadrant.

The co-ordinate lines are put in after the loop has been traced by switching the search coils out of the circuit, setting the plate current for one fluxmeter successively at values representing desired values of induction and varying the other through its entire range, then setting the plate current for the other fluxmeter successively at values representing desired values of magnetizing force and varying the former through its entire range. Values of plate

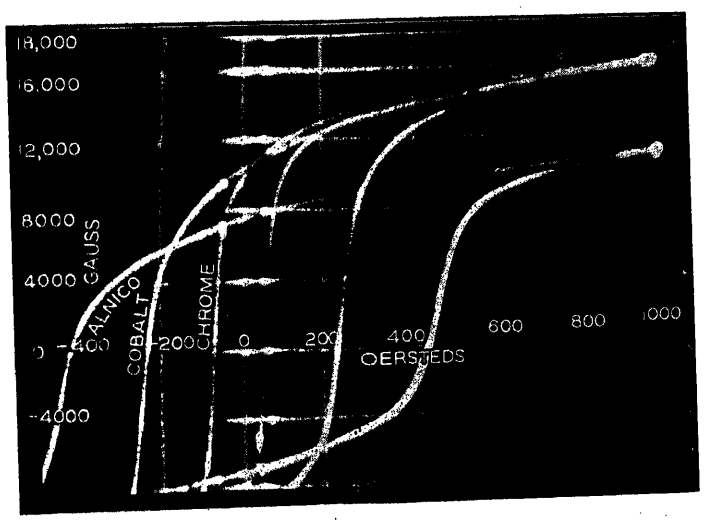

**Figure 6. Hysteresis loops for magnet materials**

current representing these quantities are calculated from a knowledge of the cross-sectional area of the sample, the number of turns and the areas of the search coils, and the mutual inductance of the inductors.

## Application

The hysteresigraph has been found particularly useful in the study of magnet materials, and in obtaining data for magnet design. Recent development of improved materials has brought about the use of permanent magnets in applications not previously considered practical, particularly in applications where the magnet may be subjected to varying external reluctance or strong demagnetizing magnetomotive force. For these applications the second quadrant of the symmetrical hysteresis loop alone is not sufficient for design calculations, but minor loops in this quadrant are also necessary. Figure 7 illustrates the type of data required.

Occasions frequently arise in which magnetic characteristics of a piece of equipment are desired for a particular

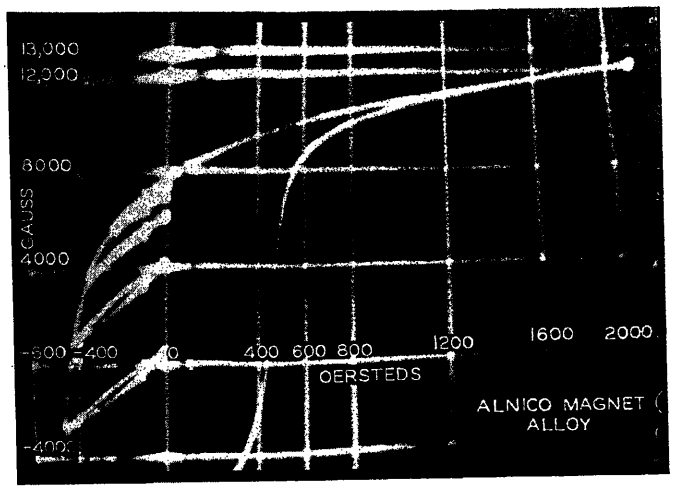

**Figure 7. Hysteresis loop for magnet material showing minor loops in the second quadrant**

type of unsymmetrical cycle. The hysteresigraph has been found to be a convenient instrument for obtaining such data.

## Conclusions

Development of the photoelectric fluxmeter and hysteresigraph was accomplished by combining only apparatus of known and tried characteristics to form a sturdy and accurate instrument simple to adjust and to operate. Testing of magnetic materials and of electrical equipment is facilitated, and magnet design data, not readily obtainable with other forms of testing equipment, are made available.

# Low-Current Ignitors

By A. H. TOEPFER
ASSOCIATE AIEE

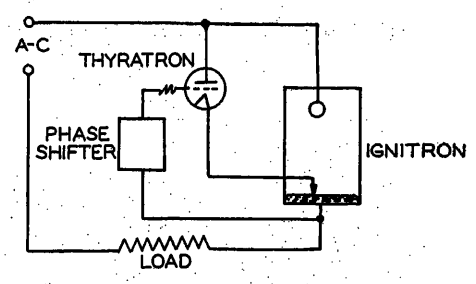
SLEPIAN AND LUDWIG'S discovery of the ignitron[1] principle of initiating the cathode spot of an arc has been followed by intensive investigation of the factors affecting the design and operation of the ignitron. Many of the design features of the ignitron follow conventional mercury-arc-rectifier practice. The distinguishing feature of the ignitron is the ignitor. An ignitor is an electrode of high resistivity material which is partially immersed in the cathode mercury. On sending a sufficiently large current through the ignitor into the mercury, a cathode spot forms upon the mercury at the ignitor mercury junction. The current to accomplish this varies in an inverse manner with the resistivity of the ignitor so that it is necessary to use relatively high resistivity material for practical ignitors. In practice the ignitor is connected to a suitable source of power with some means of switching so that the arc may be started at the proper time during the interval when the ignitron anode voltage is positive.

The most generally used circuit uses a thyratron for controlling the ignitor current as shown in figure 1.

When the grid control voltage of the thyratron and the anode voltage first become positive, the ignitor current flows and increases at a rate determined by the circuit until an arc starts in the ignitron. The current taken by the thyratron then drops to a low value depending on the relative arc drops of the thyratron and the ignitron and the resistance of the ignitor circuit. Generally this value is close to zero. The voltage across the ignitor at the same time drops to a few volts. Figure 2 shows approximately how the starting volts and amperes vary during operation.

The maximum instantaneous value of the current taken by the thyratron is many times larger than the average. It is necessary to use thyratrons with current ratings at least as large as the maximum current peaks required by the ignitors because their cathodes cannot repeatedly stand even momentary overloading without damage.

It is desirable to develop an ignitor requiring as little current as possible for several reasons. The smaller size thyratrons are cheaper than the larger, and usually the heating time of the smaller thermionic cathodes is shorter. If the starting current is reduced without changing the voltage, the load current is shifted from the ignitor circuit to the ignitron more readily at light loads. It is, therefore, more desirable to effect a reduction in starting current than to produce a cheaper thyratron to handle the ignitor load.



The theory advanced by Slepian and Ludwig[1] for the formation of the cathode spot at the ignitor mercury junction directs attention to the high current density and corresponding voltage gradient developed there, and points out the similarity between these conditions and the conditions existing at the last points of contact of separating electrodes. Other workers have used essentially the same picture.[2,3] Experience indicates that a material must satisfy the following conditions to be practically suitable for ignitors.

1. It must not be wet by mercury.
2. It must be workable.
3. It must not deteriorate in the arc.
4. It must have the proper electrical resistance.

The theory of Slepian and Ludwig suggests that the nature of the contact between the mercury and ignitor at the ignitor mercury junction is important. Hence, it is not surprising that if a material is wetted by the mercury during operation as an ignitor the starting current usually jumps to high values which may damage the thyratron. A convex meniscus seems to be necessary for low starting currents. If the material is wetted by the mercury a concave meniscus is obtained usually with large starting current. Also under these conditions the cathode spot tends to anchor at the ignitor instead of moving away from it in the usual way, and may damage it. This requirement eliminates many materials.

The substances which have been found to be useful ignitor materials are generally very hard in their crystalline form. Some of these materials are silicon carbide, boron carbide, and materials known under the trade names of Carborundum, Globar, and Silit. Shaping, mounting, and making electrical connection to these materials offers difficulties. Globar is easy to work when made up in high resistivity rods, but if processed to reduce the resistivity they become difficult to work because of increased hardness.

Figure 1

The need for working arises because it had been found desirable to shape ignitors to a point because this decreased the starting current. For example, comparing an ignitor made of quarter-inch rod and one made of the same material ground to a point, the latter required about one

A paper recommended for publication by the AIEE joint subcommittee on electronics. Manuscript submitted March 25, 1937; released for publication May 27, 1937.

A. H. TOEPFER is a research engineer with the Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

1. For all numbered references, see list at end of paper.

third of the current required by the rod at an increase in voltage of 20–25 per cent. The increase in voltage is due to the increase in the resistance of the ignitor due to reducing the section.

The cathode spot starts at the ignitor afresh each cycle and then does not have time to get very far away from it in the conducting period. Ignitrons also are usually built with the anode close to the cathode and often operate red hot. Hence, the ignitor frequently is required to run hot because it has little chance to dissipate heat through the ignitor lead or the mercury. Under these conditions the material must be stable. Materials have been found and are used that show no sign of deterioration, wear, or erosion after thousands of hours operation as ignitors. Some appear to have unlimited life.

The electrical characteristics depend on the resistivity and the geometric form of the ignitor. The geometric form and dimensions need to be a compromise between several conflicting conditions.

It is desirable to have the area of the ignitor actually under the mercury as small as possible, as this makes the ratio of the useful current which flows in the close vicinity of the junction, to the total current large. Also, it is desirable to make the length of the ignitor above the mercury as short as possible to reduce the voltage drop required to send the starting current through the length of the ignitor. The splashing of the mercury sets limits to what may be done in both of these directions. To avoid missing due to the ignitor losing contact with the mercury, it has been found necessary to use immersion depths of the order of a quarter of an inch. The distance from mercury to the conducting head, holder, or ignitor lead must be of the order of one half of an inch to prevent short circuiting of the ignitor by the splashing of the cathode mercury. Such short circuits may damage the cathode of the control tube if too much current passes through the circuit. Hence, we have the length fixed at $^3/_4$ of an inch plus the length of a head, or additional length to provide for some sort of mounting to make connection to the ignitor lead.

The thickness and shape are also reached by compromise between mechanical and electrical characteristics. The ignitor materials are brittle, therefore, they must be made in such diameters and shapes which will be strong enough to stand handling in assembly and the forces due to mercury when moving the ignitrons or during operation when some force is exerted by the mercury vapor and the motion of the mercury under the influence of the cathode spots. The shape generally used is approximately that of a cantilever beam of uniform strength. A typical ignitor is shown in figure 3. The tip diameter is of the order of 0.080 to 0.090 inch.

**Figure 4**

*W*—Width of slot

*D*—Depth of tip immersion

*S*—Surface tension of mercury = 0.0475 grams per millimeter

Pressure of immersed mercury = 0.0136 grams per square millimeter

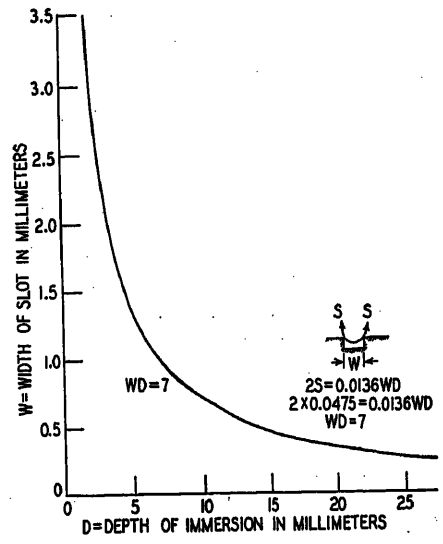


**Table I**

| Ignitor | Starting Amperes Before Slotting | Starting Amperes After Slotting | Starting Volts Before Slotting | Starting Volts After Slotting | Current Ratio After Slotting / Before Slotting |
|---|---|---|---|---|---|
| *PA N* 9 | 24 | 11 | 40 | 42 | 0.46 |
| *PA N* 14 | 20 | 7 | 50 | 50 | 0.35 |
| *PA L* 15 | 21 | 12 | 43 | 45 | 0.57 |
| *PA H* 20 | 18 | 9 | 38 | 40 | 0.50 |
| *PA H* 8 | 24 | 11 | 50 | 50 | 0.46 |
| *PA N* 19 | 14 | 7 | 75 | 80 | 0.50 |

The use of such a shape has a definite effect on the starting volts and amperes as mentioned before. For a definite size and shape of ignitor the starting voltage is directly and the starting current inversely proportional approximately to the resistivity of the material used. Thus increased resistivity generally means increased voltage and decreased current. The law has not been definitely established but examination of the characteristics of a large number of ignitors shows the trend toward such a law. The most desirable resistance to use is governed by the voltage and current limits that can be tolerated. The upper voltage limit is generally set at 100 volts for the present though it is desirable to have it as low as can be obtained. Many ignitors require less than this maximum limit. The current for an ignitor of a resistance that will give starting voltage of 100 volts would be more or less constant in value from one igniter to another if uniformly shaped ignitors were made of a material of a certain resistivity, but it happens that the problem of manufacturing ignitors is far from being as simple as that. The problem of wetting has driven the ignitor maker to treat ignitors, or make them of certain materials by processes that are

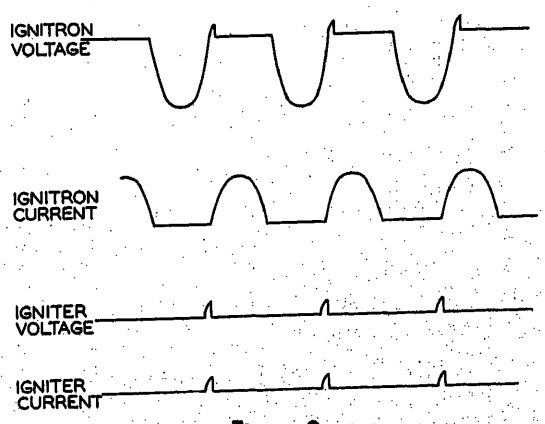

**Figure 2**

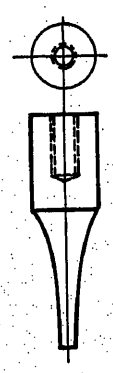

**Figure 3**

difficult to control and repeat exactly. Hence, the product varies in starting characteristics so an upper limit to the current required is set and the ignitors accepted if the current is less than 15 amperes and the voltage less than 100 volts.

The current is influenced a great deal by the surface of the part of the ignitor immersed in the cathode mercury. An ignitor with a smooth polished surface requires more current than one with a rough surface though the resistivities are the same. One may easily reduce the starting current, without affecting the voltage, by covering part of the immersed surface with insulation. However, fastening a suitable insulator on an ignitor is difficult and has been applied only in laboratory experiments.

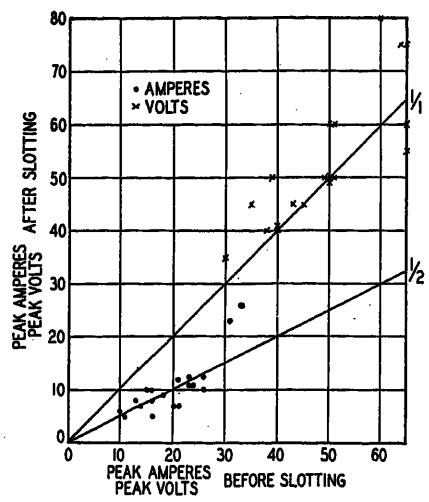

**Figure 5. Effects of slotting on starting volts and amperes**

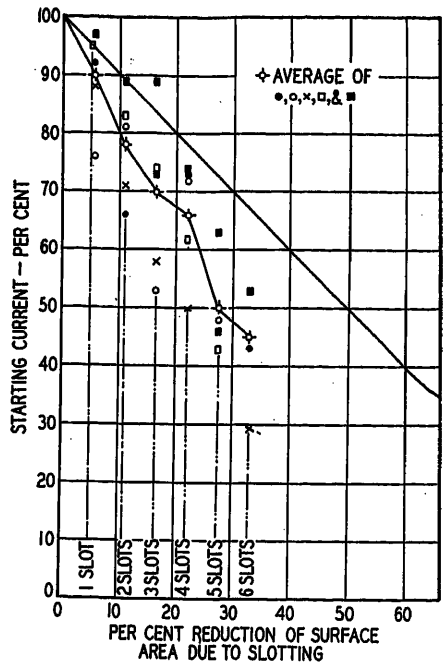

**Figure 6**

Slepian suggested a very effective method of reducing the surface area of the ignitor which could come in contact with the mercury and at the same time not appreciably increasing the resistance through the ignitor to the mercury junction. He estimated that the mercury would not enter slots of the order of one millimeter wide at ordinary ignitor immersion depths due to the high surface tension of the mercury. A simple experiment with 2 glass plates immersed in mercury proved the theory and calculations were made to show the relationship between the width of slot and depth of immersion when the surface tension forces just balance the static pressure. The results of these calculations are plotted in a curve, figure 4.

If the mercury level stayed always constant, the ideal slot would vary in width from tip to mercury surface. An ignitor with such slots has not been produced. It was convenient to take some of the present design of boron carbide ignitors which have a tip diameter of 0.080 or 0.090 inch and cut slots which were approximately 0.020 inch wide. Six slots were cut in each ignitor.

A few of the results are tabulated in table I.

A large number of ignitors were tested and the results spotted on figure 5. This shows the effect of slotting quite clearly. The slight increase in voltage may be due to the increase in resistance due to the cutting away of material. The current was reduced to nearly one half of the original. The picture figure 7 shows several slotted ignitors and an unslotted one for comparison.

It was observed that the current reduction was greater than the reduction in area. This was investigated by cutting one slot at a time and measuring the current after each slot was cut. The results are shown in figure 6, which shows starting current in per cent plotted against reduction of surface area in per cent.

An examination of the surface of the mercury at the slots and between slots showed that the line of contact of the mercury with the ignitor between slots was not a plane curve but was lower at the slots than between the slots. This fact coupled with a change in current distribution in the ignitor and mercury may account for the additional reduction in current.

The minimum current and voltage at which an ignitor will initiate an arc has not been determined. If the currents can be reduced sufficiently it becomes possible to use smaller and cheaper thyratrons and other means of supplying the ignitor current. Some ignitors do not suffer when back current passes through them so if the current requirement is reduced other methods of control become possible which, at present, are too costly or unwieldy to be useful.

# Approximating Potier Reactance

By STERLING BECKWITH
ASSOCIATE AIEE

POTIER REACTANCE is a somewhat fictitious reactance, because it is a combination of reactance, change of saturation, and change of flux form. Nevertheless, it is sometimes a rather useful fiction because it can be easily tested, and because it can be used to obtain full load field currents of synchronous machines when only the no-load saturation curve is available. It is also useful for determining effects of saturation on stability.

The following discussion attempts only to give 3 approximate empirical methods of calculating $X_p$ and to show the probable accuracy of the methods for typical machines. The value of the methods can best be judged by a comparison of calculated values with test values, as is done in table I and in figures 6 to 9. This is because the equations used involve certain approximations and in addition are made up of 3 terms, all of which must be calculated by approximate or by semiempirical formulas. A discussion of some of the difficulties involved in the accurate predetermination of $X_p$ is also included, but formulas for accurate calculation are not developed.

Potier reactance is tested as the difference between 2 saturation curves, one taken at no load, and the other taken at full current, zero power factor. These curves for a typical machine are shown in figure 1, and the geometrical construction usually employed in obtaining the reactance from these 2 curves is shown by the triangle $ABC$. (The altitude of the triangle is the Potier reactance drop in volts so that per cent $X_p$ equals $(CD/VB') \times 100$.) Expressed in words, the process is to find the triangle which will fit between the 2 curves at both the location $ABC$ and the location $A'B'C'$, where the point $A$ is at the voltage at which the reactance is desired.

The process of finding a triangle that will fit at 2 places is simple, but, as might be supposed, the actual value of reactance obtained will depend on the voltage at which the upper triangle is constructed. To illustrate this, figure 2 has been drawn showing Potier reactance of the machine of figure 1 plotted against terminal voltage, and reference can be made to several similar curves in the first article of the bibliography. Another difficulty associated with the process of fitting 2 triangles is that of determining when they fit, and to illustrate this point, the curve of figure 3 has been drawn. This curve is identical with figure 2 except that the field currents at any point on the given test saturation curves of figure 1 have been assumed to be accurate only within ±1 per cent, and the resulting effect on Potier reactance has been shown as a crosshatched band. Stated in words, this question of fit resolves itself into the fact that since Potier reactance is measured geometrically as a voltage drop parallel to the air-gap line, it can be measured accurately only when the slope of the no-load saturation curve differs appreciably from that of the air-gap line. In the following discussion, therefore, the value of $X_p$ will not be discussed below the point where the slope of the no-load saturation curve at the peak of the Potier triangle equals twice the slope of the air-gap line.

## Analysis of Machine Internal Conditions Affecting $X_p$

To get a better physical picture of what constitutes Potier reactance, let us first consider in detail the fluxes existing when a machine is operating as a synchronous condenser, that is, at the point $A$ in figure 1. Under these conditions, the internal or air-gap voltage is ordinarily considered to be greater than the terminal voltage, because of reactance drops. The end winding reactance, for example, can be considered merely as external reactance so that all machine fluxes are raised by the drop across the end winding reactance. The slot reactance causes the flux in the air gap to be greater than that in the core, since part of the flux crossing the gap is shunted across the slots (because of the armature current) and does not reach the core, but only cuts the conductors near the top of the slot. Similarly, part of the flux through the poles does not even cross the gap, but crosses directly from the side of one pole to the side of the next, and may be said to produce a field reactance drop quite similar to the slot winding or end winding reactance drop.

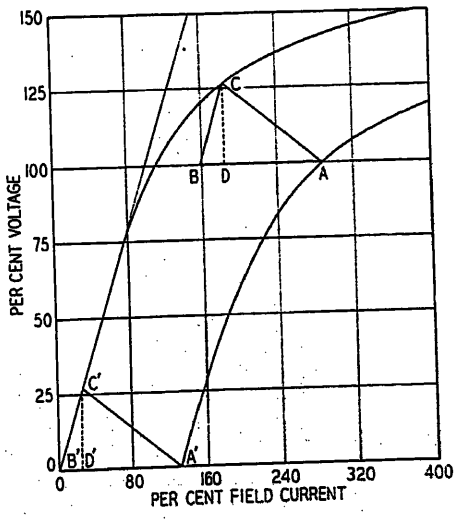

**Figure 1. Typical synchronous-machine saturation curves showing construction for obtaining $X_p$. (These are actual test curves)**

In figure 4, the no-load saturation curve has been broken up into its component parts, representing pole, air-gap,

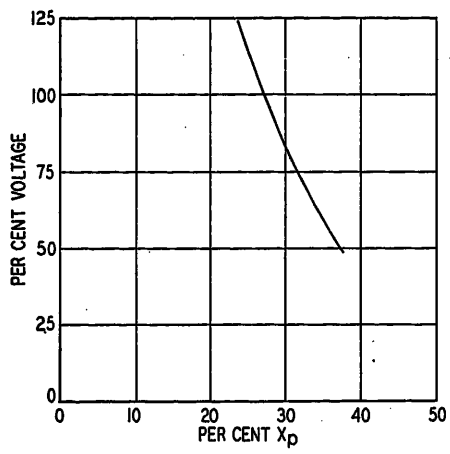

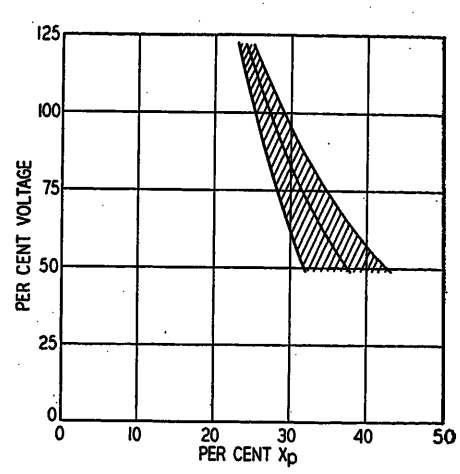

**Figure 2. $X_p$ as obtained from the test curves of figure 1**

**Figure 3. Inherent chance of error in testing $X_p$**

This curve is the same as that of figure 2, except that the field currents at any point on the given test saturation curves of figure 1 have been assumed to be accurate only within ±1 per cent, and the resulting effect on $X_p$ has been shown as a crosshatched band

tooth, and core saturation. To be exact, each of these components should be broken down into still smaller parts, and should vary with load conditions on the machine, but the additional complications would only confuse the relations to be brought out now. The reactance drops mentioned above have been shown in figure 4, so that the points $P$, $G$, $T$, and $C$ represent the internal voltages in the pole, air gap, teeth, and core, respectively. Figure 4 can be simplified by making the following assumptions: (1) the core saturation is negligible; (2) the saturation in the teeth is largely at the tips of the teeth (see appendix), so that the flux determining saturation in the teeth can be assumed to be the same as the flux in the air gap; and (3) the effective flux in the pole can be considered to be increased above no-load conditions by the amount of transient reactance drop, since transient reactance represents leakage reactance plus flux which crosses between poles and does not link the field winding. Transient reactance flux is not identical with leakage flux because of harmonics, change of wave form, saturation and other factors, but in developing the following approximate formula, it will be considered identical.

## Table I. Comparison of Test and Calculations

| Machine | | | Per Cent Reactances | | | | Per Cent Potier Reactance | | | | | | Saturation Data | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| No. | Kva | Poles | $X_d$ | $X_l$ | $X_d'$ | Test | Calculated by Eq 1 | Difference | Average Difference | Calculated by Eq 2 | Difference | Calculated by Eq 3 | Difference | Pole AT / Tooth + Pole AT | $K_{nl}$ | $K_q$ |

Note: Test values were taken from regular commercial tests and not from special tests. $X_l$ has been calculated by Kilgore's formulas. $X_d'$ has been calculated either by Kilgore's formulas or by a simplified formula. Ratio of pole ampere turns to pole plus tooth ampere turns has been calculated in several cases by more than one method.

## Approximate Graphical Method for Calculating $X_p$

Using these simplifications, then, figure 4 can be reduced to figure 5, and the point $A$ of figure 1, which is the operating point at zero power factor, can be determined as the sum of the ampere turns in the gap (equals $NG$ in figure 5) plus the tooth ampere turns (equals $NT$ in figure 5) plus the pole ampere turns (equals $SP$ in figure 5) plus the effective demagnetizing ampere turns of the armature current (equals $D'A'$ in figure 1). After the point $A$ has been obtained, the determination of $X_p$ can be made by the usual method shown in figure 1.

## First Approximation for $X_p$

The above procedure for calculating $X_p$ is a graphical one. The same procedure can easily be reduced to an approximate formula by considering 2 limiting conditions,

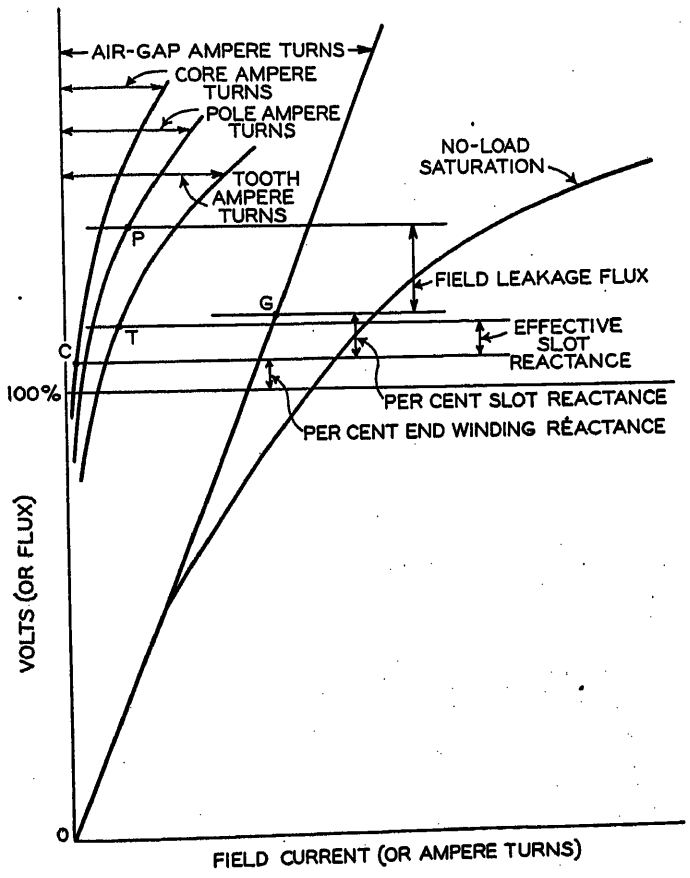

**Figure 4. Internal conditions determining $X_p$**

and assuming linear variation between these 2 conditions. The first limiting condition exists when there is no saturation in the poles, all saturation being in the teeth. For this case Potier reactance equals leakage reactance. The second limiting condition exists when all saturation occurs in the poles, and the teeth are unsaturated. For this case Potier reactance equals transient reactance. If intermediate points are assumed to depend directly upon the ratio of pole saturation to total saturation, the formula for $X_p$ becomes

$$X_p = X_l + (X_d' - X_l) \frac{\text{pole ampere turns}}{\text{pole plus tooth ampere turns}} \qquad (1)$$

This equation is a simplified form of one given by L. A. Kilgore in his discussion of reference 1.

## Second Approximation for $X_p$

For use where the ratio of pole ampere turns to pole plus tooth ampere turns cannot be determined, an average value for this ratio can be assumed, so that equation 1 becomes

$$X_p = X_l + 0.63\,(X_d' - X_l) \qquad (2)$$

## Third Approximation for $X_p$

In cases where $X_l$ is not available, an empirical formula applicable to average machines has been found to be merely

$$X_p = 0.8\,(X_d') \qquad (3)$$

## Comparison of Test and Calculated Results

Results of 34 calculations using formulas 1, 2, and 3 are compared with test in table I, and the same results are shown in graphical form in figures 6 to 9. In figures 7, 8,

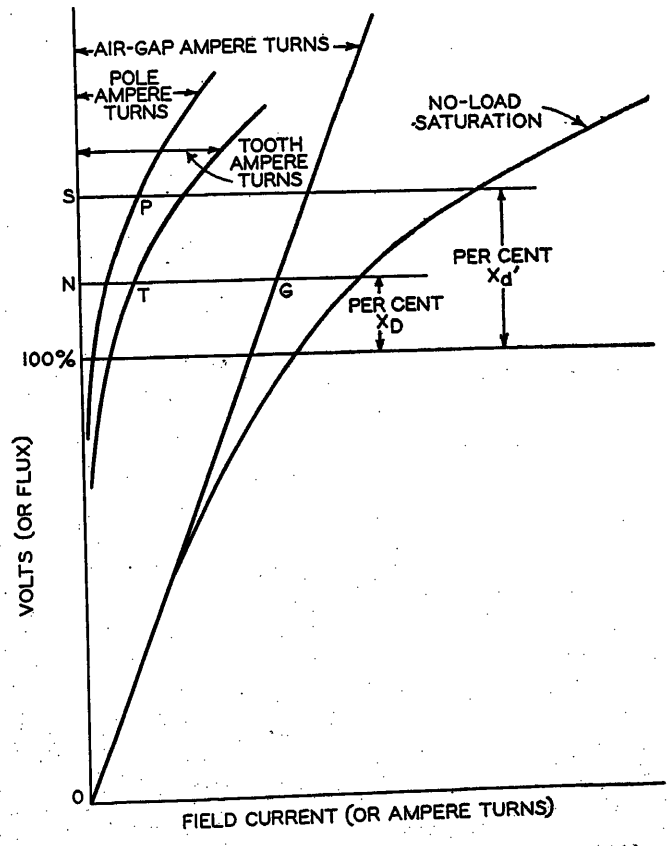

**Figure 5. Simplified internal conditions determining $X_p$**

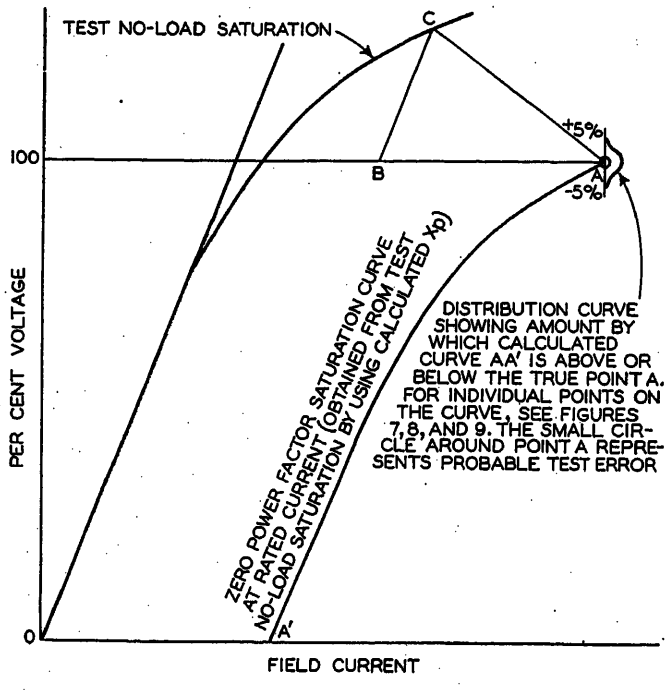
and 9, the difference between test and calculated values for each machine has been drawn as a line above or below a zero axis, and the lines have been arranged in order of descending magnitude to give in effect a distribution curve. The abscissa can consequently be labeled "number of machines exceeding a given per cent error." Thus in figure 8



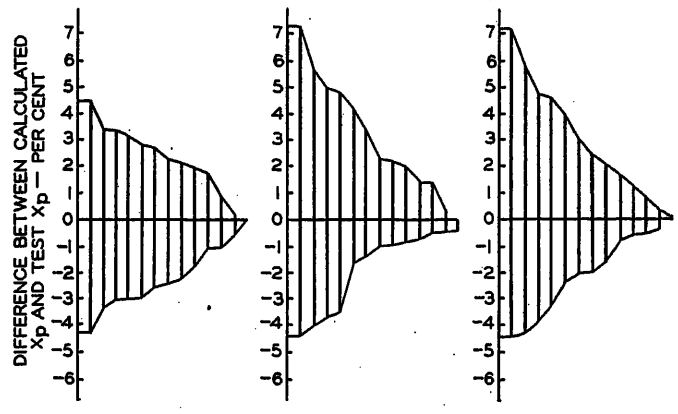


**Figure 6. Comparison of calculated $X_p$ with test $X_p$**

the ordinate for $-3$ per cent error yields an abscissa whose value is 4, which is the number of machines for which test $X_p$ was more than 3 per cent less than calculated $X_p$. Per cent has everywhere been taken as per cent of rated terminal voltage, in order to avoid confusion and so that the distribution curves of figures 7, 8, and 9 can be more easily visualized in their true significance as per cent of terminal voltage above and below the true point $A$ in figure 6. In this figure, the assumption made is that the no-load saturation curve has been obtained from test, and that calculated $X_p$ is being used to obtain the full load zero power factor curve which will then be above or below the true point $A$ by an amount exactly equal to test $X_p$ minus calculated $X_p$.

When judging the results, it should be remembered that the quantity being calculated varies with test error and voltage rating as shown in figure 3. Furthermore, the values of end winding leakage reactance and also those of transient reactance as calculated by published formulas differ slightly from each other and from test. The other term in equation 1 is the ratio of pole saturation to tooth plus pole saturation, and it is hardly necessary to say that its value will depend upon the method of calculation used, since all practical methods of calculating saturation in a magnetic circuit as complicated as a synchronous machine involve approximations or empirical factors. In table I, the ratio of pole to tooth plus pole ampere turns for several of the machines has been calculated by 2 or 3 different methods just to show the variation that is likely to be obtained.

In compiling table I, most machines were chosen at random, and the remaining few machines were chosen because they did not check the usual method of calculating saturation. All results have been included in the table, and no machines for which $X_p$ has been calculated have been omitted.

Considerable data have been included in table I just to give a better picture of each machine. Thus the values of $K_{nl}$, $K_p$, $X_d$, and $X_p$ are sufficient to permit virtual reconstruction of the saturation curves, and the division

**Figures 7, 8, and 9. Difference between test $X_p$ and $X_p$ calculated by equations 1, 2, and 3, respectively**

Note: In these figures, each machine is represented by a line from the zero axis up or down to the proper per cent difference. The lines are arranged from left to right in the order of decreasing magnitude to give, in effect, a distribution curve. These curves are indicated to a more correct scale in figure 6

of saturation between stator and rotor can be determined from the ratio of pole ampere turns to pole plus tooth ampere turns given in column 15.

## Comments on the Difficulties of Calculating Accurately Potier Reactance

As mentioned before, Potier reactance is a somewhat fictitious reactance, and consequently the more exact method of calculating it to be discussed below will be quite different from the usual method of calculating a reactance, and will consist only of calculating 2 saturation curves, one under full-load zero power factor conditions, and the other under no-load conditions. Furthermore, since the usual methods of calculating saturation curves are so well known, the following discussion will assume a knowledge of the general method, and will discuss only 3 details that have particular bearing on the difference between the no-load curve and the full current zero power factor curve.

1. At no-load, the flux form in the air gap is shown for a typical machine in figure 10. The estimated effect of saturation on this flux form is shown at 125 per cent

voltage by the dotted curve on the same figure. The flux form constants of these waves are tabulated in the figure. The ratio between the fundamental peak and the actual peak flux is $C_1$. The ratio of the average to the peak value of the actual flux wave is $C_p$.

2. Under full current zero power factor conditions, the same curve and its constants are also shown in figure 10. The obtaining of these curves, especially the ones under saturated conditions, may involve considerable cut and try work or else good approximations, but the calculation of tooth and of gap ampere turns is relatively simple once the constants have been obtained. It is assumed that tooth flux and gap flux are identical because, as shown in the appendix, tooth saturation occurs largely at the tips of the teeth. Actually, the flux form changes continuously between the tips and the base of the teeth. In general, the flux forms become flat-topped soon after saturation occurs in the teeth. Saturation in the pole between damper bars or in the pole tips has been neglected, but may be quite important in the occasional machines where it occurs.

3. Having calculated tooth and gap ampere turns by

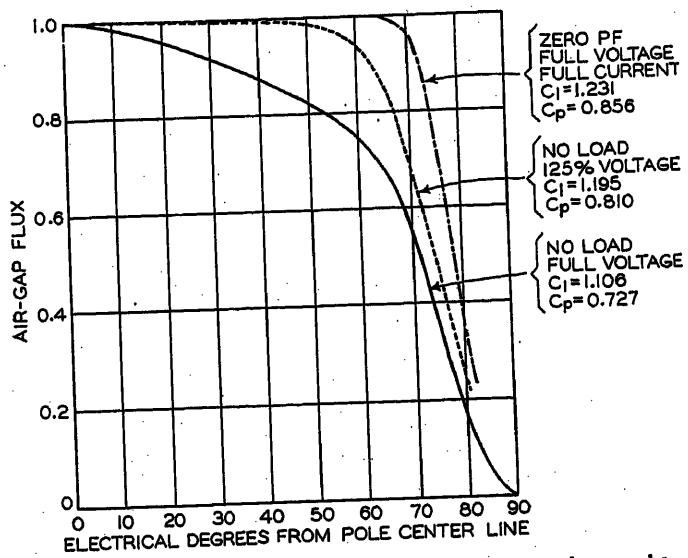

**Figure 10. Flux forms for a typical salient-pole machine under different operating conditions**

the usual methods, but using the above corrected values of $C_1$ and $C_p$, the next step is to calculate pole ampere turns; but in order to do this, the field leakage flux must be obtained. If a constant permeance is assumed in the leakage flux paths between pole sides regardless of the amount of flux or shape of the field, then the leakage flux is this permeance times the number of ampere turns acting, and the per unit leakage is this flux divided by the average flux from figure 10.

For help in approximating the ampere turns acting to produce flux between pole sides, the sketches of figure 11 have been drawn. Two things should be noted: first, that the ampere turns acting between pole heads is practically the sum of the gap ampere turns plus the demagnetizing ampere turns plus the tooth ampere turns—all under the proper conditions of flux form and saturation; second, that the ampere turns acting between the pole sides may sometimes act in a direction that tends to reduce the pole density instead of increasing it. In other words, the leakage flux between pole sides may actually become negative so that the effective permeance between pole sides does not remain constant. This second effect takes place only when the pole saturation becomes an appreciable part of the total ampere turns, but the amount of the effect will always differ between no-load and full load because of demagnetizing ampere turns, and consequently, will affect Potier reactance.

The above 3 items (1. change of wave shape with tooth saturation, 2. change of wave shape with demagnetizing ampere turns, 3. change of pole side leakage flux with pole saturation) are the major ones causing difference between the no-load and full-load saturation curves. Items 1 and 2, for example, cause the air gap ampere-turn line to bend back at higher voltages as shown in figure 12 instead of being the straight line it is often considered to be. Item 3 causes appreciable reduction in pole density at the high voltages and currents where pole ampere turns are greater than gap ampere turns.

It must be remembered in considering the above, that all practical methods of calculating synchronous machine

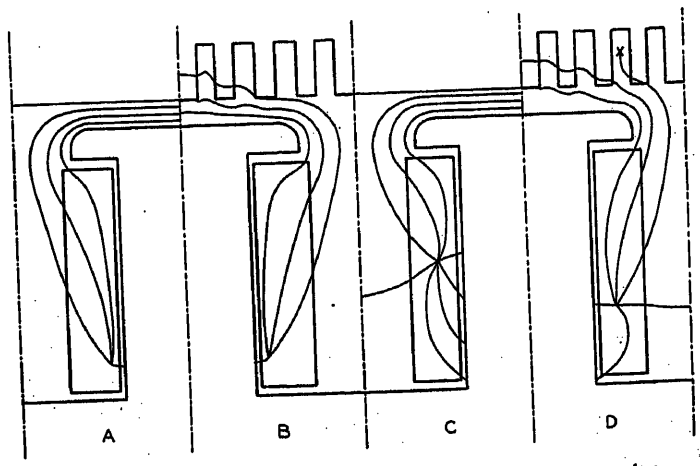

**Figure 11. Approximate flux maps for different conditions (ampere turn lines only are shown)**

*A*—No load, no saturation
*B*—No load, no pole saturation. Tooth ampere turns equal gap ampere turns
*C*—No load, no tooth saturation. Pole ampere turns equal gap ampere turns
*D*—Full load, zero power factor. Pole, tooth, gap and demagnetizing ampere turns equal

saturation are approximate, and that the only really exact method is to make flux plots of the entire circuit, including both saturated and unsaturated portions.

## Saturation of Potier Reactance

In the preceding analysis, no attempt has been made to show in detail the effect of saturation on $X_p$. In com-

piling table I, all comparisons have been made arbitrarily at rated voltage and rated current, and the unsaturated value of $X_d'$ has been used. The use of the saturated value of $X_d'$ is not thought to be justified because saturated reactance depends upon $d\phi/dI$, that is, upon rate of change of saturation, while saturated $X_p$ does not.

## Symbols

$X_{d'}$ = direct axis transient reactance
$X_p$ = Potier reactance
$X_d$ = direct axis synchronous reactance
$X_l$ = armature leakage reactance
$X_{ad}$ = direct axis demagnetizing reactance ($= X_d - X_l$)
$AT$ = ampere turns per pole
$K_{nl}$ = ratio of no-load ampere turns to gap ampere turns at 100 per cent voltage
$K_p$ = ratio of no-load ampere turns to gap ampere turns at (100 per cent plus per cent $X_p$) voltage
$C_1$ = ratio of fundamental to maximum of air gap flux form
$C_p$ = ratio of average to maximum of air gap flux form

## Appendix—Use of Exponential Formula for Saturation Curve

The saturation curve of iron very closely approximates an exponential curve over the usual ranges used in synchronous machines. In figure 13, the ampere turns per inch required by a saturated wedge-shaped tooth are shown for 2 values of maximum density—140,000 and 110,000 lines per square inch. The actual curve and the exponential representation of it have both been drawn in order to show the substantial agreement that exists between them. The

*B*—Under full-load zero - power - factor conditions

total ampere turns required to force the flux from tooth tip to any ordinate of the curve is shown by curve $B$ of the same figure, and is equal to a constant times the integral of curve $A$. The interesting thing to note is that if the exponential representation is chosen, the curve of total ampere turns (curve $B$) becomes the usual curve of exponential decay or build up, from which it can be seen that if the wedge-shaped tooth were replaced by a parallel-sided tooth whose length was equal to the distance from the tooth tip to the point where $\frac{\text{tooth width}}{\text{minimum tooth width}} = 1.10$, approximately the same total ampere turns as in the whole wedge-shaped tooth would be obtained.

If an exponential equation is used for saturation, then the ratio of tooth to pole ampere turns can be approximated as

$$\frac{\text{tooth ampere turns}}{\text{pole ampere turns}} = \left(\frac{\text{tooth length}}{\text{pole length}}\right)^{\epsilon \frac{0.07\ (\text{tooth density} - \text{pole density})}{1{,}000}} \tag{4}$$

And equation 1 will become:

$$X_p = X_l + (X_d - X_l) \times \frac{1}{1 + \left(\frac{\text{tooth length}}{\text{pole length}}\right)^{\epsilon \frac{0.07\ (\text{tooth density} - \text{pole density})}{1{,}000}}} \tag{5}$$

# Characteristics of the New Station-Type Autovalve Lightning Arrester

By W. G. ROMAN
ASSOCIATE AIEE

THIS PAPER is a description of the characteristics of a new line of station-type autovalve arresters. These arresters are designed to limit the surge voltage to a low value for all types of surges, and at the same time to have high enough 60-cycle breakdown and cut off characteristics to be practically free from trouble due to transient 60-cycle overvoltages.

The arrester elements are sealed in porcelain weather casings having aluminum-alloy castings cemented to each end. The castings serve to make electrical connection to the arrester elements and to bolt the separate units of a complete arrester together. The autovalve blocks are cemented in the porcelain casing with a hard chlorinated wax which acts as a mechanical support for the blocks and prevents any movement during shipping or erection. The gap assemblies are sealed in porcelain tubes having spun metal caps soldered directly to a band of metallic glaze on the porcelain. The gaps are dried before making the final seal by forcing hot dry air through them for several hours. Figure 1 is a cut-away view showing details of the construction of a 60,000-volt arrester.

In developing this arrester it was found that improvements in protective ratio, 60-cycle breakdown characteristics, and interrupting ability of the gaps could be made by utilizing 2 independent gap structures, each of which was designed for its particular purpose. The 2 gap structures have been called switch gap and quench gap. Normally the switch gap is located at the top, and the quench gap at the bottom of the arrester. In the higher-voltage arresters, the quench gap is in 2 or more units. Each gap unit, together with the proper number of porous blocks, is assembled in a separate casing, as in the lower half of figure 1. The complete arrester is built up of these quench-gap and block units with a switch gap either mounted directly on them or suspended above them.

The quench gap has a high 60-cycle breakdown and power follow interrupting ability, and at the same time a low surge breakdown. The high interrupting ability has been obtained by using a large number of closely spaced gaps. The high 60-cycle and low surge breakdown has been obtained by using a gap element which has an impulse ratio of very nearly unity, and by using a resistance shunt to distribute the voltage evenly across all of the gaps. In figure 2 is shown a unit of 3 gaps assembled inside the molded resistance ring. The low impulse ratio of this type of gap is probably due to the formation of a corona or similar discharge near the points of contact of of the mica washer and the electrode. This discharge furnishes an abundance of ions for the gap, and as a result the gap is very fast and has a low impulse ratio. As a check on this, tests were made in which a ring of Micarta between the outside edges of the electrodes was substituted for the mica washers. Although the gap spacing was the same, the impulse breakdown became erratic and impulse ratios as high as 2 were obtained. In the assembled gap a number of units of 3 gaps and a resistance ring stacked on top of each other are sealed in a porcelain gap tube. The spring spacer between units assures good contact to the resistor and takes up any manufacturing variation in the parts.

The switch gap insulates the arrester from the line voltage and prevents the continuous passage of leakage current through the resistance shunt of the quench gap. This is a multiple gap using pressed-brass electrodes separated by porcelain spacers. Improvement has been obtained in the impulse ratio of these gaps by using a molded insert of granulated carborundum in the face of the electrode. A double-gap element of this type is shown in figure 3. The surface of the insert is slightly below the face of the electrode and the arc takes place between the metal surfaces and not to the surface of the carborundum insert. The chart of figure 4 shows the results of tests on 4 gap assemblies, each composed of 2 gaps, as in figure 3, in series. The 60-cycle breakdown and 10 front-of-wave breakdowns were taken on each gap assembly. Each gap assembly, in series with an autovalve block, was then surged 50 times with a 4,000-ampere surge while connected to a 3,000-volt power source. Then the 60-cycle and impulse tests were repeated. This was continued until a total of 200 power follow shots had been reached In the chart the vertical lines represent the spread in the impulse ratio of a particular gap assembly for 10 tests. The number above each line designates the gap assembly tested. The line in the column at the right shows the spread in impulse ratio of a similar gap assembly without the inserts.

The operation of the dual gap in the complete arrester is as follows: When the surge voltage becomes 50 to 75 per cent above the crest of the arrester rating, the switch gap breaks down and the entire voltage is applied to the quench gap. If the voltage continues to rise, the quench gap breaks down when the voltage reaches 125 to 150 per cent above the crest of the arrester rating. The surge is then discharged through the autovalve blocks which hold the surge voltage to a safe value. After the surge is discharged, the normal-frequency current of approximately 20 amperes crest passed by the autovalve blocks is inter-

rupted at the first current zero by the quench gap. The leakage current of less than a milliampere passed by the quench-gap shunting resisters is then interrupted by the switch gap.

Figure 5 is a curve of the protective ratio as a function of the time to breakdown of the dual gap on various wave fronts. The time to breakdown was taken as the time from zero to breakdown voltage on an average front taken between the 10 and 90 per cent points. In order to get a common scale for the different ratings, the actual breakdowns in kilovolts were divided by the crest value of the maximum arrester rating in kilovolts. The actual gap breakdown of any particular arrester can be obtained by multiplying the crest of maximum arrester rating by the protective ratio for any time to breakdown. This curve shows how fast the arrester gap is. For example, on the standard rate of rise of 100 kilovolts per microsecond for each 11.5 kilovolts of arrester rating the breakdown occurs in about 0.4 microseconds and the ratio is about 2.4. Even doubling the rate of rise, which means a breakdown in the very short time of 0.2 microseconds, only increases the gap protective ratio to about 2.6.

The autovalve block has a high surge-current-discharge capacity and at the same time a low protective ratio. The protective ratio on the standard 1,500-ampere 10x20 wave is 2.1. This means that for a current of this type the voltage across the arrester elements will be limited to 2.1 times the crest of the arrester rating. In order to compare the protective characteristics of the arrester with the characteristics of insulation to be protected, its performance on various rates of rise of current, as well as crest currents must be known. The results of tests on these blocks at crest currents of 1,500, 5,000, and 10,000 amperes with the rates of rise of currents varying from 300 amperes per microsecond to 10,000 amperes per microsecond are shown in the curves of figure 6. An idea of the meaning of a current rising at the rate of 10,000 amperes per microsecond can be seen when it is considered that a traveling wave on an open line of 400 ohms surge impedance rising at the rate of 2,000,000 volts per microsecond would be needed in order to produce this rate of rise of current in an arrester connected at the end of the line. These curves strikingly show the flat characteristic of the autovalve block. Even at surge currents of 10,000 amperes and rates of rise of 10,000 amperes per microsecond, the protective ratio is held to the low value of 2.8. These data have been replotted in a more useful form in the curves figure 7. These curves give the protective ratio of the arrester at various surge current for the rates of rise of current of 1,000, 5,000, and 10,000 amperes per microsecond. Since the curves are relatively close together, rates of rise between the values shown can be easily interpolated. From these curves the voltage which will appear across any given arrester for any assumed current wave shape can be easily determined. The protective ratio for any rate of rise and crest current can be determined from the curves. The crest value of the maximum 60-cycle rating of the arrester multiplied by this ratio gives the surge voltage across the arrester.

This arrester can safely discharge surge currents in excess of 50,000 amperes without damaging the arrester. On surge currents of this high magnitude the arrester still offers protection to insulation, as can be seen by examining the oscillograms of figure 8. These oscillograms

*C, D*—A 6-kv block discharging 79,000 amperes—20,000 ampere per microsecond. The crest voltage of 29 kv represents a protective ratio of 3.4

*E, F*—Two 6-kv blocks in series discharging 53,000 amperes—13,000 amperes per microsecond. The crest voltage of 48 kv represents a protective ratio of 48/(12 × 1.41) = 2.8

were taken on 6-kv autovalve block units. Since the characteristics of the autovalve block add directly, tests on single blocks can be extrapolated to any arrester rating.

At its maximum rated 60-cycle voltage the *SV* arrester will pass a power follow current of between 20 and 30 amperes crest. This power follow current is interrupted at the first current zero by the arrester gap. The power follow current is low enough and of such short duration that it will not cause any system disturbances. Power-follow tests have been made on this design of arrester on ratings up to 60 kv, both dry and with a spray to simulate rain. Under no conditions has a failure been produced.

The results of various investigations on the surge current in the direct stroke in this country and abroad, show that the current in the majority of the strokes is below 50,000 amperes, with occasional very heavy strokes where the current reaches magnitudes of the order of 200,000 amperes. Norinder, of Sweden, has made measurements of the rate of rise of current by means of measurements of the magnetic field produced by the stroke, and he reaches the conclusion that in about 65 per cent of these strokes the maximum rate of rise of current is below 6,000 amperes per microsecond. Because of the nature of the instrument used in making these measurements, it is highly probable that a large number of strokes of low current and low rate of rise are not recorded at all, and therefore these data only include the strokes of most severity. Even taking this data as it is, we find that the new type of *SV* arrester will discharge the majority of the currents of direct strokes without damage to the arrester, and the arrester while discharging these high currents will offer a fair degree of protection to connected equipment. A station-type arrester is rarely called upon to discharge the entire current of a heavy direct stroke, because the arrester is normally

effectively shielded from direct strokes by the station itself. When heavy strokes occur to the line even in the span next to the station, they will probably cause a flashover of the line insulators, which will offer a parallel path to ground for the lightning currents.

The voltage, and therefore the current, associated with a traveling wave entering a station over the overhead lines is limited by the flashover voltage of the line insulation. It is interesting to analyze the performance of this *SV* arrester for the type of surge which would be expected to enter the station from an overhead line. On a 115,000-volt wood-pole line in Arkansas a cathode-ray oscillogram of a lightning surge was obtained which reached a crest voltage of 5,000,000 volts in slightly less than 2 microseconds and decayed to half value in about 8 microseconds.[1] This is the highest voltage lightning surge that has been

**Figure 11. Lightning arresters mounted directly on a power transformer**

recorded on a line. In figure 9*a* a replot of this oscillogram is shown,. Figure 9*b* shows the voltage which would appear across a type *SV* arrester rated at 121,000 volts maximum for ungrounded 115,000-volt application. Assuming a line surge impedance of 400 ohms, the crest current through the arrester would be approximately 24,-000 amperes and the rate of rise would be 20,000 amperes per microsecond. The arrester voltage reaches a maximum of about 530 kv. In figure 9 are also shown the time-lag curves of the 31½-inch co-ordinating gap and the transformer bushing. The co-ordinating gap has a minimum flashover of about 525 kv and therefore would probably flashover at a relatively long time lag.[2] The arrester voltage is well below the transformer bushing and the transformer major insulation level.[3] In figure 10 are shown performance curves for a 240-kv arrester applied on a 230-kv ungrounded system in which the line is on steel towers and insulated with 18 standard insulators. The arrester voltage is calculated for a line surge impedance of 400 ohms and a traveling wave rising at the rate of 2,000 kv per microsecond chopped on the rising front, at 5 microseconds, and the maximum full wave passed by the insulators. These voltages are all below the minimum flashover voltage of the 64-inch co-ordinating gap. In both of these examples the arrester for the ungrounded neutral application was used. If the neutral were solidly grounded, arresters rated at 80 per cent of these ratings would normally be used and the margin of protection would be correspondingly better.

# Relay Operation During System Oscillations

By C. R. MASON
ASSOCIATE AIEE

## Introduction

THE BETTER relays are made, the better they must be made. This is because better relays enable more economical transmission of power by permitting operation nearer to the stability limits of a system;[1] and the nearer to its stability limits a system operates, the more dependence is placed on its relays.

Relays have often been called superhuman, but they still believe what they see. Reference is made to system oscillations defined here as the oscillating interchange of power between synchronous machines when they hunt or go out of step with one another. Protective relays sometimes mistake these oscillations for short circuits, and trip important transmission lines.[2]

The chance tripping of a sound line is bad at any time. If it happens during hunting, a system might not regain synchronism through its other interconnections. If it happens when generating sources are out of step, a small source might be isolated with a large load, or vice versa. The necessary separation of generating sources on loss of synchronism should be performed by purposely designed relays at prearranged locations. Protective relays should function only for short circuits.[1]

The purpose of this paper is to show wherein a relay's vision is defective and to suggest remedies. We shall first discover what a system oscillation looks like to a relay. Then we shall compare this with short circuits and attempt to find a difference in their appearance. And finally, we shall apply whatever corrective measures are possible.

## Characteristics of System Oscillations

In order to simplify the problem, it is assumed that as far as system oscillations are concerned

1. The system can be represented by figure 1
2. All parts of the system always have the same ratio of reactance to resistance, and the impedance of each part is constant
3. The generator voltages behind transient reactance are always equal and constant in magnitude
4. All electrical quantities are referred to the secondary sides of current and potential transformers which transform without change in phase angle

Because the type of system oscillations involved here are balanced 3-phase phenomena, it is sufficient to consider the current of only one phase and its relation to its line-to-neutral voltage as in figure 2. The difference voltage $(V_A - V_F)$ impressed across the total line-to-neutral impedance of the system, causes the current $I$ to flow between the sources. The angle $\phi$ by which $I$ lags the difference voltage is a constant. As $\theta$ changes, the magnitude of $I$ and its angular relation to each of the substation voltages changes. The voltage difference between any 2 points is always a constant proportion of the total difference $(V_A - V_F)$, and hence each vector, which on figure 2 represents a substation voltage, always terminates at a constant division point on the difference voltage. This constant, which defines any location, and which will be called $n$, is often called the "per unit impedance" from the neutral of source $F$ to the given location.

The following values of $n$ are chosen to locate the various points shown in figure 1.

| Point | n |
|---|---|
| Source *F* | 0 |
| Substation *E* | 0.2 |
| Substation *D* | 0.4 |
| Substation *C* | 0.6 |
| Substation *B* | 0.8 |
| Source *A* | 1.0 |

For one cycle of slip between the 2 sources, the voltage vector of one source describes a complete rotation with re-

spect to the voltage vector of the other source. If only hunting occurs, one voltage swings within a limited sector both sides of the other.

The following equations describe the numerical relations between $\theta$ and each electrical quantity affecting relay

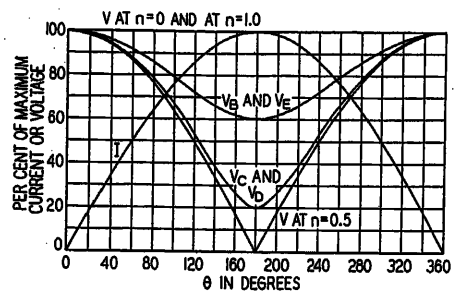

**Figure 3. Voltage and current magnitudes at each substation for one complete slip cycle, or for 0 to 360 degrees displacement between the 2 sources**

operation. In all of the following discussions, $\theta$ will be measured counterclockwise from $V_F$ to $V_A$.

$$I = \frac{2V_A}{Z'} \sin \frac{\theta}{2} \tag{1}$$

$$V = V_A \sqrt{\cos^2 \frac{\theta}{2} + (1 - 2n)^2 \sin^2 \frac{\theta}{2}} \tag{2}$$

$$\omega = (90 - \phi) + \tan^{-1}\left[(1 - 2n) \tan \frac{\theta}{2}\right] \tag{3}$$

where $\omega$ is the angle between $V$ and $I$. When $\omega$ is positive, $I$ leads $V$.

$Z'$ = total line-to-neutral impedance of the system
$V$ = voltage for any intermediate point

In these and in equations to follow, $V_A$ and $V_F$ may be used interchangeably because they are assumed to be equal in magnitude.

Figure 3 shows how $V$ and $I$ at each station vary with $\theta$, and figure 4 shows the relation between $\omega$ and $\theta$ when $\phi$ is assumed to be 75 degrees.

A step toward obtaining a clear understanding of the picture seen by relays is to put the relations of equations 1 and 3 into the form of figure 5. The arrow heads on the curves show the direction in which the head of the current vector moves as $\theta$ increases from zero. Current vectors are shown for a value of $\theta$ less than 180 degrees. Note that for a given angle, all current vectors have the same length. The curves are symmetrical about an axis inclined at the angle $\phi$ below the reference axis. The curves for $n = 1$ and $n = 0$ are equal circles externally tangent at the origin and centered on the axis of symmetry.

The curve for $n = 0.5$ is shown dotted. As $\theta$ increases, the current increases maintaining a constant angular position with respect to its reference voltage. When $\theta$ goes through 180 degrees, the line-to-neutral voltage decreases to zero and reverses, but since this voltage is the reference, the current must be shown as increasing to a maximum and reversing in zero time. What happens to the curve when $\theta$ is 180 degrees may be matter for conjecture, but for values of $n$ slightly greater or less than 0.5, the curves approach the dotted circle shown.

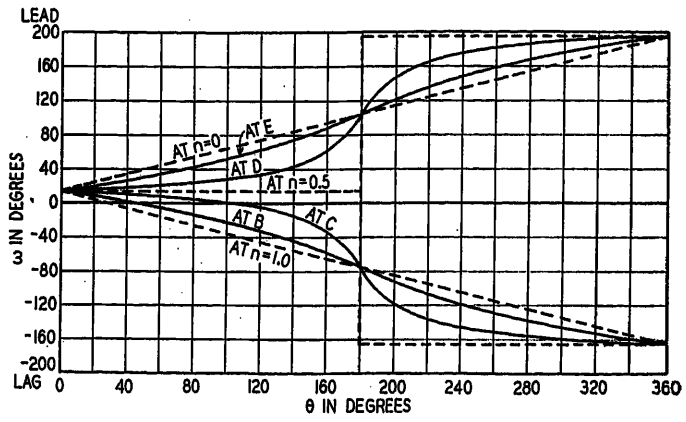

**Figure 4. Phase angle between the current and the voltage at each station for one complete slip cycle**

The final step in preparing the picture of oscillations as seen by relays is to correct some of the curves of figure 5 by taking into account the point of view of the various relays. Thus far, our picture is one looking down the line from $A$ toward $F$. The relays connected to trip breakers 1, 3, and 5 are arranged to look in this direction, but the relays at breakers 2, 4, and 6 view the oscillation from the other direction, and to them the current is reversed.

Making the necessary corrections, and separating the curves so as to place each next to the point for which it applies, we have the final picture shown in figure 6. These curves are not expected to show quantitative data, but they have been found invaluable for visualizing the oper-

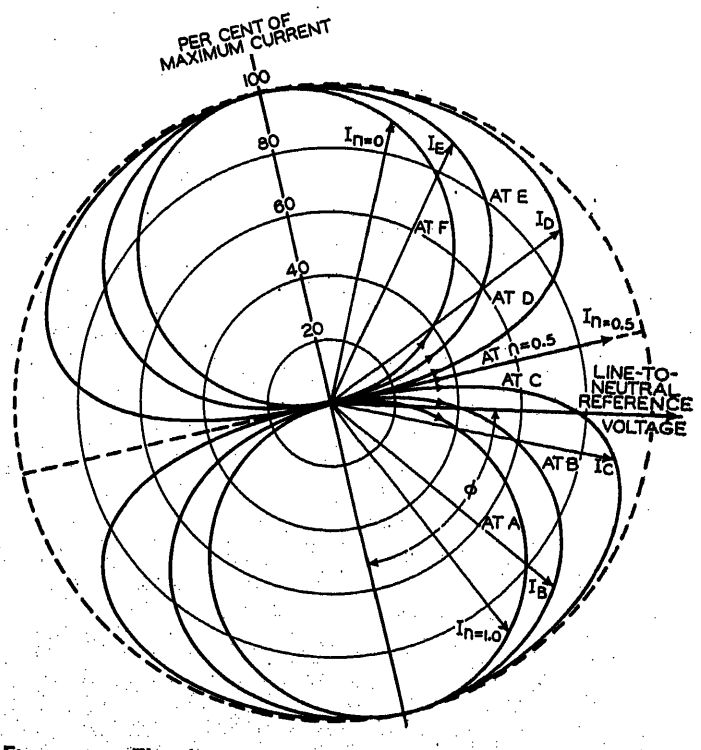

**Figure 5. The locus traced by the head of the current vector at each station with respect to the line-to-neutral voltage at the corresponding station for one complete slip cycle. Each locus is lettered to correspond to the station of figure 1 for which it applies**

ating tendencies of various relays and for interpreting quantitative data derived from trigonometric analysis.

## Operation of a Simple Directional Relay

Because system oscillations are balanced 3-phase phenomena, a polyphase directional relay operates the same as a single-phase relay. Typical operating characteristics of a single-phase directional relay are shown in figure 7 for various voltage magnitudes. The line-to-neutral voltage vector is the reference. For the relay to close its tripping contacts at a given voltage, the current vector for the phase corresponding to the reference voltage must intersect the operating characteristic for the particular voltage as shown by $I$ for 5 per cent of rated voltage. At any given voltage the least current required for operation is that at the angle $\tau$, and hence $\tau$ is called "the angle of maximum torque." The least current which will cause operation at normal, or rated, voltage of the relay is called "the minimum pick-up current." This current is shown as $I_{MIN}$.

The angle of maximum torque is chosen, and the relay is connected, so that the operating region, lying to the right of each characteristic, and extending nearly 90 degrees either side of the angle of maximum torque, will encompass any short-circuit current for which the relay must operate. Generally, the angle of maximum torque is chosen to lie approximately mid-way between the extreme angular positions which the short-circuit current can take for different faults.

If we superimpose the operating characteristic for normal voltage with the proper scale on each of the curves of figure 6, we are provided with an excellent perspective of directional-relay operation during system oscillations. Even though the effect of voltage variation is not shown, the conception gained by this procedure is of much value.

In order to obtain quantitative data, it is necessary to resort to an analysis, the result of which is given in the following equation:

$$T = K_1 V_A \left\{ \pm I_{MAX} \left[ (2n-1)\cos(\tau-\phi)\sin^2\frac{\theta}{2} - \sin(\tau-\phi)\sin\frac{\theta}{2}\cos\frac{\theta}{2} \right] - I_{MIN} \right\} \quad (4)$$

where

$T$ = relay torque; positive torque closes the relay contacts; negative torque opens the contacts
$K_1$ = a constant
$I_{MIN}$ = the minimum pick-up current of the relay
$I_{MAX}$ = the current which the relay gets when the 2 sources are 180 degrees out of phase

The $\pm$ sign before the first term in the braces is necessary to account for the fact that different relays view a system oscillation in different directions; the $+$ sign applies to relays connected to trip breakers 1, 3, and 5; the $-$ sign applies to relays at breakers 2, 4, and 6.

Equation (4) is general and can be used to determine the operation of a directional relay at any location under any assumed conditions, such as those assumed for figure 8 *a*, *b*, and *c*.

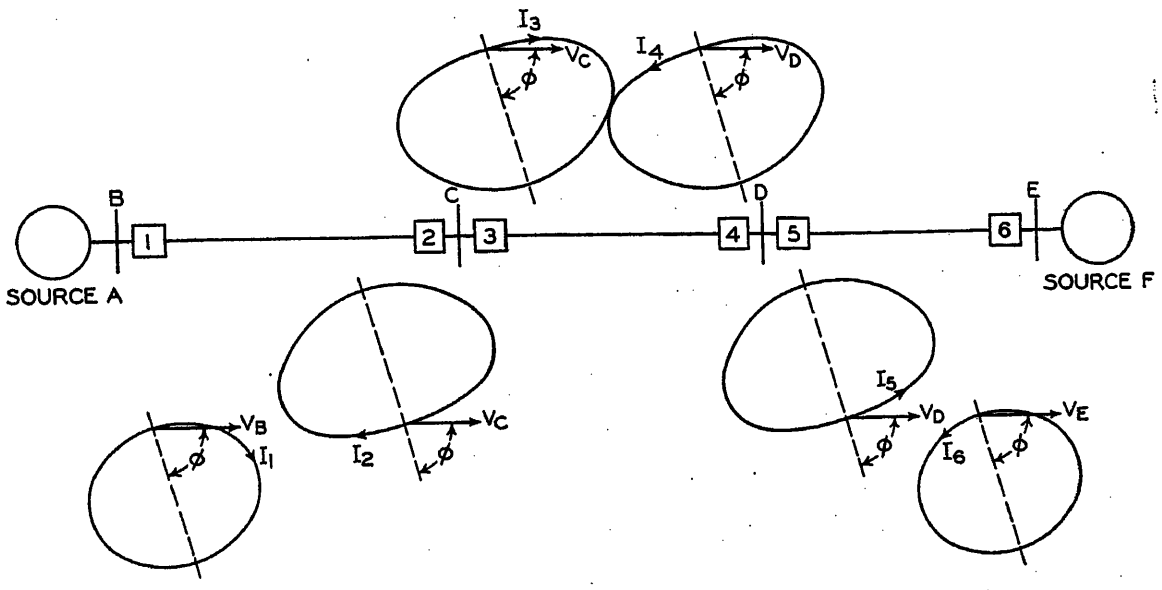

**Figure 6. Paths traced by the head of the current vector with respect to its line-to-neutral voltage at each substation for one complete slip cycle. These loci are corrected for current transformer polarity according to the direction in which relays view the current at each station**

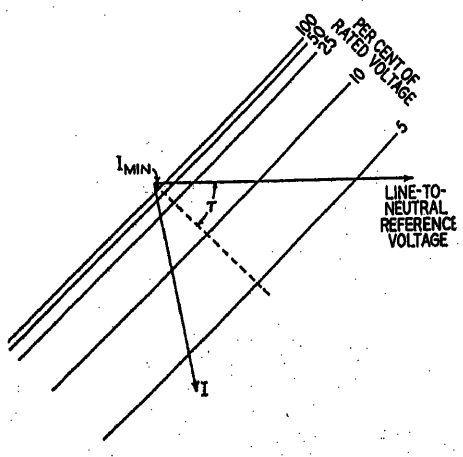

**Figure 7. Operating characteristics of a single-phase directional relay, with reference to its line-to-neutral voltage for various voltage magnitudes**

Along the abscissa of each curve of figure 8 are the angles by which source $A$ *leads* source $F$. If source $A$ starts to *lag* source $F$, we must start at 360 degrees and move to the left in reading the curves. Thus during hunting, if source $A$ leads $F$ and then swings back and goes lagging, we should start from zero degrees and move to the right until source $A$ begins to swing back; then we must retrace our path to zero, start from 360 degrees, and move to the left as $A$ goes lagging, etc.

The curves of figure 8 show that for small displacement angles between the oscillating sources, the directional relays which face in the direction from the leading to the lagging source immediately close their tripping contacts, while the relays facing in the other direction have the opposite tendency. Thus, in the early stages of an out-of-step oscillation, the relays think that there is a short circuit at the lagging end of the system. As the swing progresses, there comes a time when the relays at both ends of a line perceive a flow of current as to a short circuit in the line which they protect. This condition occurs first for a section of line nearest the lagging end, and then progresses successively through each line toward the leading end as the displacement angle increases further. And finally, as the displacement widens still more, the end which had been leading becomes lagging, and the apparent short circuit passes on toward that end.

During hunting the apparent short circuit moves in from one end, retreats, moves in from the other end, retreats, etc. If the swing is not severe, only the end sections of line alternately may seem to contain a short circuit.

The assumed value of $(\tau - \phi)$ for figure 8 is representative of most relay applications. The limiting values which $(\tau - \phi)$ may have are zero and $-90$. For the former, there would be danger of failure of the relay to operate for arcing faults near the relay location, and for the latter, the relay might operate sluggishly on highly lagging short circuit current. If $(\tau - \phi) = 0$, the relays at breakers 2 and 5 would never close their tripping contacts, while the relays at breakers 1, 3, 4, and 6 would always close their contacts regardless of the displacement or of which source went leading. If $(\tau - \phi) = -90$ the relays at opposite ends of each line would always have opposite directions of torque which would reverse with no overlap when the displacement went through 180 degrees.

It is evident that all directional relays throughout a system cannot separately be adjusted to preclude the operation of some of them during system oscillations. Since other types of relays are invariably used with directional relays, we must of course examine their characteristics too before drawing conclusions as to the over-all operation of any protective scheme.

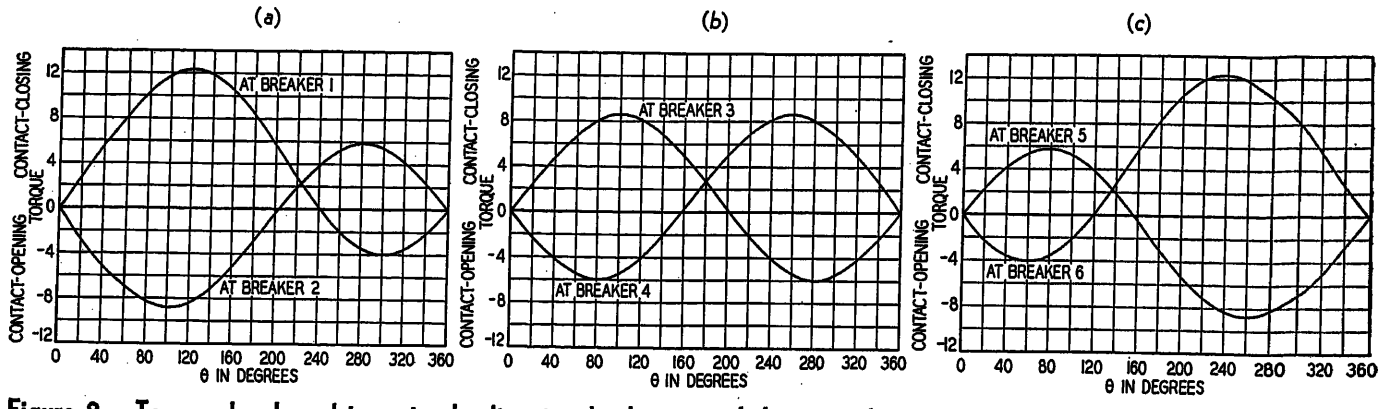

**Figure 8. Torque developed in a simple directional relay at each location during one complete slip cycle according to equation 4 with the following assumptions:**

$(\tau - \phi) = -45$ degrees. In other words, the angle of maximum torque is 45 degrees leading the natural system phase angle

$I_{MAX} = 20$ amperes $I_{MIN} = 0.1$ ampere

$K_1 V_A = 1.0$. This value has no effect on the direction of the torque, but merely on its magnitude

## Operation of Directional Relays With Voltage Restraint

A directional relay with voltage restraint is a simple directional relay which is given an impedance characteristic, or a voltage restraint, for current flow in its tripping direction. The operating characteristics of such a relay are shown in figure 9. It will be noted that the minimum pick-up current $I'_{MIN}$ is a maximum at normal, or rated, voltage, and as the voltage decreases the pick-up current decreases. However, at very low voltages where the restraint becomes negligible, the pick-up current increases the same as for a simple directional relay; to avoid confusion, this is not shown on figure 9.

The superposition of this operating characteristic on the curves of figure 6 would have much the same appearance as for the simple directional relay. It is obvious, however, that the voltage restraint will render this relay less sensitive to oscillations.

An analysis of the operating tendencies of a directional relay with voltage restraint provides the following torque equation:

$$T = K_1 V_A \left\{ \pm I_{MAX} \left[ (2n-1)\cos(\tau-\phi)\sin^2\frac{\theta}{2} - \sin(\tau-\phi) \times \sin\frac{\theta}{2}\cos\frac{\theta}{2} \right] - I_{MIN} - (I'_{MIN} - I_{MIN}) \left[ (1-2n)^2 \sin^2\frac{\theta}{2} + \cos^2\frac{\theta}{2} \right] \right\} \quad (5)$$

where $T$ and $K_1$ have the same meanings as for equation (4) and where:

$I_{MIN}$ = the minimum pick-up current of the relay if the voltage restraint is removed

$I'_{MIN}$ = the minimum pick-up current of the relay with voltage restraint

The significance of the $\pm$ sign before the first term of equation 5 is the same as for equation 4.

Curves illustrating relay operation according to equation 5 are given in figures 10*a*, *b*, and *c* The effect of the voltage restraint is largely to move the curves of a simple directional relay bodily toward the nontripping region. This effect is more pronounced for small displacement angles for which the voltage restraint is relatively high. As the voltage decreases with increasing displacement, the curves approach those of the simple directional relay more closely the nearer the relay is to the impedance center of the system. The curve for a voltage-restrained directional relay at the impedance center would converge to the curve of a simple directional relay at $\theta = 180$ degrees.

The voltage restraint chosen for the curves of figure 10*a*, *b*, and *c* does not prevent incorrect relay operation for the assumed conditions during out-of-step system oscillations. It is natural to inquire if, by a better choice of the restraint, operation can be prevented. If we revert to figures 8*a*, *b*, and *c* and read the contact closing torque of a relay without restraint for any given displacement angle, we can equate this torque to the last term of equation 5 which gives the voltage-restraint torque, and hence find a value of $I'_{MIN}$ to reduce the total torque to zero. This value of $I'_{MIN}$ will vary with the displacement angle, and several trials will be necessary to find the proper value so that at no angle does the curve go positive.

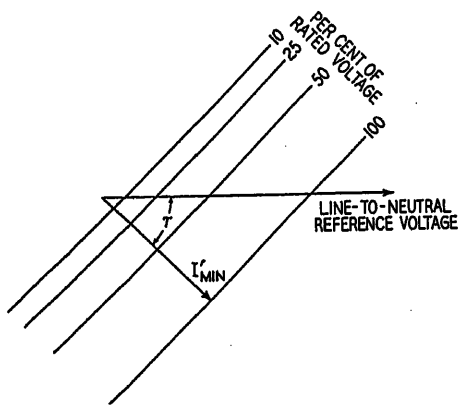

**Figure 9. Operating characteristic of a directional relay with voltage restraint, referred to its line-to-neutral voltage, for various voltage magnitudes**

The result of such a study is tabulated below:

| For No Operation During System Oscillations | | | Relay Current and Voltage for a Fault at Distant End of Line | | | Relay Pick-up for the Fault |
|---|---|---|---|---|---|---|
| For the Relay at Breaker | $I'_{MIN}$ | Must Be | I | | V | $I_{p.u.}$ |
| 1 | 28.2 amperes | 25 amperes | 0.5 | $V_A$ | 20 amperes | |
| 2 | 13.7 amperes | 12.5 amperes | 0.25 | $V_A$ | 4.9 amperes | |
| 3 | 79.0 amperes | 16.7 amperes | 0.33 | $V_A$ | 37 amperes | |
| 4 | 79.0 amperes | 16.7 amperes | 0.33 | $V_A$ | 37 amperes | |
| 5 | 13.7 amperes | 12.5 amperes | 0.25 | $V_A$ | 4.9 amperes | |
| 6 | 28.2 amperes | 25.0 amperes | 0.5 | $V_A$ | 20 amperes | |

The crucial test of the adjustment is that a relay must operate for faults in the line it protects. Hence, the tabulation lists also the fault current and voltage each relay will have for a fault at the distant end of its line, together with the pick-up current of the relay for the fault voltage. This pick-up current is obtained as follows:

$$I_{p.u.} = \frac{(I'_{MIN})\ (\text{per cent } V_A)}{100}\left[\frac{1}{\cos(\tau - \phi)}\right]$$

where we have assumed $\cos(\tau - \phi) = \cos(-45) = 0.707$.

The tabulation shows that if $I'_{MIN}$ is made large enough, all but the relays at breakers 3 and 4 can be prevented from operating during oscillations without preventing operation for faults because, except for the relays at breakers 3 and 4, $I_{p.u.}$ is always less than the fault current. It is impossible to correct for the misoperation of the relays at breakers 3 and 4 because the line they protect spans the impedance center of the system. When the 2 oscillating sources are 180 degrees out of phase, conditions at these relays are the same as for a dead 3-phase fault at the impedance center of the system which falls in the line between breakers 3 and 4. Hence, if the relays there are to operate for a 3-phase fault in the middle of their line, they cannot be prevented from operating when the oscillating

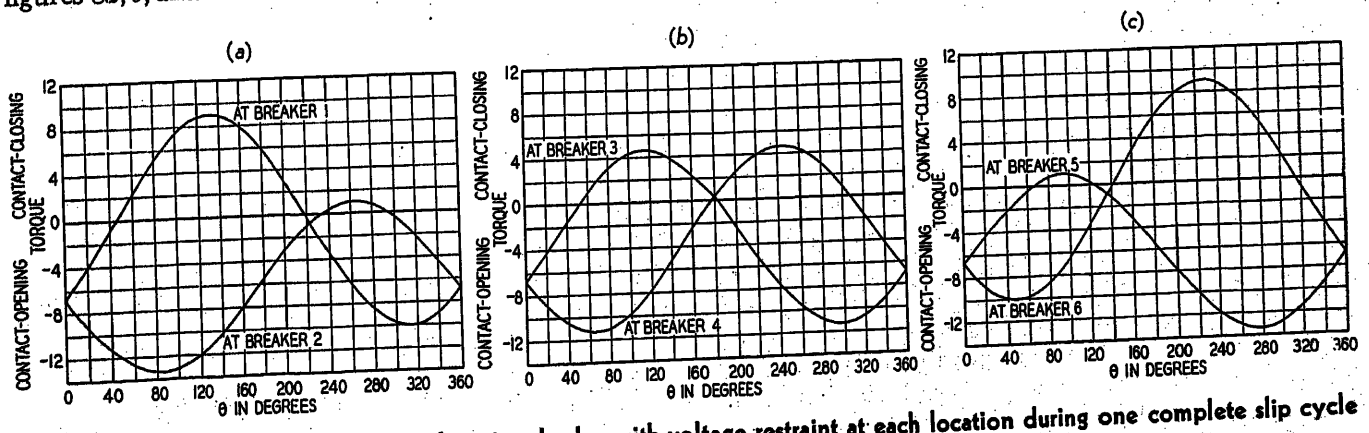

**Figure 10. Torque developed in a directional relay with voltage restraint at each location during one complete slip cycle according to equation 5 with the following assumptions:**

$(\tau - \phi) = -45$ degrees $\quad I_{MAX} = 20$ amperes $\quad I_{MIN} = 0.1$ ampere $\quad I'_{MIN} = 7.0$ amperes $\quad K_1 V_A = 1.0$

sources go through the 180-degree-out-of-phase position.

Since the angle of maximum torque also affects the operation of the relay, let us examine the effect of varying it. Was the choice of $(\tau - \phi) = -45$ the best possible? Considering only the relay at breaker 1, an analysis of its operation provides the following typical data concerning the value of $I'_{MIN}$ necessary to prevent operating during oscillations, and the pick-up current of the relay for faults at the distant end of its line, for values of $(\tau - \phi)$ either side of 45 degrees:

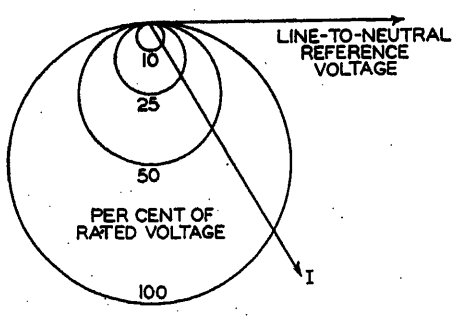

**Figure 11. Operating characteristic of a reactance element, with respect to its line-to-neutral voltage for various voltage magnitudes**

| $(\tau-\phi)$ | $I'_{MIN}$ | $I_{p.u.}$ |
|---|---|---|
| −35.0 deg | 30.0 amp | 18.3 amp |
| −45.0 deg | 28.2 amp | 20.0 amp |
| −55.0 deg | 26.1 amp | 22.7 amp |

These data indicate that as $(\tau - \phi)$ is reduced, the required $I'_{MIN}$ increases, and the pick-up current for the fault decreases. However, the particular fault considered provides highly lagging current. If the fault current should be more nearly in phase with the relay voltage, the pick-up current for that type of fault would increase when $(\tau - \phi)$ is reduced below −45 degrees. Similarly, as $(\tau - \phi)$ is increased, $I_{p.u.}$ for the highly lagging fault increases. The optimum value of $\tau$ is midway between the extreme angular positions which can be taken for the fault at the distant end of the line. For most lines this value of $\tau$ will probably lie between 45 and 85 degrees.

In the foregoing discussions concerning the choice of $I'_{MAX}$ and $(\tau - \phi)$, the attempt was made to prevent operation when the oscillating sources went out of step. The problem is obviously simpler if hunting only is considered. It is probable that, by proper adjustment, even the relays protecting a line which spans the impedance center could be restrained against operating during hunting.

These are not general conclusions, but they provide an indication of a possible solution to the problem for some cases. Where a long line exists whose impedance is a more sizeable portion of the total system impedance, it may be found impossible to adjust the relays to select between faults and severe oscillations. Similarly, it may be impossible to use a relay for back-up protection in the case of faults in adjoining lines if the relay is too highly restrained against improper operation during oscillations. And finally, we do not always have the ideal system setup, assumed for the purpose of analysis, where the location of the impedance center never changes, and where the oscillation is not accompanied by the short circuit which causes it. A general conclusion is that while in most cases the majority of voltage-restrained directional relays can probably be adjusted to improve their selectivity between faults and system oscillations, such adjustment is a satisfactory palliative, but not a complete cure.

## Operation of a Reactance Relay[2]

This discussion will be confined to the reactance element of a distance relay. Such an element responds properly only to lagging current in a given direction, and consequently it is always used in conjunction with a voltage-restrained directional element which prevents tripping except when a short circuit in the proper direction is indicated.

The operating characteristics of a reactance element are shown in figure 11. For a given voltage magnitude, such as 100 per cent, any current vector $I$, whose head lies outside of the characteristic circle for the chosen voltage, will cause the element to close its tripping contacts; the element will not operate for any current vector which falls within the circle.

The superposition of this characteristic on each of the curves of figure 6 will indicate that the element is more than likely to operate. In order completely to determine the appearance of an oscillation to a reactance element, the following equation has been derived:

$$X = \pm \frac{Z'}{2}\left[ (2n - 1) \sin \phi - \cot \frac{\theta}{2} \cos \phi \right] \qquad (6)$$

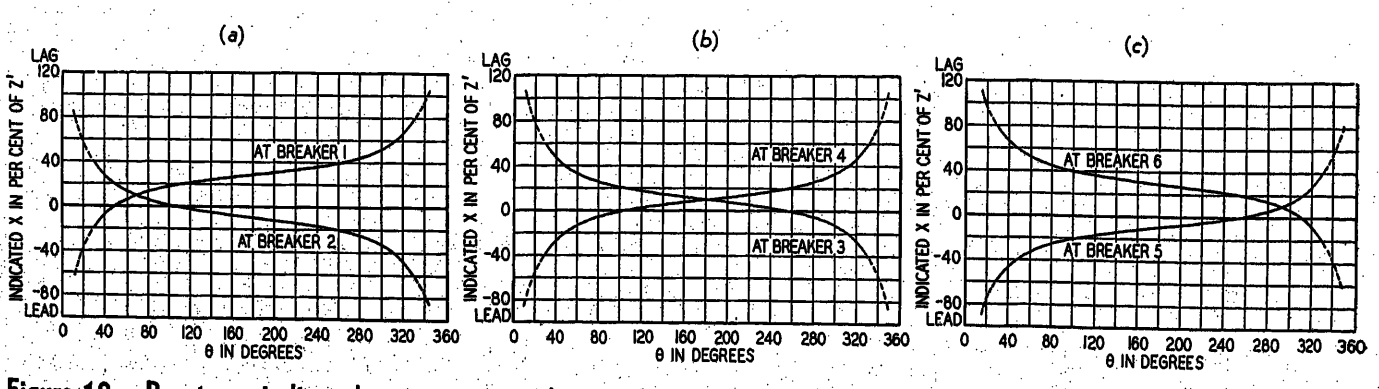

**Figure 12. Reactance indicated to a reactance element during one complete slip cycle. The element operates when the indicated reactance is less than a given positive value for which it is adjusted**

where $X$ = the reactance indicated to a relay; positive reactance means lagging current; negative reactance means leading current.

The + sign before the right-hand side of equation 6 is to be used for the relays at breakers 1, 3, and 5; the negative sign is for the relays at breakers 2, 4, and 6.

Curves according to equation 6 are shown in figure 12*a*, *b*, and *c*, for which it was assumed that $\phi = 75$ degrees.

In order to use figure 12 to determine relay operation, it is first necessary to establish a value of reactance for which the relay shall operate for faults. A distance relay having a stepped distance-time characteristic is adjusted to operate instantly on its lowest reactance setting for faults up to about 90 per cent of the length of the protected line; the second reactance setting is to provide operation for faults up to about 50 per cent of the length of an adjoining line; the reach of the relay on its third time step is determined solely by the reach of the directional unit.

Each line section of the system shown in figure 1 has a reactance of 20 per cent of the total system reactance. With $\phi$ assumed to be 75 degrees, 20 per cent of the system reactance is 19 per cent of the system impedance. The setting of the first reactance step will be approximately 17 per cent, and the second step 26 per cent, of the system impedance. This is equivalent to drawing horizontal lines on figure 12*a*, *b*, and *c* at heights of +17 per cent $Z'$ and +28 per cent $Z'$. The reactance elements will operate for all portions of the curves below these horizontal lines.

Figure 12 shows that the reactance elements at one end, and possibly both ends, of any line are likely to operate on hunting oscillations and that if out-of-step occurs, all elements will operate. It is evident, therefore, that the operation of the voltage restrained directional element will largely determine if tripping will occur. The time, or the reactance step, responsible for tripping would depend on the relay location and on the period and severity of the oscillation. The longer the time delay setting for the second and third steps, the less likelihood there is of operation. It is impossible to generalize except on the basis that if the voltage restrained directional element operates, tripping is possible.

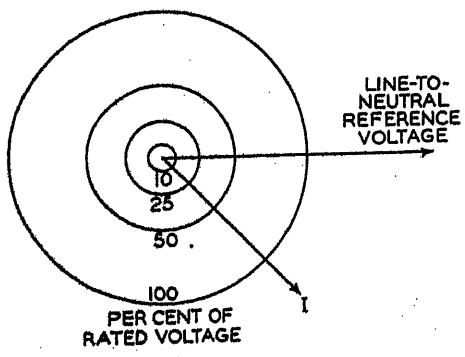

**Figure 13. Operating characteristic of an impedance relay, with respect to its line-to-neutral voltage for various voltage magnitudes**

## Operation of an Impedance Relay[2]

The operating characteristics of an impedance relay are illustrated in figure 13. This relay operates to close its tripping contacts when the head of the current vector lies outside of the circle for any given voltage, such as the current $I$ for 100 per cent of rated voltage. The superposition of this characteristic on the curves of figure 6 will indicate an increasing tendency to operate as the system displacement approaches 180 degrees.

More definite conclusions are possible based on the following equation:

$$Z = \frac{Z'}{2}\sqrt{(1-2n)^2 + \cot^2\frac{\theta}{2}} \qquad (7)$$

where $Z$ = the impedance indicated to a relay.

The operation of an impedance relay according to equation 7 is illustrated in figure 14. Conventional distance relays employing impedance elements have 3 such elements, one for each of the 3 distance-time steps. The first step covers about 90 per cent of the protected line, the second step reaches to about 50 per cent of the next adjoining line, and the third step extends to about 25 per cent of the third line section. For use with figure 14, these 3 adjustments may be taken, respectively, as 18 per cent, 30 per cent, and 45 per cent, of $Z'$, the total system impedance. Horizontal lines through these impedance values reveal the operating tendency of the elements.

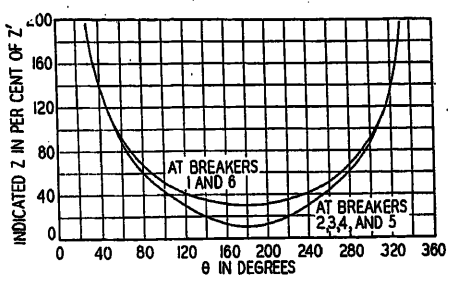

**Figure 14. Impedance indicated to an impedance relay during one complete slip cycle. The relay operates when the impedance is less than a given value for which it is adjusted**

For the assumed system, figure 14 indicates that operation of only the third step impedance elements at the end stations is likely to occur. All 3 impedance elements at the other stations will function depending on the amount of displacement. Here, as in the case of the reactance relay, a determination of which elements can cause tripping depends on their time settings and on the magnitude and the period of the oscillation. Since conventional distance relays having impedance elements employ an unrestrained directional element, the probable operation of such relays is almost solely determined by the operation of their impedance elements.

## Operation of Current and Voltage Relays

The curves of figure 3 are suitable for determining the operating tendencies of simple current or voltage relays. Only the use of time delay in the operation of such a relay can prevent it from closing contacts when its operating point is reached during an oscillation. It is desirable that the resetting time of such relays be as short as possible, else there will be a tendency for the contacts to "notch"

closed during continued oscillations. Incidentally, this quick resetting characteristic is desirable in any relay.

## Preventing Tripping During System Oscillations

The preceding analyses show that conventional relays are not individually endowed with enough discriminative ability to distinguish infallibly between any short circuit and any system oscillation. At various instants during oscillations, the electrical quantities affecting relay operation are identical to those existing during short circuits. Are there any differences between the characteristics of oscillations and of short circuits whereby discrimination can be made?

Fortunately, relays commonly used for protecting against ground faults are not affected by system oscillations. Such relays are energized with zero-phase-sequence current and voltage which are not produced by system oscillations. On the other hand, interphase faults not involving ground do not produce zero-phase-sequence quantities. Consequently, ground relays alone will not solve the problem unless protection only against faults involving ground is considered sufficient as a first line of defense.

The consideration of ground relays and the zero-phase-sequence quantities suggests the possibility of using the negative phase sequence current and voltage. System oscillations of the type considered are balanced 3-phase phenomena and hence contain only positive-phase-sequence current and voltage. Since interphase faults, except those which are balanced 3-phase, produce negative-phase-sequence quantities, this characteristic could be used for discrimination. However, there are those who will consider it heresy in view of the fact that balanced 3-phase faults have been known to occur. Barring the accidental closing in of a line on protective grounding devices which lineman have forgotten to remove, there are exceedingly few substantiated cases of short circuits originating in the balanced 3-phase state. Present-day high-speed relays would require an unbalance for only a short time in order to cause tripping. The protection against faults due to failure to remove grounding devices, however, is an easily solvable problem since these faults originate the instant the line breaker is closed. Auxiliary means could be used during that period to permit tripping even though the fault were balanced 3-phase.

The requirement that there be an unbalance in current between the 3 phases in order to permit tripping has been used as a first line of defense measure against short circuits for several years by one large power company with apparently satisfactory results.[3] This method is somewhat different from using negative-phase-sequence quantities since it employs the line currents directly, but it is a simpler and easier method to apply. Its additional shortcoming is that it may in some cases permit tripping for oscillations which accompany external faults. When an unbalance is required for tripping, the remote possibility of balanced 3-phase faults is anticipated by the use of back-up relays having long enough time settings to prevent operation on oscillations alone.

The use of time delay in a relay's operation is perhaps an obvious way to prevent tripping during oscillations. This solution will apply to a back-up relay particularly if the resetting time of the relay is short.

But there are other uses which can be made of the time variable. An important difference between faults and oscillations is that whereas the electrical quantities present during an oscillation may reach proportions identical to those during short circuits, the approach to, and the departure from, the identical state during an oscillation is different on a time basis from that accompanying short circuits. The earliest known appreciation of the possibilities residing in this fact is recorded in a proposed method[4] to prevent the operation of distance relays during hunting following the occurrence of a distant short circuit. There, the distance relay operated very sensitively for a limited time after the occurrence of the short circuit, but before the oscillation could progress far enough to cause false operation, the relay changed its sensitivity so as to be inoperative during the ensuing hunting.

An extension of the principles involved led to making present-day carrier-current pilot relaying immune to any type of system oscillation whether it be accompanied by a short circuit or not.[5] This method of protection uses directional and associated relays at the ends of a line and a simple carrier-current telegraph channel to apprise one end of what is happening at the other. During any system disturbance, if current flows *out* of one end of the line as to an external short circuit, the directional relay at that end permits a carrier-current signal to be impressed on the line which prevents tripping at the other end where the current flow is in the tripping direction.

Reverting to the description of operation of directional relays, it will be recalled that a system oscillation first has the appearance of an external short circuit beyond one end, followed by the appearance of an internal short circuit, and still later appearing again as an external short circuit. This sequence of events in the cycle of an oscillation before and after it resembles an internal fault is used to prevent tripping during that limited period when an internal fault seems to exist. This is accomplished by prolonging the carrier-current signal once it has started during a 3-phase disturbance, for a definite time after the directional relay attempts to stop it, thereby temporarily taking control from the directional relays until they have passed through the period of delusion and once more regain their sense of direction.

This solution to the problem is particularly significant because it is achieved with equipment which is both faster and more selective than any other type having comparable application. The irony of the solution is that we have not bettered the vision of a single relay, but have actually introduced a blinder against its seeing that which it should not.

## Conclusions

The content of this paper cannot be fairly revealed by a set of conclusions. The paper was written to be read and studied by those who wish to understand better why

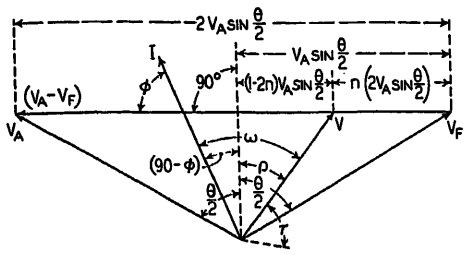

**Figure 15**

conventional relays operate as they do during system oscillations. An attempt has been made to present the analysis in an easily understandable form which has been found in actual practice to give a better insight into the apparent vagaries of relay operation.

Certain definite conclusions can be drawn (probably more or less obvious without the preceding analyses):

1. Any of the conventional relays except the zero-phase-sequence type is apt to operate in an undesirable manner during system oscillations. This is no reflection on the relay in so far as it reacts as it is intended under definite imposed conditions. The difficulty is that the conditions imposed by oscillations are the same to a single relay's perception as those during short circuits

2. It is possible to adjust some relays to better their discrimination between faults and oscillations depending on a relay's location and on the severity of the oscillation

3. Time delay and quick resetting in a relay's operation are aids toward preventing incorrect operation during oscillations

4. The problem is easily solvable if the best possible protection against balanced 3-phase faults is not required

5. Pilot protection using a wired pilot or carrier current can be made immune to the effects of system oscillations

## Appendix

### Derivation of Equation 1

If $Z'$ = total system line-to-neutral impedance,

$$I = \frac{(V_A - V_F)}{Z'}$$

From an inspection of figure 15,

$$(V_A - V_F) = 2V_A \sin\frac{\theta}{2}$$

Therefore,

$$I = \frac{2V_A}{Z'} \sin\frac{\theta}{2} \tag{1}$$

### Derivation of Equation 2

From an inspection of figure 15,

$$V \cos\rho = V_A \cos\frac{\theta}{2}$$

$$V \sin\rho = (1 - 2n)\, V_A \sin\frac{\theta}{2}$$

Squaring both sides of these equations and adding,

$$V^2 = V_A^2\left[\cos^2\frac{\theta}{2} + (1 - 2n)^2 \sin^2\frac{\theta}{2}\right]$$

Therefore,

$$V = V_A\sqrt{\cos^2\frac{\theta}{2} + (1 - 2n)^2 \sin^2\frac{\theta}{2}} \tag{2}$$

### Derivation of Equation 3

In figure 15,

$$\omega = (90 - \phi) + \rho$$

From inspection,

$$\tan\rho = \frac{(1 - 2n)\, V_A \sin\frac{\theta}{2}}{V_A \cos\frac{\theta}{2}} = (1 - 2n)\tan\frac{\theta}{2}$$

Therefore,

$$\omega = (90 - \phi) + \tan^{-1}\left[(1 - 2n)\tan\frac{\theta}{2}\right] \tag{3}$$

### Derivation of Equation 4

Referring to figure 15, and neglecting the effects of saturation in magnetic circuits of a directional relay, its torque may be expressed as

$$T = K_1 IV \cos(\tau + \omega) - K_2$$

where $K_1$ is a constant for the production of electrical torque, and $K_2$ is a constant representing the torque of the control spring.

At minimum pick-up the torque is zero.

$$0 = K_1 I_{MIN} V_A - K_2 \qquad K_2 = K_1 I_{MIN} V_A$$

$$T = K_1[IV \cos(\tau + \omega) - I_{MIN} V_A]$$

Developing this equation,

$$T = K_1\{-IV[\sin(\tau - \phi)\cos\rho + \cos(\tau - \phi)\sin\rho] - I_{MIN} V_A\}$$

But

$$I = \frac{2V_A}{Z'} \sin\frac{\theta}{2} = I_{MAX} \sin\frac{\theta}{2} \qquad V\cos\rho = V_A \cos\frac{\theta}{2}$$

and

$$V \sin\rho = (1 - 2n)\, V_A \sin\frac{\theta}{2}$$

Substituting in the torque equation,

$$T = KV_A\left\{I_{MAX}\left[(2n - 1)\cos(\tau - \phi)\sin^2\frac{\theta}{2} - \sin(\tau - \phi)\sin\frac{\theta}{2}\cos\frac{\theta}{2}\right] - I_{MIN}\right\} \tag{4}$$

### Derivation of Equation 5

The torque of a directional relay with voltage restraint may be expressed:

$$T = K_1[IV \cos(\tau + \omega) - I_{MIN} V_A] - K_3 V^2$$

At minimum pick-up the torque is zero.

$$0 = K_1 V_A (I'_{MIN} - I_{MIN}) - K_3 V_A^2$$

$$K_3 = K_1 \frac{(I'_{MIN} - I_{MIN})}{V_A}$$

$$T = K_1\left[IV \cos(\tau + \omega) - I_{MIN} V_A - \frac{(I'_{MIN} - I_{MIN})V^2}{V_A}\right]$$

Developing this equation,

$$T = K_1 \left\{ -IV[\sin(\tau - \phi)\cos\rho + \cos(\tau - \phi)\sin\rho] - I_{MIN} V_A - \frac{(I_{MIN}' - I_{MIN})V^2}{V_A} \right\}$$

But

$$I = I_{MAX} \sin\frac{\theta}{2} \qquad V\cos\rho = V_A \cos\frac{\theta}{2}$$

$$V\sin\rho = (1 - 2n)V_A \sin\frac{\theta}{2}$$

and from equation 2

$$V^2 = V_A^2\left[\cos^2\frac{\theta}{2} + (1 - 2n)^2 \sin^2\frac{\theta}{2}\right]$$

Substituting in the torque equation,

$$T = K_1 V_A \left\{ I_{MAX}\left[ (2n - 1)\cos(\tau - \phi)\sin^2\frac{\theta}{2} - \sin(\tau - \phi) \times \sin\frac{\theta}{2}\cos\frac{\theta}{2}\right] - I_{MIN} - (I'_{MIN} - I_{MIN})\left[(1 - 2n)^2 \sin^2\frac{\theta}{2} + \cos^2\frac{\theta}{2}\right]\right\} \quad (5)$$

## Derivation of Equation 6

Referring to figure 15,

$$X = -\frac{V}{I}\sin\omega = -\frac{V}{I}\sin(\rho + 90 - \phi)$$

$$= -\frac{V}{I}\cos(\rho - \phi)$$

$$= -\frac{V}{I}[\cos\rho\cos\phi + \sin\rho\sin\phi]$$

But $V\cos\rho = V_A\cos\frac{\theta}{2}$ $\qquad V\sin\rho = (1 - 2n)\,V_A\sin\frac{\theta}{2}$

Therefore,

$$X = \frac{V_A}{I}\left[(2n - 1)\sin\frac{\theta}{2}\sin\phi - \cos\frac{\theta}{2}\cos\phi\right]$$

But

$$I = \frac{2V_A}{Z'}\sin\frac{\theta}{2}$$

Therefore,

$$X = \frac{Z'}{2}\left[(2n - 1)\sin\phi - \cot\frac{\theta}{2}\cos\phi\right] \quad (6)$$

## Derivation of Equation 7

Referring to figure 15,

$$Z = \frac{V}{I}$$

But

$$V = V_A\sqrt{(1 - 2n)^2\sin^2\frac{\theta}{2} + \cos^2\frac{\theta}{2}}$$

and

$$I = \frac{2V_A}{Z'}\sin\frac{\theta}{2}$$

Therefore

$$Z = \frac{Z'}{2}\sqrt{(1 - 2n)^2 + \cot^2\frac{\theta}{2}} \quad (7)$$

## Symbols

- $V_A$ $V_F$ = line-to-neutral root-mean-square secondary voltage behind transient reactance at source $A$ and at source $F$
- $V_B$, $V_C$, $V_D$, and $V_E$ = line-to-neutral root-mean-square secondary voltage at substations $B$, $C$, $D$, and $E$
- $V$ = line-to-neutral root-mean-square secondary voltage at any location
- $I$ = root-mean-square secondary current at any location
- $I_{MIN}$ = minimum root-mean-square pick-up current of a directional relay
- $I_{MIN}'$ = minimum root-mean-square pick-up current of a directional relay with voltage restraint
- $I_{MAX}$ = maximum root-mean-square secondary current during an oscillation
- $I_{p.u.}$ = root-mean-square pick-up current of a relay
- $\theta$ = displacement angle
- $\phi$ = natural system phase angle
- $\omega$ = angle between $V$ and $I$
- $\tau$ = angle of maximum torque of a directional relay with or without voltage restraint
- $\rho$ = angle used in construction for derivation of equations
- $T$ = relay torque
- $n$ = per-unit impedance
- $Z'$ = total system secondary line-to-neutral impedance
- $Z$ = secondary line-to-neutral impedance indicated to an impedance relay
- $X$ = secondary line-to-neutral reactance indicated to a reactance relay
- $K_1$, $K_2$, and $K_3$ = constants

# A Comprehensive Method of Determining the Performance of Distance Relays

By J. H. NEHER
ASSOCIATE AIEE

## Introduction

DURING the past few years rapid progress has been made in the development of distance relay protective schemes, and there are now available a number of various types of distance measuring and directional elements which may be utilized in various combinations to afford the protection desired. In determining the performance of these elements under various fault conditions it would be of great benefit to be able to express the performance of each type of element under a given fault condition in terms of a simple quantity such as the effective line impedance between the relay and the point of fault. Unfortunately it will be found that the performance of certain elements, notably those connected to the unfaulted phases will be affected by changes in system setup and in system capacity. Lewis and Tippet have provided an excellent theoretical treatment of this problem[1] which Calabrese has supplemented by a study of the effect of wye-delta and delta-wye transformers interposed between the relay and the fault.[2]

Fundamentally, the performance of any distance element is a function of the current and voltage applied to the relay and of the vector angle between them. Unless this relationship becomes equal to a definite impedance which is present in the system network, the practice heretofore has been to determine the performance of the element for a given fault condition by the calculation of the current, voltage, and vector angle involved.

The calculation of these currents, voltages, and angles involves the use of certain fundamental impedances and current distribution factors which are characteristic of the system set-up, fault and relay location; but which are independent of the type of fault. By expressing the performance of the relay directly in terms of these fundamental quantities for any type of fault, the labor involved in the determination of the relay performance for any specific case will be reduced to a minimum.

The determination of these fundamental quantities may present considerable difficulty, and in the case of the complicated system networks commonly met with in practice, their accurate determination is practically impossible without the use of an a-c calculating table. An approximate determination is possible, however, by the use of a d-c calculating table, and the general expressions for relay performance will be presented in such a form that the approximate values thus obtained for the fundamental quantities may be used instead of the more accurate values. The accuracy of the results obtained will, of course, be dependent upon the accuracy of the fundamental assumption necessary in the use of the d-c calculating table; i.e., that all of the impedances appearing in the system networks have the same power factor angles.

A paper recommended for publication by the AIEE committee on protective devices. Manuscript submitted February 16, 1937; released for publication May 19, 1937.

J. H. NEHER is in the engineering department of the Philadelphia Electric Company, Philadelphia, Pa.

The author wishes to thank R. E. Cordray and A. R. van C. Warrington of the General Electric Company for their helpful comments during the preparation of this paper. The author particularly is indebted to Mr. Warrington for the development of the general equations for distance relays.

## Summary

This paper presents a comprehensive method of determining the performance of distance relays along the lines indicated above which may be summarized as follows:

1. A general method by which the performance of any of the types of distance elements in common use may be determined from the effective impedance presented to the element.

2. A tabulation from which the effective impedance presented to any type of distance element under any condition of fault may be obtained in terms of the effective line impedance between the relay and the fault and 4 quantities which are characteristic of the system setup and location of the fault with reference to the relay. These quantities may be determined approximately by the use of a d-c calculating table setup.

3. A method for including the effect of fault resistance in the determination of the effective impedance presented to the relay.

4. Methods by which the performance of standard directional elements under fault conditions may be determined.

5. An extension of the general method to enable the expression of the operating time of *CZ* relays in terms of the effective impedance presented to the relay.

6. An extension of the general method to include the performance of distance relays connected for protection against single-phase-to-ground faults.

## Types of Distance Relays Considered

While the method outlined in this paper is primarly intended to encompass all forms of distance relays operative on interphase faults, i.e., those relays which are connected to phase-to-phase potentials, it nevertheless is also applicable to the case of relays connected to phase-to-neutral-potentials with or without current compensation, which are intended to protect against single-phase-to-ground faults only Since this connection may be regarded as a special application, it will be treated subsequent to the general method.

With the exception of the *CZ* relay, the time of operation of which varies with the effective impedance presented to the relay, all of the distance relays in general use in the United States are either of the instantaneous

type or are composed of elements which are of that type. The method of solution will, therefore, be indicated on the basis of instantaneous elements with no further reference as to their time of operation. The *CZ* relay will be subsequently treated as a special case.

For purposes of treatment, distance elements may be classified both as to function and as to connections. Under the former classification the following types are evident:

(*a*) Impedance elements (types *CZ, HZ, IGX, IJX*)

(*b*) Reactance elements (type *HX*, ohm units of types *GAX, GCX*)

(*c*) Modified reactance elements (type *HY*)

(*d*) Directional elements with voltage restraint (starting units of types *GAX* and *GCX*, polyphase types *CHV-3, IDP, CBP*)

In regard to classification as to connections, the following distinctions may be drawn:

(*a*) One current and one voltage (types *CZ, HZ, IGX, IJX, HY, HX*, ohm units of type *GAX, GCX*, starting unit of type *GAX*)
1. Star-connected current transformers
2. Delta-connected current transformers

(*b*) One current and 2 voltages (starting unit of type *GCX*)

(*c*) Three currents and 3 voltages (type *CHV-3, IDP, CBP*)

In the above classification, the first group of elements is indicated as being operative from either star-or delta-connected current transformers. Actually the effect of delta-connected current transformers may be obtained by the delta connection of the main current transformer secondaries, the use of auxiliary secondary current transformers, or by the use of double coil elements. For simplicity, the problem will be treated as if the first method were employed. The use of any other method will not affect the theory and will merely change the value of the constant indicative of the relay setting.

## Distance Relay Equations

The operation of any simple relay element involves the resultant torque produced in the element by the application of a current and/or a voltage. This torque may be made up of torques produced by the current alone, the voltage alone, and the interaction of the current and the voltage. In the case of a distance measuring element, the resultant torque at the balance point must equal zero and the following general equation may be written to express this fact

$$K_v V^2 - K_i I^2 - K_{iv} IV \cos(\phi_V - \phi_I - \psi) = 0 \qquad (1)$$

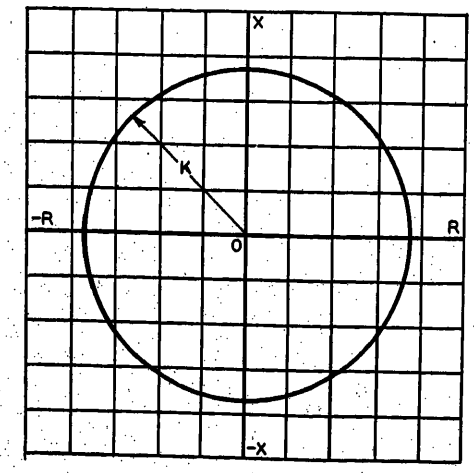
in which the first term is indicative of the torque produced by the voltage alone tending to open the contacts, the second term is indicative of the torque produced by the current alone tending to close the contacts, and the third term indicates the interaction torque in which the angle $\psi$ is the vector angle between current and voltage at which this interaction torque is a maximum.

Equation 1 may be expressed in terms of $\mathcal{Z}$ the effective impedance presented to the relay by dividing by $K_v I^2$.

$$\mathcal{Z}^2 - \frac{K_{iv}}{K_v}\mathcal{Z}\cos(\phi_z - \psi) = \frac{K_i}{K_v} \qquad (2)$$

Equation 2 may be transformed into the following form by the addition of $(K_{iv}/2K_v)^2$ to both sides.

$$\mathcal{Z}^2 + \left(\frac{K_{iv}}{2K_v}\right)^2 - \frac{K_{iv}}{K_v}\mathcal{Z}\cos(\phi_z - \psi) = \left(\frac{\sqrt{K_{iv}^2 + 4K_iK_v}}{2K_v}\right)^2 \qquad (3)$$



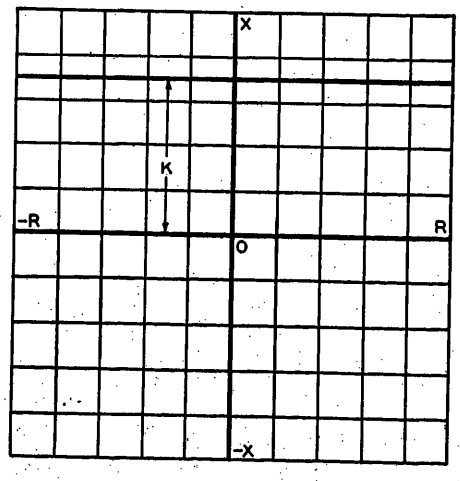
Equation 3 will be recognized as the equation of a circle expressed in terms of the polar co-ordinates $\mathcal{Z}$ and $\phi_z$. The radius of this circle is $(K_{iv}^2 + 4K_iK_v)/2K_v$ and its center is located at a distance $K_{iv}/2K_v$ from the origin at the angle $\psi$ from the reference vector.

It is therefore apparent that the balance point of any distance element may be expressed graphically on an impedance diagram as a characteristic circle and in order to determine whether or not the element will operate under a given fault condition, it is merely necessary to determine the effective impedance presented to the relay under that fault condition and to locate it on the diagram. If it falls within the circle the relay will operate, and the relay will not operate if it falls outside of the circle.

Equation 2 is a quadratic and may be solved for $\mathcal{Z}$ giving the following expression

$$\left[\frac{K_{iv}}{2K_v}\cos(\phi_z - \psi) \pm \frac{\sqrt{K_{iv}^2\cos^2(\phi_z - \psi) + 4K_iK_v}}{2K_v}\right] \angle\phi_z = \mathcal{Z}\angle\phi_z \qquad (4)$$

**Figure 1. Characteristic figure for an impedance relay**



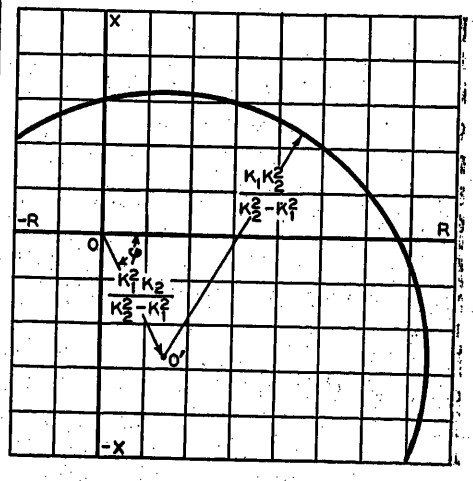


**Figure 2. Characteristic figure for a reactance relay**

**Figure 3. Characteristic figure for a modified reactance relay**

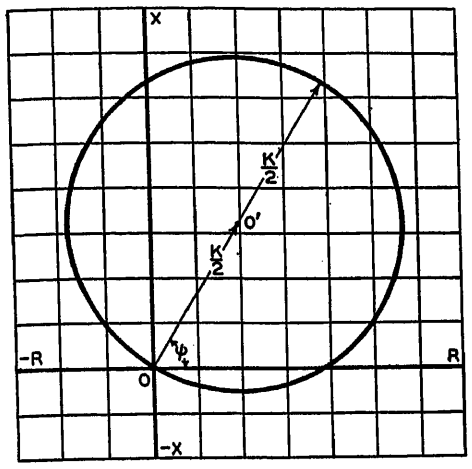

**Figure 4. Characteristic figure for a directional relay with voltage restraint**

Both sides of equation 4 have been multiplied by $\epsilon^{j\phi_z}$ (herein indicated as $\angle\phi_z$) in order to indicate that the effective impedance presented to the element is to be used as a vector quantity in determining its performance. As previously indicated the left-hand side of the equation when plotted for all possible values of $\phi_z$ will be a circle.

By the proper evaluation of the constants, equation 4 may be made to assume the following forms which are characteristic of the various types of distance elements previously classified. The derivation of these equations in the conventional manner is given in appendix $A$.

(*a*) IMPEDANCE ELEMENT

$$K_{tv} = 0; \qquad \sqrt{K_t/K_v} = K \tag{5}$$

$$K\angle\phi_z = \mathcal{Z}\angle\phi_z = \frac{V}{I}\angle\phi_V - \phi_I \tag{6}$$

The characteristic circle for this element shown in figure 1 has a radius equal to $K$ with its center at the origin.

(*b*) REACTANCE ELEMENT

$$K_v = 0; \qquad K_t/K_{tv} = K; \qquad \psi = -90° \tag{7}$$

$$\frac{K\angle\phi_z}{\sin\ \phi_z} = \mathcal{Z}\angle\phi_z = \frac{V}{I}\angle(\phi_V - \phi_I) \tag{8}$$

The characteristic circle for the element shown in figure 2 has a radius equal to infinity with its center located at infinity. It is therefore a straight line and has a minimum distance of $K$ from the origin.

(*c*) MODIFIED REACTANCE ELEMENT

In this element all of the torque terms are utilized.

$$K_1 = 1; \qquad K_v = \frac{1}{K_1^2} - \frac{1}{K_2^2}; \qquad K_{tv} = \frac{2}{K_2} \tag{9}$$

$$\angle\phi_z = \mathcal{Z}\angle\phi_z = \frac{V}{I}\angle(\phi_V - \phi_I) \tag{10}$$

The characteristic circle for this element shown in figure 3 has a radius of $K_1K_2^2/(K_2^2-K_1^2)$ with its center located $K_1^2K_2/(K_2^2-K_1^2)$ distant from the origin.

(*d*) DIRECTIONAL ELEMENT WITH VOLTAGE RESTRAINT

$$K_1 = 0; \qquad K_{tv}/K_v = K \tag{11}$$

1. *GAX Type*

$$K\cos(\phi_z - \psi)\angle\phi_z = \frac{1}{S}\mathcal{Z}\angle\phi_z = \frac{1}{S}\frac{V}{I}\angle\phi_V - \phi_I \tag{12}$$

2. *GCX Type*

$$K\cos(\phi_z - \psi)\angle\phi_z = \mathcal{Z}\angle\phi_z = \frac{V}{I}\angle(\phi_V - \phi_I) \times \frac{2}{\sqrt{3}}\sin(\phi_V - \phi_{Vq})\angle(90° + \phi_{Vq} - \phi_V) \tag{13}$$

3. *Polyphase Type*

$$K\cos(\phi_z - \psi)\angle\phi_z = \mathcal{Z}\angle\phi_z = \frac{3}{\frac{1}{\mathcal{Z}_a\angle\phi_{za}} + \frac{1}{\mathcal{Z}_b\angle\phi_{zb}} + \frac{1}{\mathcal{Z}_c\angle\phi_{zc}}} \tag{14}$$

The characteristic circle for these elements shown in figure 4 has a radius equal to $K/2$ with its center located at the same distance from the origin.

In equation 12, $S$ is a factor indicative of the variation in range of the unit with variation of the applied potential. This is discussed in appendix $A$.

In the equation 14, the quantities $\mathcal{Z}_a$, $\mathcal{Z}_b$, and $\mathcal{Z}_c$ are the effective impedances presented to the respective phase *GCX* type units as determined from equation 13.

In view of the above equations, it is evident that the performance of all of the above mentioned types of elements for a given fault can be completely expressed by 4 characteristic graphical figures (3 circles and a straight line) and the solution of the requisite equivalent expressions for $\mathcal{Z}\angle\phi_z$. Actually in the case of relays connected for protection against interphase faults, since 3 individual phase relays are involved in all but the last type and since the first 3 types of elements may or may not employ delta-connected current transformers (or their equivalent) 10 such solutions must be made. These solutions may be summarized in tabular form by the equations given below.

Since the expression $\mathcal{Z}\angle\phi_z$ and its equivalents are vectors we will be dealing hereafter entirely with vectors, which will be indicated by bold-face type.

(*a*) ONE CURRENT AND ONE VOLTAGE

(Impedance, reactance, modified reactance, *GAX* starting unit)

1. *Star-Connected Current Transformers*

$$Z_a = \frac{V_{ba}}{I_a} \tag{15}$$

$$Z_b = \frac{V_{ab}}{I_b} \tag{16}$$

$$Z_c = \frac{V_{ac}}{I_c} \tag{17}$$

2. *Delta-Connected Current Transformers*

$$Z_a' = \frac{V_{ba}}{I_a'} \tag{18}$$

$$Z_b' = \frac{V_{cb}}{I_b'} \tag{19}$$

$$Z_c' = \frac{V_{ac}}{I_c'} \tag{20}$$

## Table I. Relay Voltages and Currents in Terms of Fundamental Quantities for Various Fault Conditions

| | | Three-Phase Fault | No Phase Shift in Voltage Between Relay and Fault | | |
|---|---|---|---|---|---|
| | | | Phase-Phase Fault | Phase-Ground Fault | Two-Phase-Ground Fault |
| Voltages | $V_{ba}$ | $\sqrt{3}\frac{c_1}{Z_1} z E\angle 30°$ | $1.5\left(1+\frac{c_1 z}{\sqrt{3}Z_1}\angle 90°\right)E$ | $\frac{\sqrt{3}}{2}\left(\sqrt{3}\frac{2c_1 z+Z_0}{2Z_1+Z_0}+1\angle 90°\right)E$ | $1.5\left(\frac{c_1 z+2Z_0}{Z_1+2Z_0}+\frac{c_1 z}{\sqrt{3}\,Z_1}\angle 90°\right)E$ |
| | | $=\frac{\sqrt{3}}{2}\frac{c_1 z}{Z_1}A\,E\angle 90°$ | $=\frac{\sqrt{3}}{2}\frac{c_1 z}{Z_1}A\,E\angle 90°$ | $=\frac{\sqrt{3}}{2}AE\angle 90°$ | $=\frac{\sqrt{3}}{2}\frac{c_1 z}{Z_1}AE\angle 90°$ |
| | $V_{cb}$ | $\sqrt{3}\frac{c_1}{Z_1} z E\angle -90°$ | $\sqrt{3}\frac{c_1 z}{Z_1}E\angle -90°$ | $\sqrt{3}\,E\ \angle -90°$ | $\sqrt{3}\frac{c_1 z}{Z_1}E\angle -90°$ |
| | $V_{ac}$ | $\sqrt{3}\frac{c_1}{Z_1} z E\angle 150°$ | $1.5\left(-1+\frac{c_1 z}{\sqrt{3}Z_1}\angle 90°\right)E$ | $\frac{\sqrt{3}}{2}\left(-\sqrt{3}\frac{2c_1 z+Z_0}{2Z_1+Z_0}+1\angle 90°\right)E$ | $1.5\left(-\frac{c_1 z+2Z_0}{Z_1+2Z_0}+\frac{c_1 z}{\sqrt{3}\,Z_1}\angle 90°\right)E$ |
| | | $=\frac{\sqrt{3}}{2}\frac{c_1 z}{Z_1}BE\angle 90°$ | $=\frac{\sqrt{3}}{2}\frac{c_1 z}{Z_1}BE\angle 90°$ | $=\frac{\sqrt{3}}{2}BE\angle 90°$ | $=\frac{\sqrt{3}}{2}\frac{c_1 z}{Z_1}BE\angle 90°$ |
| Currents — Star-Connected Current Transformers | $I_a$ | $\frac{c_1}{Z_1}E$ | 0 | $\frac{2c_1+c_0}{2Z_1+Z_0}E$ | $\frac{c_1-c_0}{Z_1+2Z_0}E$ |
| | $I_b$ | $\frac{c_1}{Z_1}E\angle -120°$ | $\frac{\sqrt{3}c_1}{2Z_1}E\angle -90°$ | $-\frac{c_1-c_0}{2Z_1+Z_0}E$ | $\frac{1}{2}\left(-\frac{c_1+2c_0}{Z_1+2Z_0}-\sqrt{3}\frac{c_1}{Z_1}\angle 90°\right)E$ |
| | | | | | $=\frac{\sqrt{3}}{2}\frac{c_1}{Z_1}CE\angle -90°$ |
| | $I_c$ | $\frac{c_1}{Z_1}E\angle 120°$ | $\frac{\sqrt{3}\,c_1}{2Z_1}E\angle 90°$ | $-\frac{c_1-c_0}{2Z_1+Z_0}E$ | $\frac{1}{2}\left(-\frac{c_1+2c_0}{Z_1+2\,Z_0}+\sqrt{3}\frac{c_1}{Z_1}\angle 90°\right)E$ |
| | | | | | $=\frac{\sqrt{3}}{2}\frac{c_1}{Z_1}DE\angle 90°$ |
| Delta-Connected Current Transformers | $I_a'$ | $\sqrt{3}\frac{c_1}{Z_1}E\angle 30°$ | $\frac{\sqrt{3}c_1}{2Z_1}E\angle 90°$ | $\frac{3\,c_1}{2Z_1+Z_0}E$ | $1.5c_1\left(\frac{1}{Z_1+2Z_0}+\frac{1}{\sqrt{3}\,Z_1}\angle 90°\right)E$ |
| | | | | | $=\frac{\sqrt{3}}{2}\frac{c_1}{Z_1}C'E\angle 90°$ |
| | $I_b'$ | $\sqrt{3}\frac{c_1}{Z_1}E\angle -90°$ | $\frac{\sqrt{3}c_1}{Z_1}E\angle -90°$ | 0 | $\sqrt{3}\frac{c_1}{Z_1}E\angle -90°$ |
| | $I_c'$ | $\sqrt{3}\frac{c_1}{Z_1}E\angle 150°$ | $\frac{\sqrt{3}c_1}{2Z_1}E\angle 90°$ | $-\frac{3\,c_1}{2\,Z_1+Z_0}E$ | $1.5c_1\left(-\frac{1}{Z_1+2Z_0}+\frac{1}{\sqrt{3}\,Z_1}\angle 90°\right)E$ |
| | | | | | $=\frac{\sqrt{3}}{2}\frac{c_1}{Z_1}D'E\angle 90°$ |

(*b*) One Current and 2 Voltages

Star-connected current transformers (*GCX* starting unit)

$$Z_a'' = Z_a \times \frac{2}{\sqrt{3}} \sin(\phi_{Vba} - \phi_{Vcb}) \angle (90° + \phi_{Vcb} - \phi_{Vba}) \quad (21)$$

$$Z_b'' = Z_b \times \frac{2}{\sqrt{3}} \sin(\phi_{Vcb} - \phi_{Vac}) \angle (90° + \phi_{Vac} - \phi_{Vcb}) \quad (22)$$

$$Z_c'' = Z_c \times \frac{2}{\sqrt{3}} \sin(\phi_{Vac} - \phi_{Vba}) \angle (90° + \phi_{Vba} - \phi_{Vac}) \quad (23)$$

(*c*) Three Currents and 3 Voltages

Star-connected current transformers (polyphase directional with voltage restraint)

$$Z_p = \frac{3}{\frac{1}{Z_a''} + \frac{1}{Z_b''} + \frac{1}{Z_c''}} \quad (24)$$

## Solution of $Z$

The solution of $Z$ from equations 15–24 will be effected by the application of the method of symmetrical components to the determination of the various currents and voltages involved in these equations. It will be evident that these currents and voltages may be completely expressed in terms of the following quantities, all of which are to be considered as vectors.

$E$ = the normal primary phase to neutral voltage at the relay

$Z_1, Z_2, Z_0$ = the equivalent impedances of the positive-, negative-, and zero-phase sequence networks, respectively, expressed at the voltage $E$

$c_1, c_2, c_0$ = the respective ratios of the positive-, negative-, and zero-phase-sequence currents at the relay to the corresponding total phase sequence currents at the point of fault

$z$ = the *effective* (positive- or negative-phase sequence) impedance between the relay and the point of fault

## Table I (Continued). Relay Voltages and Currents in Terms of Fundamental Quantities for Various Fault Conditions

**Thirty-Degree Phase Shift in Voltage Between Relay and Fault**

| | | Phase-Phase Fault | Phase-Ground Fault | Two-Phase-Ground Fault |
|---|---|---|---|---|
| Voltages | | $\frac{\sqrt{3}}{2}\left(\sqrt{3}\frac{c_1 z}{Z_1}+1\angle 90^\circ\right)E$ | $1.5\left(1+\frac{1}{\sqrt{3}}\frac{2c_1z+Z_0}{2Z_1+Z_0}\angle 90^\circ\right)E$ | $\frac{\sqrt{3}}{2}\left(\sqrt{3}\frac{c_1 z}{Z_1}+\frac{c_1z+2Z_0}{Z_1+2Z_0}\angle 90^\circ\right)E$ |
| | | $=\frac{\sqrt{3}}{2}AE\angle 90^\circ$ | $=\frac{\sqrt{3}}{2}\frac{2c_1z+Z_0}{2Z_1+Z_0}AE\angle 90^\circ$ | $=\frac{\sqrt{3}}{2}\frac{c_1z+2Z_0}{Z_1+2Z_0}AE\angle 90^\circ$ |
| | | $\sqrt{3}\,E\angle -90^\circ$ | $\sqrt{3}\frac{2c_1z+Z_0}{2Z_1+Z_0}E\angle -90^\circ$ | $\sqrt{3}\frac{c_1z+2Z_0}{Z_1+2Z_0}E\angle -90^\circ$ |
| | | $\frac{\sqrt{3}}{2}\left(-\sqrt{3}\frac{c_1z}{Z_1}+1\angle 90^\circ\right)E$ | $1.5\left(-1+\frac{1}{\sqrt{3}}\frac{2c_1z+Z_0}{2Z_1+Z_0}\angle 90^\circ\right)E$ | $\frac{\sqrt{3}}{2}\left(-\sqrt{3}\frac{c_1z}{Z_1}+\frac{c_1z+2Z_0}{Z_1+2Z_0}\angle 90^\circ\right)E$ |
| | | $=\frac{\sqrt{3}}{2}BE\angle 90^\circ$ | $=\frac{\sqrt{3}}{2}\frac{2c_1z+Z_0}{2Z_1+Z_0}BE\angle 90^\circ$ | $=\frac{\sqrt{3}}{2}\frac{c_1z+2Z_0}{Z_1+2Z_0}BE\angle 90^\circ$ |
| Currents | Star-Connected Current Transformers | $\frac{c_1}{Z_1}E$ | 0 | $\frac{c_1}{Z_1}E$ |
| | | $-\frac{c_1}{2Z_1}E$ | $\frac{\sqrt{3}c_1}{2Z_1+Z_0}E\angle -90^\circ$ | $\frac{c_1}{2}\left(-\frac{1}{Z_1}-\frac{\sqrt{3}}{Z_1+2Z_0}\angle 90^\circ\right)E$ |
| | | | | $=\frac{\sqrt{3}}{2}\frac{c_1}{Z_1+2Z_0}CE\angle -90^\circ$ |
| | | $-\frac{c_1}{2Z_1}E$ | $\frac{\sqrt{3}\,c_1}{2Z_1+Z_0}E\angle 90^\circ$ | $\frac{c_1}{2}\left(-\frac{1}{Z_1}+\frac{\sqrt{3}}{Z_1+2Z_0}\angle 90^\circ\right)E$ |
| | | | | $=\frac{\sqrt{3}}{2}\frac{c_1}{Z_1+2Z_0}DE\angle 90^\circ$ |
| | Delta-Connected Current Transformers | $1.5\frac{c_1}{Z_1}E$ | $\frac{\sqrt{3}\,c_1}{2Z_1+Z_0}E\angle 90^\circ$ | $\frac{\sqrt{3}}{2}c_1\left(\frac{\sqrt{3}}{Z_1}+\frac{1}{Z_1+2Z_0}\angle 90^\circ\right)E$ |
| | | | | $=\frac{\sqrt{3}}{2}\frac{c_1}{Z_1+2Z_0}C'E\angle 90^\circ$ |
| | | 0 | $\frac{2\sqrt{3}\,c_1}{2Z_1+Z_0}E\angle -90^\circ$ | $\frac{\sqrt{3}\,c_1}{Z_1+2Z_0}E\angle -90^\circ$ |
| | | $-1.5\frac{c_1}{Z_1}E$ | $\frac{\sqrt{3}\,c_1}{2Z_1+Z_0}E\angle 90^\circ$ | $\frac{\sqrt{3}}{2}c_1\left(-\frac{\sqrt{3}}{Z_1}+\frac{1}{Z_1+2Z_0}\angle 90^\circ\right)E$ |
| | | | | $=\frac{\sqrt{3}}{2}\frac{c_1}{Z_1+2Z_0}D'E\angle 90^\circ$ |

It is important to notice that $z$ is the *effective* impedance between the relay and the point of fault and take into account not only the impedances of the lines and equipment in this path, but the relative current distribution as well. For instance, if the path comprises the impedances $z$, $z'$, and $z''$, etc., with the corresponding current distribution factors $c$, $c'$, and $c''$, then

$$z=\frac{cz+c'z'+c''z''\ldots.}{c} \tag{25}$$

With relay elements not employing phase-to-neutral voltages the corresponding effective zero-phase-sequence impedance $z_0$ will not be needed since the phase-to-phase voltages are not dependent upon the voltage distribution through the zero-phase-sequence network.

In order to simplify the expressions to follow, the assumption has been made that the positive- and negative-phase-sequence networks are identical. This assumption is felt to be justifiable in work of this kind and considerably reduces the amount of calculation necessary to obtain the desired results. On this basis all currents and voltages may be expressed in terms of the fundamental quantities $E$, $Z_1$, $Z_0$, $c_1$, $c_0$, and $z$.

In considering the effect of the type of fault, 7 distinct types of faults must be recognized, since in addition to the symmetrical case of a 3-phase fault and the 3 unsymmetrical cases of phase-to-phase, phase-to-ground, and 2-phase-ground faults, these unsymmetrical faults occurring beyond a transformer bank which produces a phase shift in voltage constitute 3 more different cases.

If a wye-delta or delta-wye transformer bank is interposed between the relay and the fault, the positive-phase-sequence currents and voltages will be displaced 30 degrees in one direction (depending upon the bank connections)

and the negative-phase-sequence currents and voltages will be displaced 30 degrees in the other direction when passing through the bank. The effect of this upon the vector diagrams at the relay is such that they will be similar for a given type of fault irrespective of the direction of phase shift and may be made identical by choosing the phases to be involved in the fault with reference to the direction of the phase shift.

Three-phase faults produce no negative-phase-sequence components so that the presence of a bank between the point and the fault has no effect upon the vector diagram. Similarly delta-delta or wye-delta-wye banks produce no net phase shift and do not affect the vector diagram.

To summarize, the 7 distinct cases of faults must be recognized which are as follows:

1. Three-phase fault under any condition.
2. *B* phase — *C* phase fault with no voltage phase shift between the relay and the point of fault. This includes faults beyond a delta-delta or wye-delta-wye transformer bank.
3. *A* phase — ground fault under the conditions outlined in 2.
4. *B* phase — *C* phase — ground fault under the conditions outlined in 2.

5*a*. *A* phase — *B* phase — fault beyond a transformer bank connected so that the voltage on the fault side lags the voltage on the relay side by 30 degrees.

5*b*. *C* phase — *A* phase fault beyond a transformer bank connected so that the voltage on the fault side leads the voltage on the relay side by 30 degrees.

6*a*. *C* phase — ground fault under the conditions outlined in 5*a*.

6*b*. *B* phase — ground fault under the conditions outlined in 5*b*.

7*a*. *A* phase — *B* phase — ground fault under the conditions outlined in 5*a*.

7*b*. *C* phase — *A* phase — ground fault under the conditions outlined in 5*b*.

The values of the phase currents and voltages at the relay for each of these 7 cases in terms of the fundamental quantities are given in table I. Currents applicable to relays fed from delta-connected current transformers are indicated by a prime mark ($'$). The derivation of these expressions is given in appendix *B*.

The expressions for currents and voltages given in table I when substituted in equations 15–24 give the solutions of $\boldsymbol{Z}$ sought for each of the 7 cases of fault. These expressions are given in table II. In order to simplify the expressions thus obtained factors have been introduced in certain cases as indicated. These factors are, of course, vectors, and in the case of the factors applied to the simplification of the voltage expressions, their vector angles are indicative of certain of the angles of the voltage triangle. This fact permits the formulation of the expressions for $\boldsymbol{Z}''$ in terms of the vector angles of the factors.

In utilizing the expressions given in tables I and II it is very important to realize that the quantities $\boldsymbol{c}_1$ and $\boldsymbol{c}_0$ which are vectors should be formulated on the basis of the direction of phase sequence current flow in the line under consideration with respect to the fault and not with respect to the direction of connection of the relay for which the effective impedance presented to it is desired. If the fault lies behind the relay the vector expression obtained for the impedance presented to the relay should be rotated 180 degrees.

## Effect of Fault Resistance Upon $\boldsymbol{Z}$

In dealing with the problem of fault resistance, it should be realized that the fundamental quantity to be considered in the usual case of an arc fault is the voltage drop across the arc. This is essentially dependent upon the length of the arc and independent of the fault current. Since we have chosen to express the performance of the relay in terms of a quantity having the dimensions of impedance, it is desirable to express the effect of the fault arc in terms of a resistance, realizing that this resistance, unlike the fundamental quantities dealt with heretofore, is a function of the actual fault. Futhermore, this fault resistance will affect the value of all of these fundamental quantities except $\boldsymbol{E}$.

In formulating the effective fault resistance, the quantity $\boldsymbol{R}_f$ is to be treated as a phase sequence resistance at the point of fault which is in series with $Z_1$, $Z_2$, and $Z_0$ in the respective phase sequence networks. The values of $\boldsymbol{R}_f$ introduced into each network are all equal for any given type of fault, but are different for different types of faults. In order to determine the actual value of $\boldsymbol{R}_f$ for the various types of faults, a 3-phase fault will be assumed to consist of 3 simultaneous single-phase-to-ground arcs of equal length and a 2-phase-to-ground fault to consist of 2 simultaneous phase-to-ground faults of equal length. The magnitude of $\boldsymbol{R}_f$ will then be equal to $\boldsymbol{V}_A$, the voltage drop across the arc divided by the total faulted phase current for 3-phase, phase-to-ground, and 2-phase-to-ground faults, and equal to half the arc voltage divided by the faulted phase current for a phase-to-phase fault. If we assume that the magnitude of the total faulted phase current is unaffected by the presence of $\boldsymbol{R}_f$ the following relationships are evident.

(*a*) *Three Simultaneous Phase-to-Ground Faults*

$$\boldsymbol{R}_f = \frac{\boldsymbol{V}_A}{\boldsymbol{E}}\, Z_1 \tag{26}$$

(*b*) *Phase-to-Phase Fault (not involving ground)*

$$\boldsymbol{R}_f = \frac{\boldsymbol{V}_A}{\boldsymbol{E}}\,\frac{Z_1}{\sqrt{3}} \tag{27}$$

(*c*) *Single Phase-to-Ground Fault*

$$\boldsymbol{R}_f = \frac{\boldsymbol{V}_A}{\boldsymbol{E}}\,\frac{2Z_1 + Z_0}{3} \tag{28}$$

(*d*) *Two Simultaneous Phase-to-Ground Faults*

$$\boldsymbol{R}_f = \frac{\boldsymbol{V}_A}{\boldsymbol{E}}\,\frac{2Z_1}{\sqrt{3}C'} \tag{29}$$

The value of $\boldsymbol{C}'$ to be used in equation 29 is that for the case of a 2-phase-to-ground fault without phase shift in voltage between the relay and the fault. Equations 26–29 yield the magnitude of $\boldsymbol{R}_f$, and the vector angle which results from their solution has no significance. $\boldsymbol{R}_f$ thus determined should be used as a resistance vector and

## Table II. Effective Impedances in Terms of Fundamental Quantities Presented to Distance Relay Elements for Various Fault Conditions

| | | | No Phase Shift in Voltage Between Relay and Fault | | | Thirty-Degree Phase Shift in Voltage Between Relay and Fault | | |
|---|---|---|---|---|---|---|---|---|
| | | Three-Phase Fault | Phase-Phase Fault | Phase-Ground Fault | Two-Phase-Ground Fault | Phase-Phase Fault | Phase-Ground Fault | Two-Phase-Ground Fault |
| Factors | $A$ | $2\angle -60°$ | $1-\frac{\sqrt{3}Z_1}{c_1 z}\angle 90°$ | $1-\sqrt{3}\frac{2c_1 z+Z_0}{2Z_1+Z_0}\angle 90°$ | $1-\frac{\sqrt{3}\,Z_1}{c_1 z}\left(\frac{c_1 z+2Z_0}{Z_1+2Z_0}\right)\angle 90°$ | $1-\sqrt{3}\frac{c_1 z}{Z_1}\angle 90°$ | $1-\sqrt{3}\frac{2Z_1+Z_0}{2c_1+Z_0}\angle 90°$ | $1-\sqrt{3}\frac{c_1 z}{Z_1}\left(\frac{Z_1+2Z_0}{c_1 z+2Z_0}\right)\angle 90°$ |

**Elements With One Current and 2 Voltages—Star-Connected Current Transformers**

$$Z_a''=Z_a\times\frac{2}{\sqrt{3}}\sin(-\phi_A)\angle(-90°-\phi_A) \qquad Z_b''=Z_b\times\frac{2}{\sqrt{3}}\sin\phi_B\angle(\phi_B-90°) \qquad Z_c''=Z_c\times\frac{2}{\sqrt{3}}\sin(\phi_B-\phi_A)\angle(90°+\phi_A-\phi_B)$$

**Element With 3 Currents and 3 Voltages—Star-Connected Current Transformers—90-Degree Potential Connection**

$$Z_p=\frac{3}{\frac{1}{Z_a''}+\frac{1}{Z_b''}+\frac{1}{Z_c''}}$$

should be applied if necessary in the correction of the fundamental quantities.

$R_f$ must be included in the determination of $z$ and equation 25 may be rewritten as follows

$$z = \frac{cz + c'z' + c''z'' \ldots + R_f}{c} \tag{30}$$

## Use of a D-C Calculating Table

If a d-c calculating table is employed to obtain the fundamental quantities mentioned above, it is of course impossible to treat them as vectors with different vector angles. If the usual practice of setting up the calculating table on the basis of the reactive components of impedance is followed, then the vector angles of $c_1$ and $\doteq c_0$ will be zero and the vector angles of $Z_1$ and $Z_0$ will be 90 degrees. It is still possible to synthesize $z$ with a fair degree of accuracy from equations 25 or 30 and a knowledge of the impedances of the branches in the path between the relay and the fault. The effect of arc resistance is included only in the computation of $z$.

The results obtained by this procedure will usually be sufficiently accurate for most purposes, but it must be realized that in the case of a fault on the end of a line having a relatively large resistive component and fed by a system which is highly reactive, the impedances thus determined for the unfaulted phase relays may be subject to an appreciable error. The limitations introduced are, of course, due to the use of the d-c calculating table and not to the expressions given in tables I and II which are rigorous except for the assumption that the positive- and negative-phase-sequence networks are identical.

Under the assumptions necessitated by the use of the d-c calculating table the solution for $Z_p$ the effective impedance presented to the polyphase unit is greatly simplified and the following expressions may be used in place of equation 24.

*Three-Phase Fault*

$$Z_p = \sqrt{3}z \tag{31}$$

*Phase-to-Phase Fault*

$$Z_p = 2\sqrt{3}z \tag{32}$$

*Phase-to-Ground Fault*

$$Z_p = \sqrt{3}\left(\frac{2c_1z + Z_0}{c_1}\right) \tag{33}$$

*Two-Phase-to-Ground Fault*

$$Z_p = \sqrt{3}\left(\frac{c_1z + 2Z_0}{c_1z + Z_0}\right)z \tag{34}$$

Equations 31–34 apply whether or not there is a phase shift in voltage between the relay and the fault.

## Performance of Directional Elements Without Voltage Restraint

Distance relays are almost invariably of the directional type. The type *GAX* and *GCX* reactance relays are given directional characteristics by means of the starting units discussed above. The *CZ*, *HZ*, *HY*, and *IGX* types are made directional by the use of a conventional directional element suitably connected to the circuit. In interpreting the performance of such relays, it is necessary to know whether or not the various phase distance elements will be released by their associated directional elements.

In the case of *CZ*, *HZ*, and *HY* relays a true wattmetric type of element is used with a 30 degree connection. That is the *A*-phase relay is connected to the current $I_a$ and the voltage $V_{ac}$ reversed and so on. It will be evident, therefore, that the vector angle between the voltage and current applied to the directional element is equal to the vector angle of the impedance presented to the distance element minus the corresponding internal angle of the voltage triangle. The directional element will operate if the angle thus obtained lies between $\doteq$ 90 degrees. Solutions of the following expressions are therefore required.

*A* phase: $\phi z_a - 180° + \phi_{Vac} - \phi_{Vba}$ (35)

*B* phase: $\phi z_b - 180° + \phi_{Vba} - \phi_{Vcb}$ (36)

*C* phase: $\phi z_c - 180° + \phi_{Vcb} - \phi_{Vac}$ (37)

In view of the angular relationships developed in appendix *B* expressions 35–37 become:

*A* phase: $\phi z_a - 180° + \phi_B - \phi_A$ (38)

*B* phase: $\phi z_b + \phi_A$ (39)

*C* phase: $\phi z_c - \phi_B$ (40)

If delta connected current transformers are employed for the directional elements, $\phi_z'$ should be substituted for $\phi_z$ in expressions 35–40.

In the case of the *IGX* relay, a 90 degree connection is used for the directional element. (*A*-phase relay is connected to the current $I_a$ and the voltage $V_{bc}$ and so on) and the angle of maximum torque of the element is variable within certain limits. The angular range of operation of this element is therefore similar to that ot the type *GCX* starting unit and therefore the element will operate if the vector angle of $Z''$ lies within $\doteq$90 degrees of $\psi$ where $\psi$ is now to be interpreted as the angle of maximum torque of the directional element.

If delta-connected current transformers are used with the directional element of *IGX* relay, $Z''$ should be formulated from $Z'$ rather than from $Z$.

It should be noted, however, that by the use of auxiliary current transformers it is possible to obtain the effect of delta-connected current transformers on the distance elements and at the same time maintain the more desirable effect of star-connected current transformers on any type of directional element.

## Determination of CZ Relay Operating Times

Unlike the instantaneous distance elements previously discussed which either do or do not operate according to the value of $Z$ presented to the element, the *CZ* relay operates in a time which is more or less a direct function of the magnitude of $Z$. The characteristic time curves for this relay have usually been expressed as a set of current-

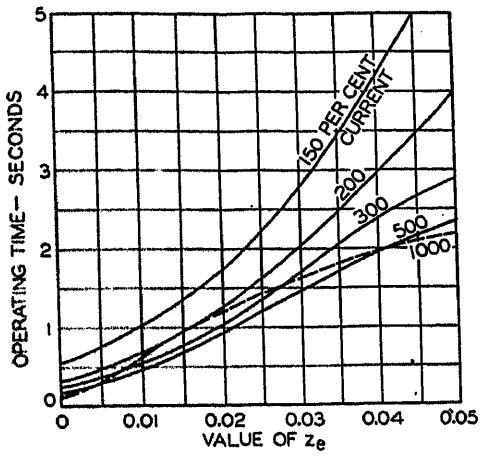

**Figure 5. Time-impedance characteristics of CZ relays**

time curves, each curve being for a constant voltage maintained at the relay terminals. This method is unsatisfactory because it fails to bring out the constant time-impedance relationship which is the inherent principle of operation for which the relay is designed. This may be done by plotting a set of time-impedance curves, each curve being for a constant current applied to the relay. Figure 5 shows such a set of curves plotted in terms of an impedance parameter $z_e$ for various values of current expressed in per cent of current tap setting. The parameter $z_e$ is so constituted that it bears the following relationship to $Z$

$$z_e = \frac{T_c R_c}{T_p R_p} Z \tag{41}$$

in which:

$T_c$ = the current tap setting of the relay
$T_p$ = the voltage tap setting of the relay
$R_c$ = the current transformer ratio
$R_p$ = the potential transformer ratio

The derivation of equation 41 and the curves of figure 5 is given in appendix $A$. Having determined the value of $Z$ in exactly the same manner as for the case of an instantaneous impedance element, equation 41 and the use of the curves of figure 5 permit the determination of the relay operating time. Unfortunately, as is evident from the curves of figure 5, this operating time is a function of the current in the relay. It will, therefore, be necessary to solve the proper expression for current given in table I and express this value as a percentage of $T_c R_c$ in order to determine which curve of figure 5 applies.

## Distance Relays for Ground Faults

The application of distance relays for protection against single-phase-to-ground faults has been discussed by Lewis and Tippett,[1] A. R. van C. Warrington,[3] and Goldsborough and Smith.[4] From these discussions it appears that a reactance type of element is indicated, connected to the the phase-to-neutral potential of the phase at fault and supplied with the faulted phase current compensated by a certain amount of residual current dependent upon the ratio of the effective zero-phase-sequence impedance between the relay and the fault to the effective positive-phase-sequence impedance between the same points. Further it is generally agreed that the relay so connected must be rendered inoperative in case more than one phase is involved in the fault. On this basis the effective impedance presented to the relay in the case of a single-phase-to-ground fault will be:

$$Z_{a0} = \frac{V_{oa}}{I_a + \frac{M-1}{3} I_n} \tag{42}$$

This becomes:

$$Z_{a0} = \frac{2c_1 z + c_0 z_0}{2c_1 + M c_0} = z \tag{43}$$

If

$$M = \frac{z_0}{z} \tag{44}$$

It should be remembered that $z_0$ in the above expression is an *effective* value and takes into account not only the zero-phase-sequence impedances of the lines and equipment in the path between the relay and the fault, but also the relative current distribution and, most important, the effect of mutual induction of zero-phase-sequence currents flowing in parallel circuits.

## Appendix A—Derivation of Distance Element Equations

In an instantaneous distance element 2 torques, an operating torque and a restraining torque are placed in opposition. The relay will be assumed to operate under conditions such that the operating torque is equal to or greater than the restraining torque and to be balanced when these torques are equal. These torques are functions of the fluxes produced in the relay coils and the angles between them. Since these fluxes are proportional to and have angles equal to the currents in the relay coils, the following balance equations will be derived from the currents themselves without further reference to the fluxes produced by them. The following nomenclature will be used.

$I$ = current in the current coil
$V$, $V_q$ = voltages applied to the potential coils
$z_p$, $z_p'$ = impedances of the potential coil circuits
$k$, $k'$ = balance constants
$K$, $K_1$, $K_2$ = derived constants indicative of the distance setting or range of the element
$S$ = a factor indicative of the variation of the range of the $GAX$ starting unit with applied voltage
$\psi$ = an angle characteristic of the element at which the operating torque is a maximum

(*a*) Impedance Element

$$kI^2 = \left(\frac{V}{z_p}\right)^2 \tag{A1}$$

$$K = z_p\sqrt{k} \tag{A2}$$

$$K = \frac{V}{I} \tag{A3}$$

$$K\angle\phi_z = Z\angle\phi_z = \frac{V}{I}\angle(\phi_V - \phi_I) \tag{A4) (6}$$

(*b*) REACTANCE ELEMENT

$$kI^2 = I\frac{V}{z_p}\sin(\phi_V - \phi_I - \phi_{zp}) \tag{A5}$$

In order for this element to indicate reactance $\phi_{zp}$ must be made $= 0$. If this is done

$$K = kz_p; \qquad \phi_{zp} = 0 \tag{A6}$$

$$\frac{K}{\sin(\phi_V - \phi_I)} = \frac{V}{I} \tag{A7}$$

$$\frac{K}{\sin\phi_z}\angle\phi_z = \mathcal{Z}\angle\phi_z = \frac{V}{I}\angle(\phi_V - \phi_I) \tag{A8) (8}$$

(*c*) MODIFIED REACTANCE ELEMENT

The construction and principle of operation of this relay is fully described in reference 5 to which the reader is referred.

$$I^2 + \left(\frac{V}{k'z_p'}\right)^2 + 2I\frac{V}{k'z_p'}\cos(\phi_V - \phi_I - \phi_{zp}) = \left(\frac{V}{kz_p}\right)^2 \tag{A9}$$

$$K_1 = kz_p; \quad K_2 = k'z_p'; \quad \psi = \phi_{zp}' \tag{A10}$$

Substitute equations $A10$ in equation $A9$ and divide by $I^2$

$$1 = \left(\frac{1}{K_1^2} - \frac{1}{K_2^2}\right)\left(\frac{V}{I}\right)^2 - \left(\frac{2}{K_2}\cos(\phi_V - \phi_I - \psi)\right)\left(\frac{V}{I}\right) \tag{A11}$$

Equation $A11$ is a quadratic which may be solved for $V/I$ and the solution expressed in the polar form yields equation 10 given in the text.

(*d*) DIRECTIONAL ELEMENTS WITH VOLTAGE RESTRAINT

Two types of single-phase elements must be distinguished, the *GAX* starting unit type which employs a single voltage and current, and the *GCX* starting unit type which employs 2 voltages and a current.

1. *GAX Type.* In this element the operating torque is obtained from the current $I$ in the current coil and the current in a potential coil which is connected to the source of potential $V$ through a condenser (to obtain the desired phase shift) and a Thyrite stack in order to give the current in the potential coil an amplified value at low values of $V$. The impedance of this potential circuit $z_p'$ is, therefore, not a constant, but is dependent upon the value of $V$. The power factor angle of this circuit $\phi_{zp}'$, however, is substantially a constant. The restraining torque is obtained from a second potential coil operating from $V$ without amplification.

$$kI\frac{V}{z_p'}\sin(\phi_I - \phi_V + \phi_{zp}') = \left(\frac{V}{z_p}\right)^2 \tag{A12}$$

$$KS = \frac{kz_p^2}{z_p'}; \; 90° + \psi = \phi_z'_p \tag{A13}$$

$$K\cos(\phi_V - \phi_I - \psi) = \frac{1}{S}\frac{V}{I} \tag{A14}$$

$$K\cos(\phi_z - \psi)\angle\phi_z = \frac{1}{S}\mathcal{Z}\angle\phi_z = \frac{1}{S}\frac{V}{I}\angle(\phi_V - \phi_I) \tag{A15) (12}$$

In the above equations $K$ is a constant indicative of the relay range at normal voltage. $S$ is a function of $V$ and represents the ratio of the range of the relay at any given value of $V$ to the range at normal voltage. Figure 6 shows the relationship between $S$ and $V$ for the standard *GAX* relay starting unit. For a given fault condition the value of $V$ is readily determined from the proper expression given in table I.

2. *GCX Type.* In this element the operating torque is obtained by the interaction of the current $I$ in the current coil and the current in a potential coil which is connected to a second source of potential $V_q$ which is in quadrature to $I$ at unity power factor. No Thyrite stack is employed so that the impedance of this potential circuit is a constant. The restraining torque is obtained by the interaction of the current in the above mentioned potential coil and the current in a second potential coil connected to the potential $V$.

$$kI\frac{V_q}{z_p'}\sin(\phi_I - \phi_V - \phi_{z'p}) = \frac{V_q}{z_p'}\frac{V}{z_p}\sin(\phi_V - \phi_{Vq}) \tag{A16}$$

$$K = \frac{2}{\sqrt{3}}kz_p; \; \psi = \phi_{z'p} \tag{A17}$$

$$K\cos(90° + \phi_{Vq} - \phi_I - \psi) = \frac{2}{\sqrt{3}}\frac{V}{I}\sin(\phi_V - \phi_{Vq}) \tag{A18}$$

$$K\cos(\phi_z - \psi)\angle\phi_z = \mathcal{Z}\angle\phi_z \tag{A19) (13}$$

$$= \frac{2}{\sqrt{3}}\frac{V}{I}\sin(\phi_V - \phi_{Vq})\angle 90° + \phi_{Vq} - \phi_I$$

$$= \frac{V}{I}\angle(\phi_V - \phi_I) \times \frac{2}{\sqrt{3}}\sin(\phi_V - \phi_{Vq})\angle(90° + \phi_{Vq} - \phi_V)$$

3. *Polyphase Element.* This element has 2 restraining potential coils mechanically balanced against the torque produced by a conventional polyphase directional element. The equations will be derived on the basis of the usual quadrature connections to the operating potential coils. Since we are to deal with 3 phase currents and 3 phase-to-phase voltages, these currents and voltages will be given the usual phase notation.

$$k\Big[I_a\frac{V_{cb}}{z_p'}\sin(\phi_{Ia} - \phi_{Vcb} + \phi_{z'p}) +$$

$$I_b\frac{V_{ac}}{z'_p}\sin(\phi_{Ib} - \phi_{Vac} + \phi_{z'p}) + \tag{A20}$$

$$I_c\frac{V_{ba}}{z_p'}\sin(\phi_{Ic} - \phi_{Vba} + \phi_{z'p})\Big]$$

$$= \frac{V_{cb}}{z_p}\frac{V_{ba}}{z_p}\sin(\phi_{Vba} - \phi_{Vcb})$$

$$= \frac{V_{ac}}{z_p}\frac{V_{cb}}{z_p}\sin(\phi_{Vcb} - \phi_{Vac})$$

$$= \frac{V_{ba}}{z_p}\frac{V_{ac}}{z_p}\sin(\phi_{Vac} - \phi_{Vba})$$

By making the substitution

$$K = 2\sqrt{3}\,k\frac{z_p^2}{z_p'}; \quad \psi = \phi_{z'p} \tag{A21}$$

and transposing the terms, the following equation is obtained.

$$\frac{K\cos(90° + \phi_{Vcb} - \phi_{Ia} - \psi)}{\frac{2}{\sqrt{3}}\frac{V_{ba}}{I_a}\sin(\phi_{Vba} - \phi_{Vcb})} +$$

$$\frac{K\cos(90° + \phi_{Vac} - \phi_{Ib} - \psi)}{\frac{2}{\sqrt{3}}\frac{V_{cb}}{I_b}\sin(\phi_{Vcb} - \phi_{Vac})} +$$

$$\frac{K\cos(90° + \phi_{Vba} - \phi_{Ic} - \psi)}{\frac{2}{\sqrt{3}}\frac{V_{ac}}{I_c}\sin(\phi_{Vac} - \phi_{Vba})} = 3 \tag{A22}$$

It will be noted that the 3 left-hand terms of equation $A22$ are composed of terms identical with the terms of equation $A18$ for the *GCX* unit. Substituting their equivalents from equation $A19$ the following equation is obtained:

$$\frac{K\cos(\phi_{za} - \psi)\angle\phi_{za}}{\mathcal{Z}_a\angle\phi_{za}} + \frac{K\cos(\phi_{zb} - \psi)}{\mathcal{Z}_b\angle\phi_{zb}}\angle\phi_{zb} +$$

$$\frac{K\cos(\phi_{zc} - \psi)\angle\phi_{zc}}{\mathcal{Z}_c\angle\phi_{zc}} = 3 \tag{A23}$$

Equation *A*23 may be reduced to the following form

$$K\cos(\phi_z - \psi)\angle\phi_z = \mathcal{Z}\angle\phi_z = \frac{3}{\frac{1}{\mathcal{Z}_a\angle\phi_{za}} + \frac{1}{\mathcal{Z}_b\angle\phi_{zb}} + \frac{1}{\mathcal{Z}_c\angle\phi_{zc}}} \qquad \text{(A24) (14)}$$

(*e*) TYPE *CZ* IMPEDANCE RELAY

In this type of relay the operating torque is balanced against the restraining torque through what may be considered as an ideal spring. It is apparent, therefore, that the effect of the operating torque in opposing the restraining torque is a function of the extension of the spring which in turn is a function not only of the current, but also of $T$, the time of application of the current. The restraining torque is produced by a voltage solenoid so constructed that the torque produced is proportional to the first power and not to the square of current in it.

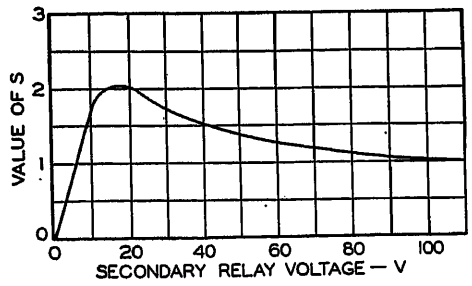

**Figure 6. Variation in range of GAX starting unit with applied voltage**

The relay operates when:

$$kTI = \frac{V}{z_p} \qquad \text{(A25)}$$

$$K = \frac{I}{kz_p} \qquad \text{(A26)}$$

$$T = K\frac{V}{I} = K\mathcal{Z} \qquad \text{(A27)}$$

Unfortunately, equation *A*27 is not satisfactory for the accurate determination of $T$ from $\mathcal{Z}$ due to the fact that $k$ and, therefore, $K$ is not an exact constant but is affected by variations in $V$ and $I$. In order to best express this variation it is desirable to write the following equations.

$$T = f\left(z_e, \frac{I}{T_c}\right) \qquad \text{(A28)}$$

$$z_e = \frac{T_c}{T_v}\mathcal{Z} \qquad \text{(A29)}$$

where

$T_c$ = the current tap setting of the relay
$T_v$ = the voltage tap setting of the relay
$z_e$ = an impedance which would have to be applied to the relay terminals if the relay were connected on the 1-ampere current tap and the 1-volt voltage tap to produce equivalent results

The above relationships assumed that $I$ is a secondary current and that $\mathcal{Z}$ is a secondary impedance. For primary values equation *A*29 will become

$$z_e = \frac{T_cR_c}{T_vR_v}\mathcal{Z} \qquad \text{(A30) (41)}$$

where:

$R_c$ = the current transformer ratio
$R_v$ = the potential transformer ratio

The relationship between $T$ and $z_e$ for various values of $I/T_cR_c$ can be readily determined and plotted as a family of curves. If a set of conventional *CZ* relay curves are available in which $T$ is plotted against current in per cent of tap setting for various voltages applied to the relay on a given voltage tap, then the $T - z_e$ curve may be determined for a given per cent current by making use of the relationship

$$z_e = \frac{\text{voltage applied}}{T_v} \times \frac{100}{\text{per cent current}}$$

$T$ = the time shown by the voltage curve for the given per cent current

## Appendix B—Derivation of Expressions for Voltages and Currents

The expressions for voltages and currents will be derived on the basis that the positive- and negative-phase-sequence networks are identical. The following nomenclature will be used.

$E$ = the normal primary phase to neutral voltage at the relay in the reference phase
$v_1, v_2, v_0$ = the respective positive-, negative-, and zero-phase-sequence voltages at the relay in the reference phase
$V_{0a}, V_{ba}, V_{ab}, V_{ac}$ = phase-to-neutral and phase-to-phase voltage at the relay as indicated
$Z_1$ = the equivalent impedance of the positive- (or negative) phase-sequence network expressed at the voltage $E$
$Z_0$ = the equivalent impedance of the zero-phase-sequence network expressed at the voltage $E$
$z$ = the effective positive- or negative-phase-sequence impedance between the relay and point of fault expressed at the voltage $E$
$z_0$ = the effective zero-phase-sequence impedance between the relay and point of fault expressed at the voltage $E$
$z_1'$ = the effective positive- (or negative) phase-sequence impedance behind the relay expressed at the voltage $E$
$z_0'$ = the effective zero-phase-sequence impedance behind the relay expressed at the voltage $E$
$I_1, I_2, I_0$ = the respective total positive-, negative-, and zero-phase-sequence currents at the point of fault transferred to the relay and in the reference phase at the relay
$i_1, i_2, i_0$ = the respective positive-, negative-, and zero-phase-sequence currents at the relay in the reference phase flowing in $z$ or $z_0$
$i_1', i_2', i_0'$ = the respective positive-, negative-, and zero-phase-sequence currents behind the relay in the reference phase flowing through $z_1'$ or $z_0'$
$I_a, I_b, I_c, I_n$ = primary phase and neutral currents flowing through the relay with star-connected current transformers
$I_a', I_b', I_c'$ = primary phase currents flowing through the relay with delta-connected current transformers
$c_1 = i_1/I_1 = i_2/I_2$ = the positive- (or negative) phase-sequence current distribution factor at the relay
$c_0 = i_0/I_0$ = the zero-phase-sequence current distribution factor
$A, B$ = factors used to simplify the expressions for the voltages $V_{ba}$ and $V_{ac}$

$C, D$ = factors used to simplify the expressions for the currents $I_b$ and $I_c$ in the case of 2 phase-ground faults

$C', D'$ = factors used to simplify the expressions for the currents $I_a'$ and $I_c'$ in the case of 2 phase-ground faults

The following equations express the phase sequence voltages at the relay in the reference phase.

$$v_1 = E - i_1'z_1' = E - (I_1Z_1 - i_1z) \quad \text{(B1)}$$

$$v_2 = -i_2'z_1' = -(I_2Z_1 - i_2z) \quad \text{(B2)}$$

$$v_0 = -i_0'z_0' = -(I_0Z_0 - i_0z_0) \quad \text{(B3)}$$

From these the following equations are derived to express the phase-to-neutral and phase-to-phase voltages at the relay.

$$V_{0a} = v_1 + v_2 + v_0 = E - (I_1 + I_2)Z_1 - I_0Z_0 + (i_1 + i_2)z + i_0z_0 \quad \text{(B4)}$$

$$V_{ba} = \sqrt{3}(v_1\angle 30° + v_2\angle -30°) = \sqrt{3}[E\angle 30° - (I_1\angle 30° + I_2\angle -30°)Z_1 + (i_1\angle 30° + i_2\angle -30°)z] \quad \text{(B5)}$$

$$V_{cb} = \sqrt{3}(v_1 - v_2)\angle -90° = \sqrt{3}[E - (I_1 - I_2)Z_1 + (i_1 - i_2)z]\angle -90° \quad \text{(B6)}$$

$$V_{ac} = \sqrt{3}(v_1\angle 150° + v_2\angle -150°) = \sqrt{3}[E\angle 150° - (I_1\angle 150° + I_2\angle -150°)Z_1 + (i_1\angle 150° + i_2\angle -150°)z] \quad \text{(B7)}$$

The phase and neutral currents in the relay may be expressed in terms of the phase sequence components in the reference phase as follows:

$$I_a = i_1 + i_2 + i_0 \quad \text{(B8)}$$

$$I_b = i_1\angle -120° + i_2\angle 120° + i_0 \quad \text{(B9)}$$

$$I_c = i_1\angle 120° + i_2\angle -120° + i_0 \quad \text{(B10)}$$

$$I_n = 3i_0 \quad \text{(B11)}$$

$$I_a' = \sqrt{3}(i_1\angle 30° + i_2\angle -30°) \quad \text{(B12)}$$

$$I_b' = \sqrt{3}(i_1\angle -90° + i_2\angle 90°) \quad \text{(B13)}$$

$$I_c' = \sqrt{3}(i_1\angle 150° + i_2\angle -150°) \quad \text{(B14)}$$

The above equations are general and apply for any type of fault. The following relationships apply for the particular case of fault under consideration.

1. *Three-Phase Fault*

$$E = I_1Z_1; \quad I_2 = 0; \quad I_0 = 0 \quad \text{(B15)}$$

$$i_1 = c_1\frac{E}{Z_1}; \; i_2 = 0; \; i_0 = 0 \quad \text{(B16)}$$

2. *Phase-Phase Fault (no phase shift in voltage between relay and fault)*

$$E = 2I_1Z_1; \quad I_2 = -I_1; \quad I_0 = 0 \quad \text{(B17)}$$

$$i_1\frac{c_1E}{2Z_1}; \quad i_2 = -i_1; \quad i_0 = 0 \quad \text{(B18)}$$

3. *Phase-Ground Fault (no phase shift in voltage between relay and fault)*

$$E = I_1(2Z_1 + Z_0); \quad I_2 = I_1; \quad I_0 = I_1 \quad \text{(B19)}$$

$$i_1 = \frac{c_1E}{2Z_1 + Z_0}; \; i_2 = i_1; \; i_0 = \frac{c_0E}{2Z_1 + Z_0} \quad \text{(B20)}$$

4. *Two Phase-Ground Fault (no phase shift in voltage between relay and fault)*

$$E = (I_1 - I_2)Z_1;$$

$$I_2 = -\frac{Z_0}{Z_1 + Z_0}I_1; \quad I_0 = -\frac{Z_1}{Z_1 + Z_0}I_1 \quad \text{(B21)}$$

$$i_1 = \frac{c_1(Z_1 + Z_0)}{Z_1(Z_1 + 2Z_0)}E;$$

$$i_2 = -\frac{c_1Z_0}{Z_1(Z_1 + 2Z_0)}E; \quad i_0 = -\frac{c_0}{Z_1 + 2Z_0}E \quad \text{(B22)}$$

5. *Phase-Phase Fault (30-degree phase shift in voltage between relay and fault)*

$$E = 2I_1Z_1; \quad I_2 = I_1; \quad I_0 = 0 \quad \text{(B23)}$$

$$i_1 = \frac{c_1E}{2Z_1}; \quad i_2 = i_1; \quad i_0 = 0 \quad \text{(B24)}$$

6. *Phase-Ground Fault (30-degree phase shift in voltage between relay and fault)*

$$E = I_1(2Z_1 + Z_0); \quad I_2 = -I_1; \quad I_0 = 0 \quad \text{(B25)}$$

$$i_1 = \frac{c_1E}{2Z_1 + Z_0}; \quad i_2 = -i_1; \quad i_0 = 0 \quad \text{(B26)}$$

7. *Two Phase-Ground Fault (30-degree phase shift in voltage between relay and fault)*

$$E = (I_1 + I_2)Z_1; \quad I_2 = \frac{Z_0}{Z_1 + Z_0}I_1; \quad I_0 = 0 \quad \text{(B27)}$$

$$i_1 = \frac{c_1(Z_1 + Z_0)}{Z_1(Z_1 + 2Z_0)}E; \; i_2 = \frac{c_1Z_0}{Z_1(Z_1 + 2Z_0)}E; \; i_0 = 0 \quad \text{(B28)}$$

Equations *B*15–*B*28 when substituted in equation *B*5–*B*7 and *B*8–*B*14 yield the expressions for voltages and currents given in table I.

Equations *B*14 and *B*20 when substituted in equations *B*4, *B*8, and *B*11 give rise to equation 43 in the text.

The vector angles between the voltages are obtained by division of the voltage expressions given in table I. In all cases:

$$\frac{V_{ba}}{V_{cb}} = -\frac{A}{2} \quad \text{(B29)}$$

$$\phi_{Vba} - \phi_{Vcb} = 180° + \phi_A \quad \text{(B30)}$$

$$\frac{V_{cb}}{V_{ac}} = -\frac{2}{B} \quad \text{(B31)}$$

$$\phi_{Vcb} - \phi_{Vac} = 180° - \phi_B \quad \text{(B32)}$$

$$\frac{V_{ac}}{V_{ba}} = \frac{B}{A} \quad \text{(B33)}$$

$$\phi_{Vac} - \phi_{Vba} = \phi_B - \phi_A \quad \text{(B34)}$$

# Tests on Oil-Impregnated Paper—II

## Effects of Gas Pressure

By HUBERT H. RACE
MEMBER AIEE

## Synopsis

In 1934 tests were started to investigate the important factors influencing the life of oil-impregnated paper at high voltage. Last year we described the techniques developed to date in this investigation. The present paper presents all data taken on specimens tested under a gas pressure of 200 pounds per square inch and compared all results obtained with one commercial mineral oil and one commercial wood-pulp paper for 3 conditions of gas pressure. The results indicate that under the conditions of these tests *there is no correlation between dielectric loss and electrical life* and that *gas-free specimens are superior to any specimens saturated with gas up to 200 pounds per square inch pressure.*

## A. Introduction

THE TECHNIQUE developed in our laboratories for studying the causes of electrical failure in oil-impregnated paper using miniature specimens has been described in an earlier paper.[1] Three types of cells were developed to allow life tests to be made under 3 conditions of gas pressure; namely, gas saturated at atmospheric pressure (figure 2), gas saturated at 200 pounds per square inch pressure (figure 4), and gas free (figure 3). This paper also showed the results obtained with 23 specimens which were saturated with gas at atmospheric pressure. It is the object of the present paper to present the data obtained on all the specimens which we have saturated with gas at 200 pounds per square inch pressure, and to compare the data obtained using one commercial mineral oil (oil *A*) and one commercial wood-pulp paper (paper *D*) for 3 conditions of gas pressure in the specimen.

The most general criticism of the work presented in the previous paper was the lack of check tests. The same criticism can be applied to the data presented in this paper since all specimens listed were made in 1934 during the preliminary stages of this investigation. Our subsequent efforts have been directed toward studying *gas-free* specimens and no check tests on the gas saturated or gas pressure specimens have been attempted. Also, we exhausted our supply of oil *A* so that no check tests with identical samples of oil and paper are now possible. However, I believe that the marked differences in life shown by figure 1 are significant and worthy of publication.

The important characteristics of oil *A* and paper *D* are shown in tables I and II.

## B. Specimens Saturated With Gas at Atmospheric Pressure

Table III gives a summary of the life-test data for specimens containing oil *A* and paper *D* and maintained during life under a gas pressure of one atmosphere. All but one of these specimens failed at 22 kv in less than 150 days. Number 165, however, was raised to 30 kv at the end of 150 days and failed immediately. The power factor life history of all specimens is shown in figure 1.

## C. Specimens Saturated With Gas at 200 Pounds Per Square Inch Pressure

Table IV gives a summary of the life-test data for all specimens made with 10 layers of paper *D* and maintained during life under a gas pressure of 200 pounds per square inch. Specimens numbers 182*B* and 300 were dried, impregnated and immersed with degasified oil in the pressure vessel, and then charged with gas to 200 pounds per square inch pressure. The other specimens were dried and impregnated in a glass cell and then allowed to drain while still under good vacuum. After draining, they were transferred as quickly as possible to the pressure vessel and charged with gas at 200 pounds per square inch pressure. Specimens numbers 184, 185, and 186 were drained hot while the oil-impregnated samples were drained cold so that they would retain the maximum volume of oil. The drained samples were made up so as to simulate the worst possible conditions of a high-pressure-gas cable, such as a high spot in the line from which the impregnant would gradually drain away because of temperature cycles during operation. Specimen number 188 was made to see whether 200 pounds per square inch gas pressure was sufficient to prevent ionization in unimpregnated paper. The result was quite conclusive. It was unfortunate that the pressure cell containing specimen number 300 developed a leak which was not detected until the sample had failed electrically because this specimen would probably have had the longest life of any of this series.

One very interesting observation in connection with the preparation of these specimens was the difference in absorption of $N_2$ and $CO_2$. The oil and paper became saturated with $N_2$ in about one hour whereas several days were

A paper recommended for publication by the AIEE committees on research and power transmission and distribution. Manuscript submitted March 1, 1937; released for publication May 27, 1937.

HUBERT H. RACE is a research engineer for the General Electric Company, Schenectady, N. Y. The information reported in this paper is obviously the result of the co-operative efforts of many individuals. In particular, the author wishes to express appreciation to those who have been responsible for important phases of the work, namely: S. I. Reynolds, for preparation of specimens, preliminary and post-mortem electrical measurements; H. M. Bousman, for life tests; and Doctor E. H. Winslow, for acid and metal determinations.

1. For all numbered references, see list at end of paper.

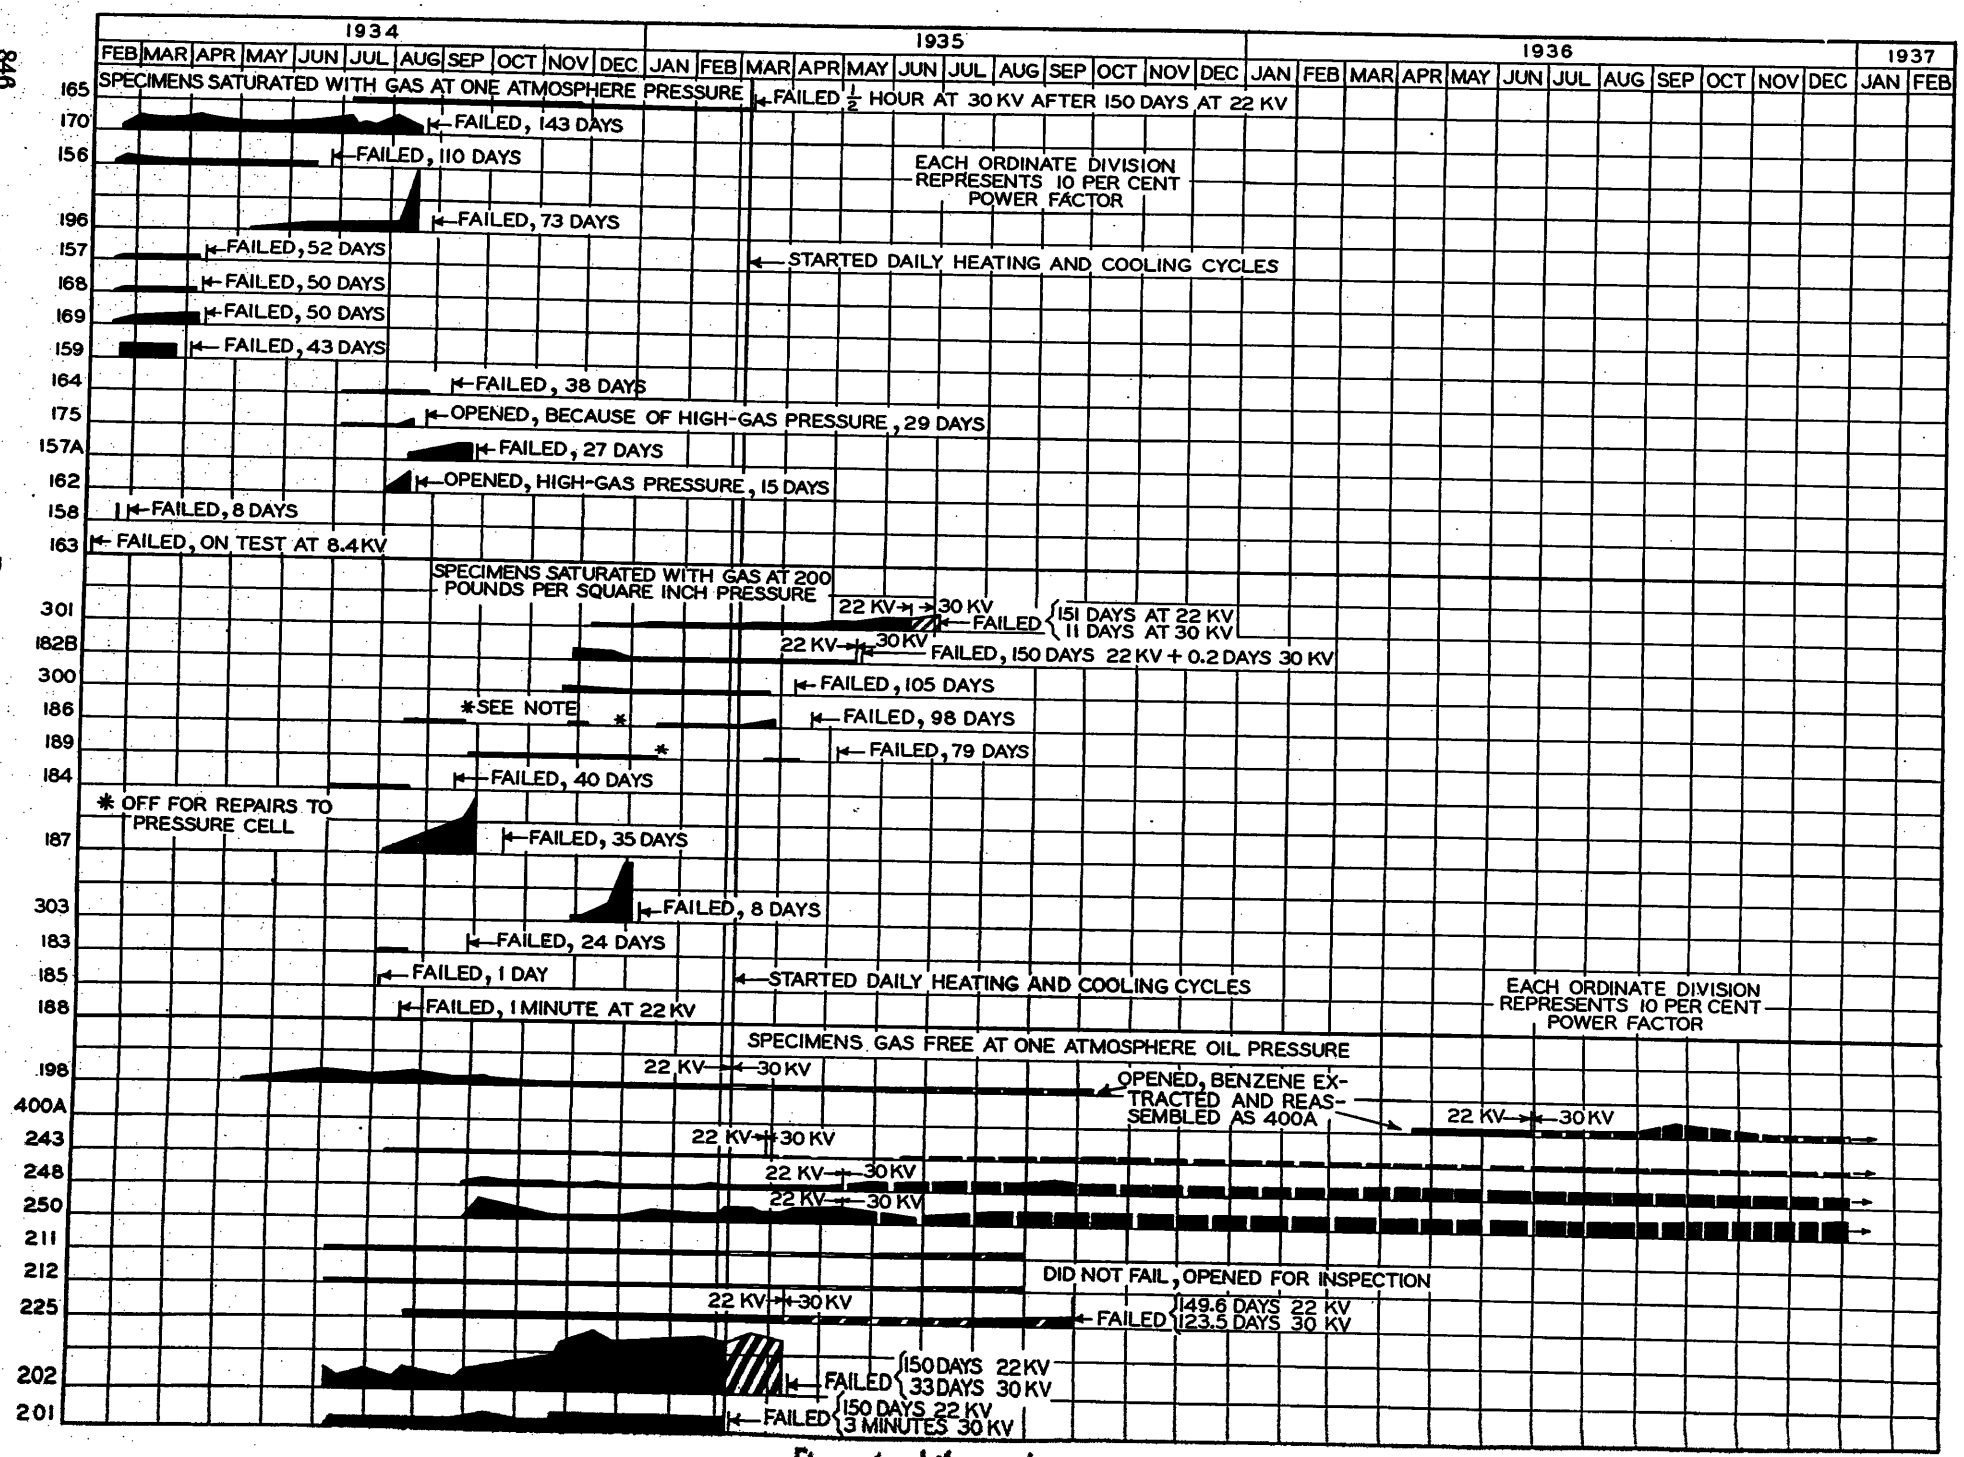

Figure 1. Life-test data

required to completely saturate the specimens with $CO_2$. Also the quantity of $CO_2$ absorbed was correspondingly very much greater.

Table V gives the data obtained by post-mortem examination of the 3 high-pressure specimens having longest life.

After specimens numbers 300 and 301 were prepared it was found that the tank $N_2$ used to charge them may have contained up to 1 per cent $O_2$. This may account for the high values of power factor, acid number, hydrophil number, and lead in solution in the oil from the latter specimen.

### Table I. Properties of Oil A

| | |
|---|---|
| Flash point | about 165 degrees centigrade |
| Fire point | about 185 degrees centigrade |
| Pour point | about −40 degrees centigrade |
| Specific gravity at 15.6 degrees centigrade | about 0.904 |
| Viscosity (Univ. Saybolt) at 37.8 degrees centigrade | about 105 sec. |
| Iodine unsaturation number (grams per 100 grams) | about 15 |
| Slight oxidation number | about 15 |
| Neutralization number (milligrams KOH per gram) | ≤0.015 |
| Chlorides | None |
| Free sulphur | None |
| Power Factor at 60 cycles per second and 60 degrees centigrade | ≤0.0002 |

### Table II. Properties of Paper D

| | |
|---|---|
| Type | 100 per cent sulphate kraft |
| Thickness | 0.0065 inch ± 0.0005 inch |
| Apparent density | 0.75 |
| Ash content | 1.2 per cent |
| Alkalinity (milligrams $H_2SO_4$ per gram) | 0.1 |
| Tensile strength strip one inch wide (machine direction) | 80 pounds |
| Tensile strength strip one inch wide (cross direction) | 22 pounds |
| Tearing strength (Elmendorf) machine direction | 140 pounds |
| Tearing strength (Elmendorf) cross direction | 280 pounds |

By contrast, note the low values for all these quantities for the oil removed from specimen number 182*B*, which was charged with dry $CO_2$.

## D. Specimens, Gas Free, at One Atmosphere Hydraulic Pressure

Table VI summarizes the life histories of all gas-free specimens that have been made with oil *A* and paper *D*. Specimen number 198 was the first gas-free specimen made. After it had been on high-voltage test for a total of 355 days it was taken out of its glass cell without disturbing the electrodes or the wrapping of the paper, extracted in benzene vapor for 24 hours, remounted in a new glass cell, reimpregnated and returned to test as number 400*A*. This was done to determine whether extraction of free oil with benzene and reimpregnation with new oil would improve the power factor. Since no improvement was obtained, we conclude that the materials responsible for dielectric loss in this specimen either are not benzene-soluble or are bound so tightly to the paper fibers that they cannot be washed out with benzene.

Specimens numbers 211 and 212 did not fail but were removed from test after a total life of 295 days, dissembled and examined by the micro methods described in the previous paper.[1] These are the only specimens which have been removed from test for examination before failure has started and therefore they have been included in this comparison. The papers used in these specimens had the same physical characteristics as paper *D*, the only difference being that they had been given special treatment to lower the ash content. There was no sign of incipient failures although there were dark brown stress marks on the inside of the inner layer showing the pattern of the edges of the copper threads on the inner electrode and light gray marks on the outside of the outer layer at the edge of the lead electrode. The results of the microanalyses on these specimens are given in table VIII.

Specimen number 225 has been included in this comparison because it was impregnated with oil similar to oil *A* but removed from the joint of an oil-filled cable in service and delivered to our laboratory in a standard reser-

| 188 | $CO_2$ | *D* | None | | <1 minute | |

* Cell leaked so that pressure dropped to 30 pounds per square inch. This probably caused failure

Specimen number 225 has been included in this comparison because it was impregnated with oil similar to oil *A* but removed from the joint of an oil-filled cable in service and delivered to our laboratory in a standard reser-

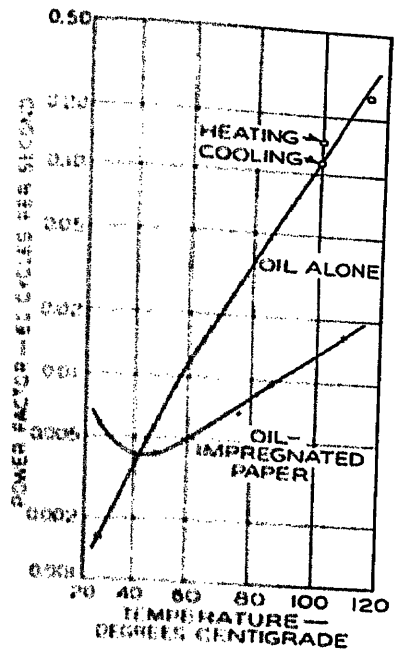

**Figure 2. Comparison of power factor of used cable oil alone and cable paper impregnated with this oil under vacuum**

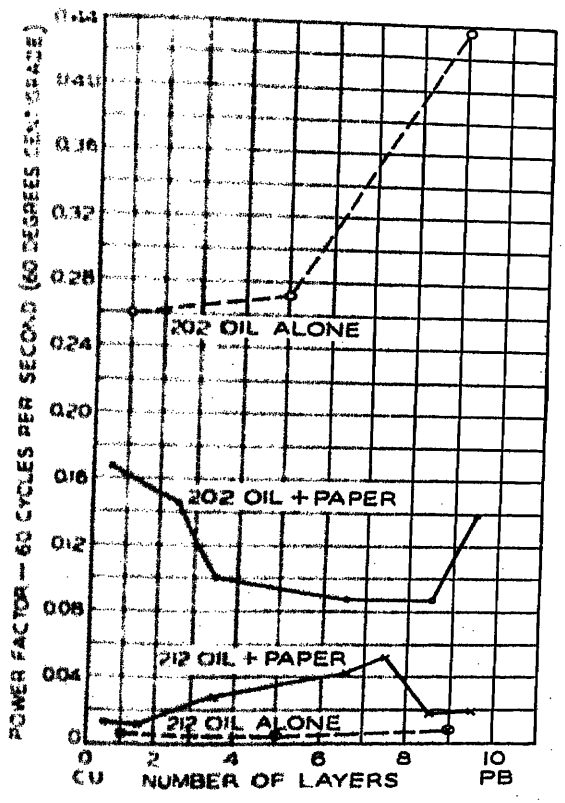

**Figure 3. Radial power measurements of oil alone and oil-soaked paper from specimens 202 and 212**

voir without exposure to air. The important properties of this oil which were different from those of new oil are shown in table VII. These were probably caused by contact with limited amounts of oxygen and black varnished cambric tape in the joint. The important observations from this test are the stability, relatively long life, and relatively low power factor of the specimen impregnated with this oil. That high power factor of oil does not mean correspondingly high power factor of oil-impregnated paper is shown by the life history of specimen number 225 shown in figure 1 and the comparison of oil alone and oil-impregnated paper shown in figure 2.

Specimens numbers 201 and 202 are particularly interesting in that they were impregnated with portions of oil *A*, one without and one with 0.1 per cent of a commercial oxidation inhibitor and preoxidized 96 hours at 115 degrees centigrade in a standard aging oven used by cable manufacturers for making oil-oxidation control tests. The specimen without an oxidation inhibitor gradually developed considerably higher power factor but had a longer life than the specimen containing the inhibitor (see figure 1). Neither had a life comparable with unoxidized speci-

| 225 | Used oil from oil-filled cable in service | 150+ | 123 |
| 202 | Oil *A* oxidized 96 hours at 115 degrees centigrade | 149+ | 33 |
| 201 | Oil *A* + 0.1 per cent oxidized 96 hours at 115 degrees centigrade | 149+ | 3 minutes |

* Opened for inspection—did not fail

mens (198, 401, 211, 243, 248, 250). Apparently, although a cable may contain no free oxygen, if the oil has been oxidized before it is used to impregnate a cable, chemical reactions thus started continue during the life of the cable to the detriment of its electrical properties.

Table VIII shows the results of micro examinations which were made on gas-free specimens shown in table VI. Specimens for which no analysis is given are still running. Tests 4–7 are not reported because the measurements were made several days after the specimens were opened and the results are questionable. It is interesting to note that the specimens containing preoxidized oil showed measurable neutralization numbers concentrated at the electrodes whereas the unoxidized oils had neutralization numbers below our ability to measure them when these specimens were opened. Since these measurements were made the sensitivity of the acid and soluble metal measurements has been considerably improved. The technique will be described in later papers when more experience has been gained with the new methods.

The major difference between specimens 202 and 212 is that the oil used in number 202 was preoxidized before degasification and filling. Therefore, it is very interesting

a power factor curve similar to that observed in commercial cables,[2] being higher in the layers closest to the copper core and lead sheath and lowest in the center layers away from the metal electrodes. These data indicate that oxidized oil is the cause of this type of results observed in tests on commercial cable.

## E. Conclusions

The following general conclusions seem justified by the data presented in this paper.

1. At high electric stress, *gas-free*, oil-impregnated paper at one atmosphere oil pressure (oil and paper having properties like the components of oil-filled cable) should have longer life and less tendency to fail by gaseous ionization than similar cable under $N_2$ or $CO_2$ gas pressure up to at least 200 pounds per square inch gas pressure

2. High power factor of oil-impregnated paper does not necessarily mean short life as long as temperature equilibrium is maintained

3. The presence of oxidized oil will cause high dielectric losses, particularly in the layers of paper near the metal electrodes

to compare the electrical data shown in figure 3 taken after these 2 specimens were opened.

The oil removed from specimen number 212 showed low losses throughout. The oil-soaked paper from specimen number 212 showed higher losses in the center and lowest at both the copper and lead ends. A plausible explanation for this variation is that *in the absence of oxygen or oxidation products* there was negligible chemical action at the 2 electrodes but that some thermal deterioration occurred in the center layers where the temperature would be highest because of dielectric losses. Now considering specimen number 202 the findings are entirely different. The oil extracted from the paper shows very high losses, particularly at the lead end. The oil-soaked paper gives

## Synopsis

In order to make possible the prediction of the attenuation and distortion of lightning waves on transmission lines an equation is proposed that relates the change of shape of a traveling wave to the corona loss on the line at normal operating frequency. Results obtained by computation from this formula are compared with experimental results of various investigators.

THE ATTENUATION of high-voltage traveling waves by corona is of importance because of the protection it affords to terminal equipment when lightning strikes a transmission line at some distance from the nearest transformer station. The traveling wave that results from the lightning discharge has been found by many observers to lose energy quite rapidly as long as its crest voltage is well above the corona-forming voltage of the line on which it travels. A line of several miles length may usually be depended upon, therefore, to reduce the initial voltage of the lightning wave to a safe value.

Various equations have been proposed to express the rate of attenuation of the wave. These are reviewed by Bewley.[3] All of them, including an equation proposed by one of the present authors,[2] are purely empirical and have one or more adjustable constants which cannot be predetermined. It is now proposed to relate the distortion and attenuation of a traveling wave to the loss of power in corona at the line's normal operating frequency.

## The Mechanism of Corona Loss

The energy loss that accompanies corona is due to motion of free electric charge in the space surrounding conductors at high potential. This was pointed out by Ryan and Henline[4] in 1924, and the study of space charge which has since been carried on leads to the following conclusions:

1. There is a critical electric gradient for air that cannot be exceeded. Any attempt to increase the gradient above the critical value results in profuse ionization of the air, and the charges liberated by ionization take up such positions in space that the gradient is maintained at (or below) the critical value

2. Shortly after its formation space charge becomes relatively immobile. This is doubtless due to the formation of relatively heavy ions, for which the mobility is almost negligible as compared to electrons

3. The supply of space charge to the region about a conductor commences when the critical gradient is reached, and continues as long thereafter as the applied voltage continues to increase. During this time there is loss of energy from the conductor

4. After the crest of a voltage wave is reached, and the voltage begins to decrease, the space charge remains (approximately) constant in magnitude and fixed in position. During this time there is little loss of energy from the conductor, what loss there is being due to diffusion of the ions in the electric field at a slow rate. This interval ends when the critical gradient of opposite sign is reached and a new interval of active ionization commences

Space charge may be considered as forming a protective sheath about a conductor—a sheath that receives and terminates much of the incoming dielectric flux, so that no part of the air about the conductor is subjected to electric stress greater than the critical value. If voltage were raised so that the electric stress at any point exceeded the critical value, the gradient at the overstressed point would immediately be reduced by further ionization and the production of additional protective space charge. The action is analogous to the relief of mechanical stress in a piece of overstressed steel by inelastic deformation of the material.

When the voltage applied to a conductor is alternating it is necessary to locate a protective sheath of space charge about the conductor as the voltage rises to a crest, and then to neutralize that charge and replace it with one of opposite sign as the voltage changes to a crest of opposite polarity. Energy is consumed in the production of the space charge; the amount of energy consumed per cycle depends on the crest voltage of the wave but, as the amount of space charge required is independent of the duration of a cycle, the energy per cycle consumed in its production is independent of the frequency of the applied voltage. The power, consequently, or energy per second, is proportional to frequency. But this is not the total loss.

There is another kind of loss that is due to migration of the ions of space charge in the electric field. The protective sheath of space charge can never be stationary, for it is at all times acted upon by the electric field of the applied voltage and that of other parts of the space charge. When space charge moves in response to the electric field of the applied voltage it consumes power. So there is a continuous drain of power due to the *motion* of the space charge, quite apart from that due to its *formation*. Both are dependent upon the amount of applied voltage, but the loss due to migration differs from that due to formation by being a nearly constant loss that (at low frequency) is independent of the frequency. At moderately high fre-

A paper recommended for publication by the AIEE committee on power transmission and distribution. Manuscript submitted February 25, 1937; released for publication May 25, 1937.

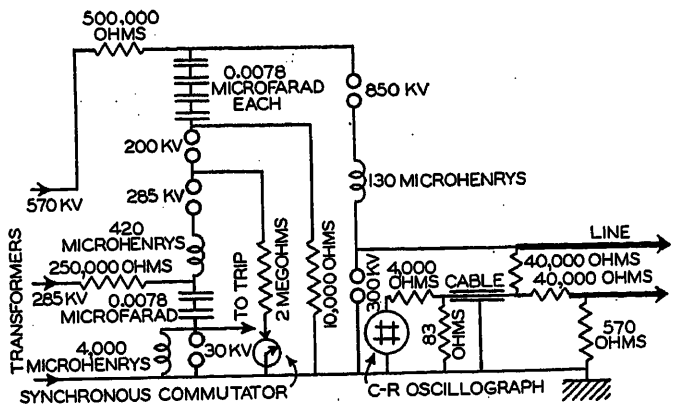

**Figure 1. Impulse generator and oscillograph**

quencies it becomes a negligible part of the total loss, while at 60 cycles per second it is about one-third of the total.[5]

The energy required to produce a protective sheath of space charge about a conductor is dependent upon the height to which the applied voltage rises. Each increase of voltage requires an increase of space charge, with a corresponding consumption of energy. As the applied voltage is raised from $e$ to $e + \Delta e$ the energy which has been used to produce space charge increases from $E$ to $E + \Delta E$. The ratio of the increments is (for very small increments) $dE/de$, which may be found by differentiation. The loss corresponding to a given increment of voltage is of course not constant, but is in general greater when the increase of voltage takes place at a high voltage than when the same increase takes place at a low voltage.

In developing the above concept of corona loss the mechanism of corona formation has been greatly idealized, and many small factors have been entirely neglected. One of these is a difference in loss on the positive and negative half-cycles of corona. This particular factor requires special mention, for it will arise again in the discussion of traveling waves.

## Loss From a Traveling Wave

A wave of electric energy traveling along a transmission line will necessarily produce ionization about the line as it passes and, since the only source of energy is the wave itself, it will lose energy as it travels. There is ample direct evidence of corona produced by traveling waves, for it may be both seen and heard.

Moreover, the voltage of a wave is related to its energy, although the relationship is not at all simple in a wave which is changing in shape as it travels. On a line without loss, or a distortionless line, energy is proportional to the square of the voltage for each element of the wave. This simple relationship is an approximation when applied to waves that are producing corona, but under any circumstances the voltage of a wave becomes less as its energy is decreased. And oscillographic measurements and sphere-gap measurements both show a rapid reduction of the voltage of traveling waves as long as their voltage exceeds the corona-forming voltage of the line.

## Analysis of Oscillograms

Oscillograms of waves attenuated by corona are shown in figure 2. The figure shows at the top, left, the record of a 320-kv wave impressed upon a line of number 10 copper wire, and at the top, right, the record of the same wave as it was received after traveling 836 feet along the line. Below this is a similar record of a wave of negative polarity, with an equal initial voltage but showing rather less attenuation as received. The time scale of the record is given by the 5-million-cycle wave at the bottom of the figure; the initial waves rise from zero to maximum voltage in 0.3 microseconds, the wave fronts being practically straight lines. These are typical of a collection[1] of several dozen of such oscillograms.

The network shown in figure 1 was used in obtaining these records. In producing a wave, the sphere gap set to flash at 285 kv is first to trip, the polarity of discharge being determined by a synchronous commutator. This immediately actuates the trip circuit of the cathode-ray oscillograph, and then, with a slight time delay, because of inductance, the gap set for 200-kv sparks. One set of condensers is charged by the transformers to 285 kv, and the other set to 570 kv; operation of the first 2 sphere gaps connects the condensers in series and so trips the main gap which is set at 850 kv. The condensers now commence to discharge into the line, producing the test surge, but when the voltage across the line has risen to 300 kv the surge is "chopped" by a sphere gap, and the surge voltage drops almost immediately to zero.

By adjusting the values of inductance, waves were produced having wave fronts of 0.3 to 1.63 microseconds duration. All waves were substantially triangular in shape. The oscillograms show a superimposed ripple, but this originated in the oscillograph circuit; it could be removed by introduction of damping resistance in the oscillograph circuit, but it was found best not to do so because of resulting loss of accuracy of the record.

The generated surge was sent out as a traveling wave on the test line. The line was laid out as a large loop, returning to the laboratory, and terminated in a resistor having the surge resistance of the line. Both outgoing and returning waves were recorded on a cathode-ray oscillograph.

Examination of the oscillograms yields the following information. The received wave has a wave front that is less steep than was that of the initial wave. The time re-

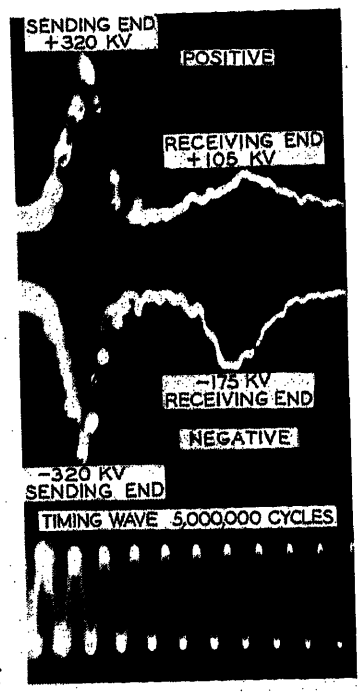

**Figure 2. Oscillograms of traveling waves, showing distortion by corona**

quired for the received voltage to rise from zero to maximum is equal to the time required for the initial voltage to rise from zero to maximum and then to descend to a value equal to the maximum received voltage. In other words, if the received wave were superimposed on the initial wave its crest would fall upon the "tail" of the initial wave, as shown in figure 3. At the same time the received wave has acquired a longer tail than was possessed by the initial wave. The appearance of the whole is as if the wave front had been cut down to a gentler slope as a result of having traveled along the line, so that the front and crest of the wave have been reduced, while the tail has somewhat gained.

Various attempts to deduce a law of action by *a posteriori* reasoning from the oscillograms failed, but they served at least to indicate the nature of the differential equation from which the law would have to be derived. It was seen to be related to the "quadratic law" of corona loss as promulgated by Peek,[5] and so the quadratic law was adopted as a starting point for the *a priori* deduction of a law of distortion by corona.

## Deduction of a Law of Action

Power loss from the experimental transmission line was determined by measurement, and is shown in figure 4. By plotting on a logarithmic scale it was found that the curve may well be expressed analytically as

$$\text{Loss} = k'(e - e_0)^2 \qquad (1)$$

in which $e$ is voltage, and $e_0$ and $k'$ are constants. The constants as so determined are in good agreement with those computed from the coefficients of Peek's law.

Corona loss is measured as power; that is, as energy per second. After that part of the power loss which is not proportional to frequency has been subtracted, the remainder may be divided by the number of voltage crests per second, and by the length of the line. The result, loss per unit length per half cycle, is expressed by an equation similar to equation 1 but with a different value for the coefficient which (for reasons that will appear later) may be written as $k/n$:

$$(\text{Loss as voltage rises to } e) = \frac{k}{n}(e - e_0)^2 \qquad (2)$$

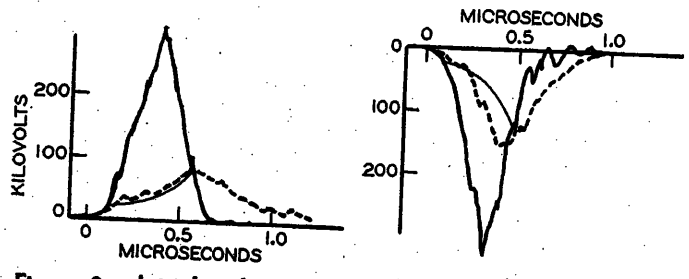

**Figure 3. Initial and received waves of oscillograms, superimposed. Computed curves are also shown**

The rate of energy loss as voltage increases is then found by differentiating equation 2:

$$\frac{dE}{de} = 2\frac{k}{n}(e - e_0) \qquad (3)$$

so that for a differential increase of voltage the loss is

$$dE = 2(k/n)(e - e_0)de \qquad (4)$$

When an electric wave is traveling on a line the voltage at a point of the line rises as the front of the wave passes. During the passage of the wave front, space charge is placed about the conductor, and energy is lost from the wave. Consider a specific point of the line $P$ at a distance which may be called $s$ from some stationary reference axis. (See figure 5.) Consider a short section of the traveling wave at the point $P$, which section of the wave may be specified as being at a distance $x$ from a reference axis which is moving along the line at the speed of the traveling wave. It follows that for a given point on the line $s$ is constant, while for a given section of the wave $x$ is constant. The 2 systems of co-ordinates are related by $s = x + y$. By definition, then, $y$ is the distance between the reference axes, so $y = vt$ wherein $v$ is the velocity of propagation of the wave (practically that of light) and $t$ is the time that has elapsed since $y$ was zero.

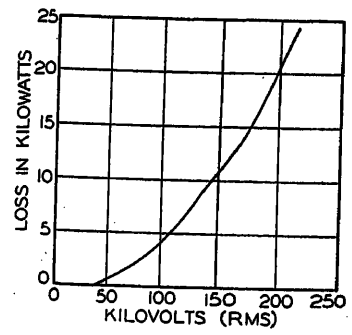

**Figure 4. Corona loss from a number 10 American wire gauge copper conductor, 836 feet long, 12.5 feet above ground. Voltage: 60-cycle sine-wave, wire to ground**

The energy loss at the point $P$ from a section of wave of length $dx$ while the wave is traveling a short distance $dy$ is

$$\text{Loss} = 2\frac{k}{n}\,dx\,(e - e_0)\,de \qquad (5)$$

in which $de$, the change of voltage at the point $P$, is

$$de = \frac{\partial e}{\partial x}dx + \frac{\partial e}{\partial y}dy$$

But since at a fixed point $s$ is constant, $dx = -dy$ and

$$\text{Loss} = 2\frac{k}{n}\,dx\,(e - e_0)\left(-\frac{\partial e}{\partial x}dy + \frac{\partial e}{\partial y}dy\right) \qquad (6)$$

It is now necessary to express energy of a section of traveling wave in terms of voltage. In the absence of distortion the energy of a section of wave of length $dx$ would be

$$E = c\,dx\,e^2 \qquad (7)$$

$c$ being the capacitance per unit length of line. Half of the energy is in the electric field, and half in the magnetic.[13] When distortion of the wave is taking place this equation

becomes an approximation only. Although of uncertain accuracy in the presence of corona, it will nevertheless be used in the following discussion, for it must be of the right order of magnitude.

Differentiation of equation 7 gives the rate of change of energy of a section of wave as its voltage changes, so the change of energy corresponding to a differential change of voltage is

$$dE = 2\,c\,dx\,e\,de \tag{8}$$

But loss due to corona, as expressed in equation 6, must be supplied from the energy of the wave, so

$$2\,c\,dx\,e\,de = 2\,\frac{k}{n}\,dx\,(e - e_0)\left(\frac{\partial e}{\partial x} - \frac{\partial e}{\partial y}\right)dy \tag{9}$$

Since $de$ of equations 8 and 9 is the change of voltage of a section of the wave it is the partial differential with constant $x$, and is equal to $(\partial e/\partial y)\,dy$. Introducing this into equation 9, and performing obvious simplifications,

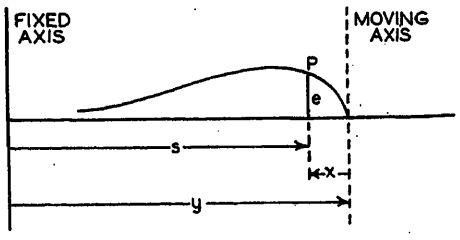

**Figure 5. Coordinates of traveling wave**

$$c\,e\,\frac{\partial e}{\partial y} = \frac{k}{n}\,(e - e_0)\left(\frac{\partial e}{\partial x} - \frac{\partial e}{\partial y}\right) \tag{10}$$

Rearrangement gives the partial differential equation

$$-\frac{k(e - e_0)}{k(e - e_0) + nce}\,\frac{\partial e}{\partial x} + \frac{\partial e}{\partial y} = 0 \tag{11}$$

for which the solution is an arbitrary function

$$f\left(t - \frac{k(e - e_0) + nce}{ncve}\,s\,,\,e\right) = 0 \tag{12}$$

(Elimination of $x$ and $y$ between equations 11 and 12 has been accomplished by use of the expressions defining $s$ and $y$.)

The form of function to be used in equation 12 is determined by some known relationship between $e$ and $t$ at some known value of $s$; for example, at the point where the voltage wave is applied to the line. If the initial wave is the function of time $e = f_0(t)$, it follows from equation 12 that at a distance $s$ the wave will have become

$$e = f_0\left(t - \frac{k(e - e_0) + nce}{ncve}\,s\right) \tag{13}$$

The initial voltage as a function of time may also be expressed $t = F_0(e)$, and corresponding to this is the equation (derived from equation 13) which applies at distance $s$:

$$t = F_0(e) + \frac{k}{ncv}\,\frac{(e - e_0)}{e}\,s + \frac{s}{v} \tag{14}$$

## Use of Derived Equation

This form of the equation is easily applied to any traveling wave. The only information regarding the wave that is needed is a curve of voltage and time; an oscillogram, that is, of the initial voltage (or if this is not available, of the voltage at any point on the line). There is no necessity to express $f_0(t)$ or $F_0(e)$ analytically, for the equation has been arranged to allow a graphical solution. The equation gives the information that at a point at distance $s$ there will correspond to each value of voltage $e$ a value of time $t$. This will differ from the value of time that corresponded to the same voltage at the initial point on the line by the last term of equation 14, which is merely the time required for the wave to travel the distance $s$, and by the next-to-last term which alone describes the distortion of the wave due to corona.

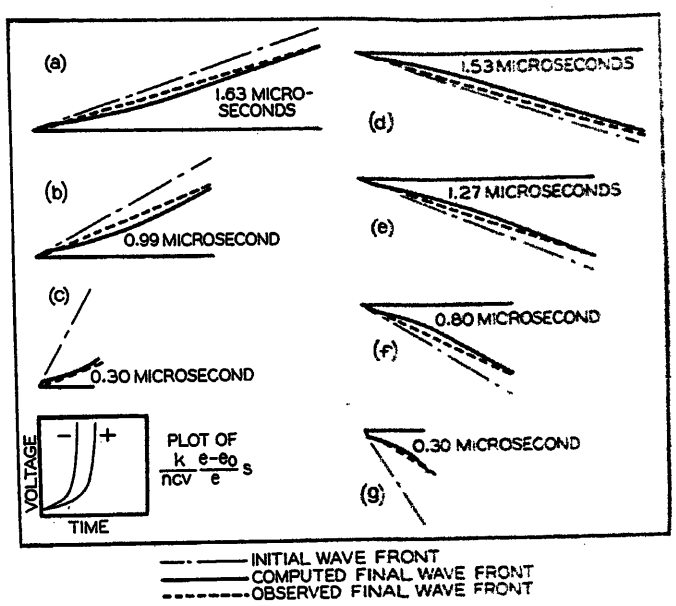

**Figure 6. Comparison of computed and recorded waves after attenuation and distortion by corona. All initial waves have crest voltage approximately 310 kv**

To determine the shape of the wave at distance $s$, plot the initial voltage-time curve. Then, at each value of voltage increase the value of time by an amount $Ks(e - e_0)/e$. The result is the wave as distorted by corona. (It must be noted, however, that this procedure applies only on the front of the wave, while the voltage is rising to a higher value than it has before attained. In the absence of further information it must be assumed that the tail of a wave is not affected by corona. This will be discussed in a later paragraph.) Reference to equation 14 gives a value of $k/ncv$ for $K$.

Symbols have the following meanings:

$t$ = time in seconds
$e$ = voltage in volts
$e_0$ = corona-starting voltage in volts (crest)
$c$ = capacitance of the line in farads per foot
$v$ = velocity of the wave in feet per second (practically $0.985 \times 10^9$)

$s$ = distance of travel in feet
$k$ = the constant of equation 2 which relates crest voltage in volts to energy loss in joules per foot per half cycle, and which may be found from Peek's quadratic law or otherwise
$n$ = a factor which differs for positive and negative waves, and as discussed below

## The Factor n

The factor $n$ is a more or less constant factor which is needed to account for 3 differences between the corona of traveling waves and the corona at power frequency. These are (1) the effect of mobility of charge, (2) the fact that when voltage is alternating there is space charge left over from one half cycle to the next, and (3) the difference between positive and negative corona.

The effect of mobility of charge has already been mentioned; at power frequency there is considerable loss due to mobility that is essentially constant regardless of frequency. Peek[5] shows that this is 25/85 of the 60-cycle loss. Other investigators give a slightly higher value, and it will be approximately correct to consider that the loss at 60 cycles due to cyclic reversal of space charge is 2/3 of the total loss. It was partly to take care of the division of power loss into cyclic and constant parts that the factor $n$ was introduced, and this consideration alone gives $n$ a value of 3/2. (See equation 2.) But this value of $n$ may be altered to take care of other considerations also.

Each crest of alternating voltage leaves the conductor surrounded by a sheath of space charge. Some of this returns to the conductor from which it came, some reaches the other conductor or is lost in space, but most remains until it is cancelled by a discharge of opposite sign as the applied voltage is reversed. During each half cycle of voltage, therefore, it is necessary not only to supply space charge of the same polarity as the voltage, but also to remove (or cancel) space charge of the opposite polarity. Consequently the total loss per half cycle is greater than would be the loss if there had been no previous opposite charge by a factor of uncertain magnitude that is something between 1 and 2. The use of $n$ may be extended to care for this factor, and the value of $n$ therefore becomes approximately 3.

Moreover, it is found that the loss of energy from a positive conductor is greater than that from a negative conductor. This is observed even with alternating voltage, although in the steady state the loss is largely equalized by the production of a rectified space charge. It is impossible for the charge that escapes from a conductor in corona to be continuously unbalanced, for the resulting excess of charge of one sign will accumulate until the voltage gradient about the conductor is so adjusted that the production of charge on alternate half cycles is equalized. But many observers of impulse voltages and traveling waves have found that the loss is greater from a positive conductor. It is, of course, natural that there should be a difference due to polarity because of different details of action of positive and negative ions. The ratio of loss from a positive wave to loss from a negative wave appears to be about 3 to 2. It is helpful, therefore, to assign different values to $n$ for positive and negative waves; $n^+$ (for positive waves) would on this basis be about $2^1/_2$, while $n^-$ (for negative waves) would be about 4.

## Comparison With Oscillograms of Waves

In figures 3, 6, 8, and 9 a comparison is shown of distortion as predicted by equation 14 and actual oscillographic voltage records. The oscillographic curves of figure 3 have been described above; superimposed on them are computed curves based on equation 14. The values of $n$ used in making the computations were $2^1/_2$ and 4 for positive and negative waves, respectively. These are the predicted values of $n$, and they give reasonably good agreement.

Figure 6 shows a comparison with the fronts of the same waves and with longer ones also. Each curve shows the average of data from several oscillograms; in most cases 5 or 6 photographic records were averaged. The term from equation 14 that expresses wave distortion due to corona is plotted in the lower left corner of the figure: in computing the shape of the distorted wave the abscissas of the appropriate curve are added to the values of time of the initial wave front, at the corresponding value of voltage.

It will be seen that agreement with measured waves is within the probable experimental error. However, computation for this figure was done with $n^+ = 4$ and $n^- = 6$, which values are about 50 per cent higher that the predicted ones.

It was also possible to compare the results of computation with equation 14 to data obtained some years ago.[2] A series of measurements with sphere gaps gave crest values of very short traveling waves as they were attenuated by corona. Only maximum voltages were measured, so the comparison must necessarily be with computed maximum values. It is known that the waves employed in the experimental work had practically uniform rise of voltage from zero to maximum, at which point they were "chopped," so that they were essentially triangular waves without tails. The slope of the impressed wave front was of the order of 2,000 kv per microsecond, and the crest voltage varied from 100 to 220 kv, so the duration of the wave is computed to be from $^1/_{20}$ microsecond for the short waves to $^1/_{10}$ microsecond for the longer ones. It will be seen that these are of a shorter order of magnitude than the waves of figure 6. Comparison of experimental and computed results is shown in figure 7; the agreement is surprisingly good. The value of $n$ used for the computed curves was 5, but the polarity of the experimental waves is not known.

The line used for the data of figure 7 was similar in size and height to that used later, so its loss at 60 cycles was taken from figure 4. Its total length was 1,000 feet but the first 500 feet were most significant and data for that part of the line only are shown in figure 7. The complete experimental curves appear in figure 1 of a previous paper,[2] and agreement with computed values is good throughout.

For comparison with completely independent experi-

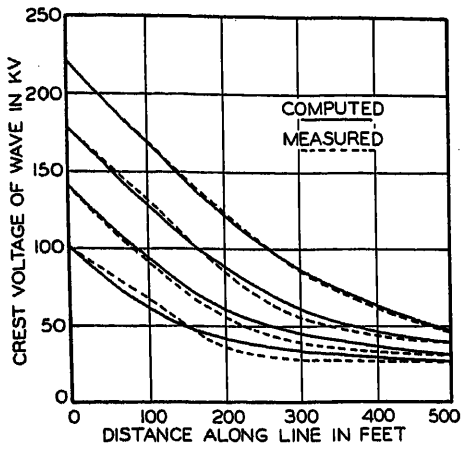

**Figure 7. Comparison of computed and measured wave crests as traveling waves are attenuated by corona**

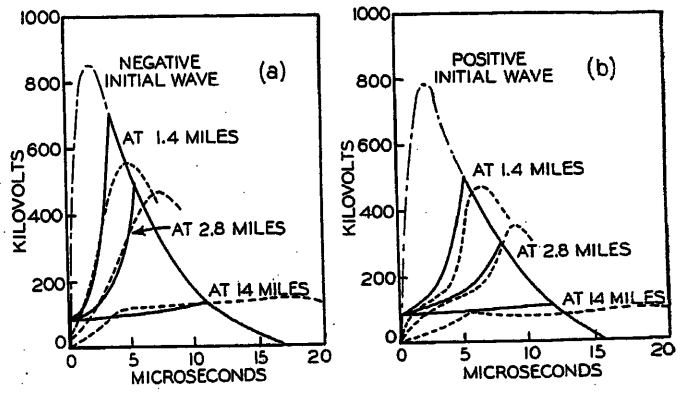
mental work, computations were made of the change of shape to be expected in waves on one wire of the *S*-19 line of the Consumers Power Company (Michigan). Dimensions of the line are given in a paper[8] by McEachron, Hemstreet, and Rudge; corona loss on the line was computed according to the quadratic law, and the change of shape as predicted for traveling waves by equation 14 was determined on that basis. The experimentally recorded distortion of waves on the *S*-19 line is shown in a paper[7] by Brune and Eaton, and one set of their oscillograms is particularly fitted for comparison with computed distortion. Experimental and computed waves are shown in figure 8. The initial wave is shown, and also the received waves at 3 different distances along the line.

In computing distortion of the negative wave of figure 8*a*, a value of 4 was used for $n^-$, and for the positive wave of figure 8*b* a value of $2^1/_4$ was taken for $n^+$. See table I.

The general form of the computed and observed wave fronts of figure 8 is quite comparable. It is not at all surprising that there is difference of detail, for the computed curves consider only the effect of an ideal distribution of corona and completely neglect resistance of line and ground, the presence of other conductors, insulators and towers, variation of ground level, and other irregularities of the line. It is natural that the shorter the distance of travel, and the more rapid the attenuation by corona, the better is the agreement.



Several of the other curves shown by Brune and Eaton offer further interesting comparisons, but will not be reproduced here.

A study of the change of shape of traveling waves on the Bushkill-Roseland line of the Public Service Electric and Gas Company (New Jersey) is reported by Cox and Beck[9] and by Conwell and Fortescue.[10] The latter paper gives data that make possible the computation of corona loss at power frequency (using the quadratic law) and both papers show a number of oscillograms of waves affected by corona. Comparison of a wave from the latter paper with a curve of wave form computed from line dimensions appears in figure 9. The agreement is seen to be satisfactory. The value of $n^+$ used in computation was $2^1/_2$. There are several other sets of oscillograms of waves in these papers for comparison with computed distortion, but unfortunately there are no records of waves of negative polarity.

Behavior of waves on the Bushkill-Roseland line is of particular interest because it is typical of 220-kv lines in general dimensions, and therefore in corona loss. The conductors are 795,000-circular-mil-steel-reinforced aluminum cables, some 60 feet above ground. Conductors are spaced 28 feet, 6 inches, in a horizontal plane.

It will be noted that in all cases of comparison the agreement of recorded and computed distortion is good, but that different values of the factor $n$ have been employed. The values used for $n$ are shown in table I.

It is not improbable that the apparent variation of $n$ with duration of wave front is entirely fictitious, being due to experimental difficulty. On the other hand, it may be due to an actual decrease of loss when the duration of the wave front under consideration is very short. If the decrease of loss is real it may be due to inability of ions to move with great enough speed, although this is improbable because the motion required for the formation of space charge is largely electronic and electrons in a critical field travel several meters per microsecond; it may more probably be attributed to ground resistance

**Figures 8a (left) and 8b (right). Comparison of computed waves (solid lines) with oscillograms by Brune and Eaton (dash lines) as a traveling wave is distorted and attenuated by corona**

and a consequent decrease of gradient about the conductor due to what may be loosely spoken of as a lowered equivalent ground plane.

Imperfect agreement of the values determined for $n^+$, and for $n^-$, is not at all surprising when it is remembered that the duration of the waves varies from about 10 microseconds for Brune and Eaton's waves to less than $^1/_{20}$ microsecond for Skilling's, or a factor of over 100 to 1, and that a half cycle at 60-cycle frequency is nearly 1,000 times the duration of the waves of Brune and Eaton. It appears, on the contrary, that there must be some element of truth in the theory proposed since the discrepancy in $n$ is less than a factor of 2 over a time range of 1 to 100,000, particularly considering that the crest voltage varied from 100 kv (Skilling) to 900 (Conwell and Fortescue), the line from a number 10 wire (Dykes and Skilling) to a one-inch aluminum cable (Conwell and Fortescue), and the distance of travel from 50 feet (Skilling) to 2.8

miles (the greatest distance for really significant comparison with Brune and Eaton).

## The "Tail" of the Wave

While the front of a wave is passing a short section of line it is surrounding that section with a sheath of space charge. This reduces the potential gradient in the immediate vicinity of the conductor. But after the crest of the traveling wave has passed, and the line voltage has dropped to well below its instantaneous maximum, there will be some return of space charge to the conductor. Because of the presence of space charge, the gradient about the conductor will be reversed in polarity even before the wave has completely passed, and it is this that will return some of the inner part of the charge to the conductor. As the charge returns, the tail of the passing wave is built up and lengthened. This effect is visible in all oscillograms. (See figures 3, 8, and 9.) Whether an important part of the energy of the wave is thus regained depends on the shape of the wave and the relation of its maximum voltage to corona-forming voltage of the line. In general the tail of the wave is not *greatly* altered from point to point of the line. It will be seen from any of the oscillograms that voltage at a given point on the tail is continuously but slowly increasing, but that the total increase is small compared to the crest voltage of the initial wave. It seems entirely practicable, therefore, to neglect any change of the tail in computing the change of shape of a traveling wave.

This is done in figures 3, 6, 8, and 9. It will be seen that the wave form at any point of the line is determined by

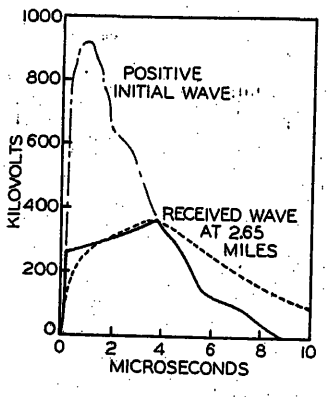


**Figure 9. Comparison of computed wave (solid line) with oscillogram by Conwell and Fortescue (dash line) as a traveling wave is distorted and attenuated by corona**

extending the computed curve (based on equation 14) until it intersects the initial wave, and thereafter following the tail of the initial wave. This does not give an accurate representation of the tail of the distorted wave, but it does give a satisfactory curve for the front of the wave and a good approximation of the wave's maximum voltage. It is this last value that is usually of greatest practical importance.

The shape of the computed wave will usually more nearly approach the shape of the actual wave if its sharp corners are slightly rounded. Physically this is due to the resistance of the line and ground, particularly as influenced by skin effect.[7]

**Table I**

| Data From | $n^+$ | | $n^-$ |
|---|---|---|---|

| Skilling (figure 7) | | | 5† |

* Average of polarities.
† Polarity unknown.

## Other Theories

So far as is known to the author, there has been no previous attempt to account *in detail* for the change in shape of traveling waves due to corona loss. Boehne[11] in 1931 suggested that the change in shape is due to a change of the capacitance of a line during corona (in this connection, see also a paper by Gardner[12]). Bewley[6] in 1933 discussed the change of shape of waves due to ground resistance, and offered a theory of traveling waves which involved 2 or more velocities of wave components. He proposed the extension of this discussion, which appears to give beautiful results at voltages below the corona-forming voltage, to explain distortion due to corona on the basis of a change of capacitance of that part of the line on which there is corona. There would be no sharp distinction between such a theory and the one that is used in this paper if it were possible to express the postulated change in capacitance as a function of the voltage and to include the loss of energy involved. But when loss of energy is omitted, and only distortionless wave components of different velocities are considered, the extremely large attenuation which is actually produced by corona does not appear.

The following comment should be made in this connection. Distortion due to corona becomes less as the voltage of a surge is diminished, and the wave tends to flatten out, with the voltage of its flattish top equal, generally speaking to the corona-forming voltage. This is illustrated by both waves of figure 8, at the 14-mile position. But many factors which are of negligible importance when the surge voltage is high make themselves felt when the surge voltage is low. Energy lost due to line resistance and ground resistance, and energy transferred inductively to nearby conductors, are overshadowed at high voltage by the great loss of energy due to corona. At lower voltage they have much to do with determining the shape of the wave. It can be seen, for instance, by reference to the original oscillograms of the paper by Brune and Eaton,[7] that the waves of figure 8 at the 14-mile position do not have a simple flat top, but appear, in detail, to have 2 rather distinct humps. It is interesting to consider this shape in the light of the theory of multivelocity components. But it will also be seen from Brune and Eaton's curves that this is a minor effect which does not appear while rapid attenuation by corona is taking place. In other words, the reduction of lightning voltage from a dangerous value to a safe value is the result of energy loss in corona.

Any of the various empirical formulas which have been proposed can only hope to be true for an imposed wave of some standard form. This is clearly true when one considers that the corona loss at any particular voltage depends not only on the value of that voltage but also on the rate of change of voltage at that point; and consequently the rate of decrease of the crest voltage of a traveling wave depends on the shape of the entire wave. It is perfectly certain that any successful formula for the distortion and attenuation of waves that are affected by corona must take into account the whole wave, and not just the maximum voltage at the wave's crest.

## Conclusions

This paper is a derivation and discussion of a formula for the change of shape of a traveling wave that is distorted and attenuated by corona. The formula, equation 14 of the paper, is

$$t = F_0(e) + \frac{k}{ncv}\frac{(e - e_0)}{e}s + \frac{s}{v}$$

The first term of the right-hand member is the initial shape of the wave, and the second term is the change of shape due to corona. (The third term merely accounts for the lapse of time while the wave travels.)

All quantities in this formula, except $n$, can easily be predetermined. The factor $k$ is found from the measured or computed corona loss of the line at normal frequency. Approximate values of $n$ are 2.5 for positive waves and 4 for negative waves, but more data are needed to substantiate these values and to determine their range of application.

The derivation of the proposed law involves several approximations, but its agreement with experimental results over a wide variety of conditions is reassuring.

## Relaxation of Copper

With the present tendency to employ higher temperatures in various industries, more extensive investigation of the behavior of metals at elevated temperatures has become important. Under a grant received from the Engineering Foundation during the years 1935–36, work on this subject was done by John Boyd with the facilities offered by the research laboratories of the Westinghouse Electric & Manufacturing Company in co-operation with the University of Pittsburgh, and reported in the paper "Relaxation of Copper at Normal and at Elevated Temperatures," which was presented at the annual meeting of the American Society for Testing Materials at New York, N. Y., June 28–July 2, 1937. The problem was suggested by Doctor A. Nadai of the Westinghouse laboratories.

The phenomenon of the decrease of stress at constant length, such as occurs in bolts, has been called relaxation. Some investigation of this phenomenon has been made, but few of the methods used have attempted to produce pure relaxation conditions. The tests described in this paper were made with an apparatus designed to eliminate the principal difficulties of former methods. Special attention was directed toward fulfilling the conditions of pure relaxation, that is, measuring the decrease in stress while the length of the test piece is carefully kept constant. Copper was chosen as a test material because of its importance in electrical machinery as well as its relative simplicity, and was used in the form of wire 0.204 inch in diameter.

A complete correlation has not as yet been made between data for relaxation and creep, which is the increase in length with time for material at constant stress. All experimental evidence seems to show that the creep rates found in relaxation tests are greater than those obtained from creep tests under what were assumed to be similar conditions. As a result, the magnitude of the decrease in stress in relaxation is larger than at first would be expected from considerations based upon creep rates observed in tests made with constant stress. A brief summary of the results is as follows:

1. For practical purposes, the relaxation of copper at room temperature and probably up to 200 degrees centigrade may be represented by an expression of the form:

$$\sigma = \sigma_i [1 - A \log (1 + Bt)]$$

where $\sigma$ is the stress at any time $t$, $\sigma_i$ is the initial stress, and $A$ and $B$ are constants.

2. A marked increase in relaxation takes place when the temperature is raised above about 80 degrees centigrade. At 200 degrees centigrade the stress is estimated to fall to about 20–25 per cent of its initial value in a service time of 20 years.

3. Recovery effects tend to decrease the creep rate found in the early part of a relaxation test.

4. The dissimilarity between the speed laws for decreasing and for increasing stress gives rise to rather large amounts of relaxation.

Further creep and relaxation tests are at present under way and may be expected to add to knowledge of this subject.

# The Saturated Synchronous Machine

C. F. DALZIEL
ASSOCIATE AIEE

WHILE the unsaturated synchronous machine is in general well understood, the effects of saturation upon its performance are still subject to discussion. Knowledge on the influence of saturation is important because of power-angle relations, steady-state stability limits, and excitation requirements. The problem of saturation may be approached in several ways. One method[1] is to determine empirical factors which modify characteristics of the unsaturated machine, the saturation factors being single average values for a group of machines. A second way[2] leads to the introduction of equivalent reactances which allow calculation of the effects of saturation on small load changes about an initial operating point. Third, there is the derivation[3] of saturated synchronous reactances to be used in the investigation of power-angle curves and maximum power.

It is the purpose of this paper to present the physical concepts underlying the highly saturated synchronous machine operating under steady load, and to show how the theory developed for such a machine is in agreement with test results. With terminal voltage, current, and power factor known, the torque-angle and excitation may be determined accurately.

**Figure 1. General vector diagram of an alternator**

The analysis here proposed is general in that it applies to both salient-pole and cylindrical-rotor machines. It is based on Blondel's[4] 2-reaction theory of synchronous machines, and is a modification of the vector diagram given by Doherty and Nickle[5] in their extension of Blondel's work. The diagram for the unsaturated machine assumes constant values for armature resistance and the several reactances, and linear relations existing throughout the machine. Assuming no saturation in the armature or cross-field paths, figure 27 of the paper by Doherty and Nickle shows an additional field excitation along the pole axis to take into account saturation in the pole body. Under these assumptions, the torque-angle is not affected by saturation. Under conditions of saturation, and certainly for high saturation, all of the machine reactances are decreased in magnitude. The cross-field path, by way of the pole tips, and the armature teeth, will saturate as well as the pole body. Torque-angle therefore is appreciably affected as well as is the excitation requirement.

## Machine Constants

The machine constants which must be considered in any steady-state analysis of the synchronous machine are armature resistance, armature leakage reactance, and the direct and quadrature synchronous reactances. The effective armature resistance may be determined by methods previously described.[6] Tests on armature leakage reactance[7] have shown that it varies somewhat with saturation, being a function of the density in the armature teeth which in turn depends upon the air-gap flux. The variation, however, is relatively small, and without introducing appreciable error this quantity may be taken as a function of terminal voltage.

The synchronous reactances are a measure of the flux which the armature magnetomotive force produces in its magnetic circuit. In the case of the direct synchronous reactance the magnetic circuit consists of the armature iron, the air-gaps, and the rotor poles and spider. For the quadrature synchronous reactance the magnetic circuit consists of the armature iron, the air-gaps, the pole tips, and the interpolar region. With increasing flux through these circuits, the synchronous reactances decrease. While $x_q$ is a function of the voltage behind leakage reactance, or the total air-gap flux, $x_d$ depends also upon the field leakage to the extent that this flux increases saturation in the pole body.

The synchronous reactances are defined in terms of armature quantities, i.e., $x_d$, the direct synchronous reactance, is the ratio of the fundamental component of the reactive armature voltage, due to the fundamental direct-axis component of armature current, to this component of current under steady state conditions and at rated frequency. The quadrature synchronous reactance, $x_q$, is defined similarly. Slip tests,[9] which are used to obtain both $x_d$ and $x_q$, also may be used to determine the saturated values of these quantities. Subtracting vectorially the armature resistance and leakage reactance voltages from the terminal voltage, the synchronous reactances may be

A paper recommended for publication by the AIEE committee on electrical machinery. Manuscript submitted October 26, 1937; released for publication May 25, 1937.

B. L. ROBERTSON is associate professor of electrical engineering and T. A. ROGERS and C. F. DALZIEL are iustructors in electrical engineering at the University of California, Berkeley.

1. For all numbered references, see list at end of paper.

plotted as functions of the air-gap voltage. The air-gap voltage, $e_a$, may be expressed[8] as

$$e_a = e_t[\sqrt{1 - (r_a/x)^2} - x_l/x]$$

where $x = x_d$ or $x_q$, as desired. $e_t$ is the terminal voltage and $r_a$ the armature resistance. The treatment presented in this paper makes use of the unsaturated direct and quadrature synchronous reactances, and the saturated quadrature synchronous reactance.

## The Vector Diagram

The steady-state performance of the unsaturated synchronous machine may be represented by a vector diagram. Figure 1 shows such a diagram for an alternator operating at a lagging power factor. The purpose of the diagram is ultimately to give the torque-angle and excitation requirement of the machine under load. This paper follows the per-unit notation, and the nomenclature is given in the following tabulation:

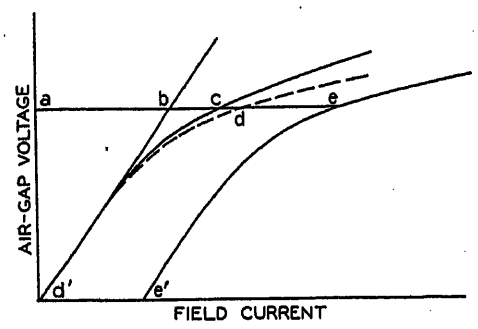

**Figure 3. Relation between zero-power-factor curve and field current required for pole leakage under saturation**

$e_t$ = machine terminal voltage
$i$ = armature current
$\theta$ = power factor angle
$r_a$ = effective armature resistance
$x_l$ = armature leakage reactance
$e_a$ = air-gap voltage (voltage behind leakage reactance)
$x_d$ = direct-axis synchronous reactance
$x_q$ = quadrature-axis synchronous reactance
$x_{ad}$ = direct-axis reactance of armature reaction
$\delta$ = torque-angle
$i_d$ = direct-axis component of armature current
$i_q$ = quadrature-axis component of armature current
$e_d$ = excitation voltage giving field current for no saturation
$I_f$ = field current

The vector diagram of figure 1 is general, and is essentially that shown by Doherty and Nickle in "Synchronous Machines–I."[5] From it, for the unsaturated machine, may be obtained directly the displacement

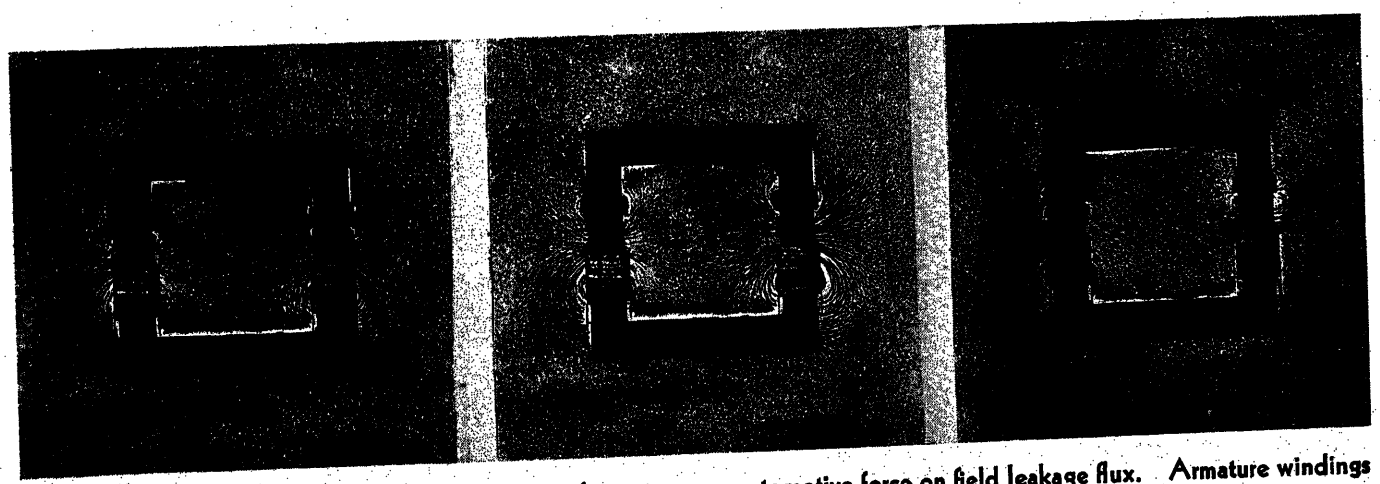

**Figure 2. Iron-filing pictures to illustrate effects of armature magnetomotive force on field leakage flux. Armature windings above, field windings below**

Left—No-load representation. Armature $NI = 0$, field $NI = 150$. Center—Demagnetization. Armature $NI = 150$, field $NI = 300$. Right—Magnetization. Armature $NI = 75$, field $NI = 75$

angle, $\delta$, and the field current, $I_f$, corresponding to the excitation voltage, $e_d$. It is assumed that the reader is familiar with the method.

With saturation, however, the torque angle is decreased, and the required field current is increased. These statements hold regardless of motor or generator action, or of power factor. The angle obtained by way of the unsaturated machine constants must be corrected, and the proposal made in this paper is to determine that angle directly by using the saturated value of $x_q$ to locate the true direct axis. The angle is thus given immediately without subtracting a correction angle. The closeness with which test results agree with this method of determining torque angle is shown in tables I–IV.

In appendix *D* of "Synchronous Machines–I and II," Doherty and Nickle outline a manner of obtaining the increase in excitation to care for saturation. Figure 27 of that paper contains the fundamental ideas involved. The projection on the direct axis of the voltage behind leakage reactance is carried to the saturation curve, the field current to be added being that measured by the horizontal separation between the air-gap line and the no-load saturation curve. This added field current, however, is not sufficient for the saturated machine with demagnetizing armature current. Depending upon the degree of saturation and the armature current, it may be far less than is required. On the other hand, the machine with magnetizing armature reaction is overcompensated in field current.

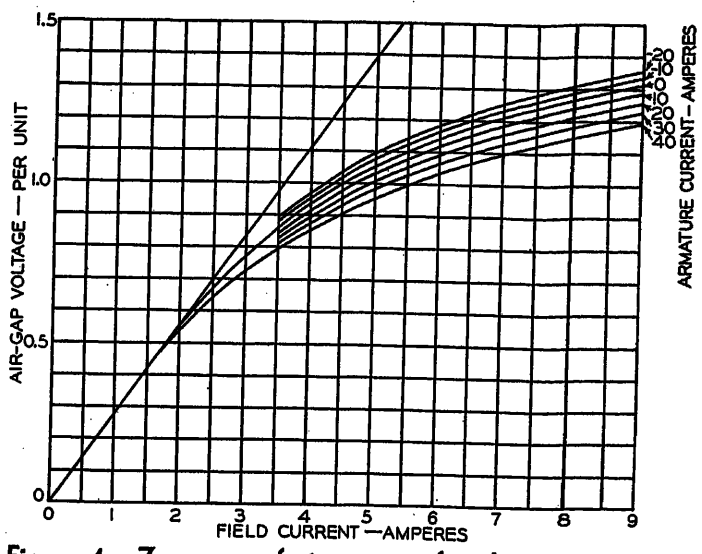

**Figure 4. Zero-power-factor curves for determination of field current required for saturation**

Part of the field magnetomotive force which must be added to care for saturation is that required to force the flux through the entire saturated circuit, and is represented by the distance between the air-gap line and the no-load saturation curve. This component takes care of normal field leakage at this flux density. In addition a second component of magnetomotive force is required to force an increased leakage flux through the saturated path at the base of the pole due to the demagnetizing effect of the $i_d$ component of armature current. The second portion of magnetomotive force may be represented by an additional number of ampere turns indicated on the saturation curve by the distance between the no-load curve and what may be called the field leakage curves.

## Field Leakage

The magnetomotive forces of the field and armature windings act on the main magnetic circuit of the machine to produce the resultant flux. These magnetomotive forces may wholly oppose each other, as in the case of the zero-power-factor-lagging generator (zero-power-factor-leading motor), or they may wholly assist each other. Between these 2 extremes the armature current will have one component which is directly magnetizing or demagnetizing, and a second component which acts on the cross-field magnetic circuit. The first of these supplies the direct component of armature magnetomotive force, and the second is synonomous with the quadrature component of armature magnetomotive force. The strength and relative direction of the components depend, of course, upon both load current and power factor.

Under no load, and below saturation, equal increments of field current produce equal increments of total flux through the field coils. By far the greater part of the flux follows the main magnetic circuit and is mutual to both field and armature windings. The other part encloses

the field winding alone and is known as field leakage flux, most of it being located near the base of the pole. Both parts increase in the same proportion up to the point of saturation. With saturation, successive equal increments of field current produce diminishing increments of total flux, the increments of the mutal or air-gap flux being less in proportion to the increments of field leakage flux up to a certain point of saturation which usually is beyond the working range of any machine. The reason for this phenomenon is that the main flux follows a path consisting mostly of iron, while the path of the leakage flux has a far greater ratio of air to iron. At extremely high saturation, when the reluctance of the iron in the main path is very great, the increments of air-gap and leakage fluxes approach a constant ratio again, although not the same ratio as for no saturation.

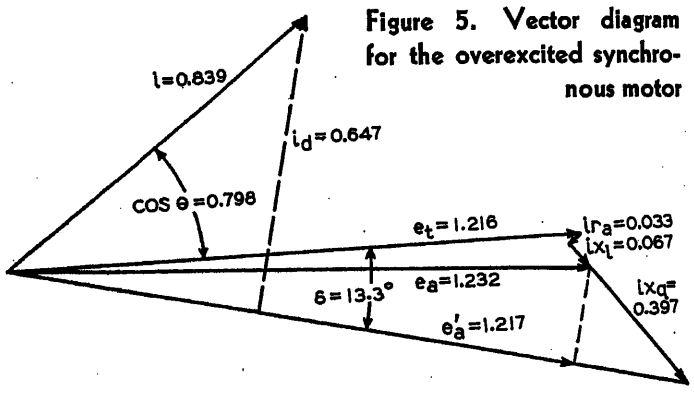

**Figure 5. Vector diagram for the overexcited synchronous motor**

With no saturation, and for a given air-gap flux, any demagnetizing ampere turns of the armature must be met by an equal rise in field ampere turns. The field leakage obviously increases. Similarly, magnetizing armature current requires an equal decrease in field magnetomotive force with a corresponding reduction in field leakage flux. Although this leakage flux varies, it maintains the same linear relation with respect to total field magnetomotive force as exists at no load, no saturation.

Under saturation, and at no load, there exists a given field current to provide a desired air-gap flux. If with the application of demagnetizing armature ampere turns the field ampere turns are increased by an equal amount, there will be an increase in pole saturation due to the increase in field leakage flux. This increased saturation decreases the air-gap flux, and to maintain the desired air-gap flux the field ampere turns must be increased by an additional amount to overcome the effects of the greater pole saturation. Conversely, magnetizing armature ampere turns will require a decrease in field ampere turns greater than the corresponding change in armature magnetomotive force.

The iron-filing pictures of figure 2 are given as an aid in visualizing field leakage, the circuit representing the elements of the sychronous machine. Figure 2*a* indicates conditions of no load. Figures 2*b* and 2*c* show the effects of armature magnetomotive force on field leakage for the 2 cases of demagnetizing and magnetizing armature ampere turns. The same air-gap ampere turns exist in all cases.

## Field Leakage Curves

The full lines *d'c* and *e'e* of figure 3 show, respectively, the no-load and the full-load zero-power-factor overexcited saturation curves of a synchronous machine. Whereas the horizontal separation at the zero ordinate in the usual manner of treatment is that value of field current which would produce a voltage on the air-gap line equal to $ix_d$, in figure 3 the separation corresponds to $ix_{ad}$. Similar curves may be obtained for any value of magnetizing or demagnetizing armature current.

The dotted curve *d'd* of figure 3 is the zero-power-factor curve moved to the left by that amount of field current corresponding to the voltage of armature reaction for unsaturated conditions. The distance *ae* represents the total field current required to produce, with full-load demagnetizing ampere turns on the armature, the air-gap voltage indicated. This total field current may be thought to consist of several components. The first is that which produces the magnetomotive force to overcome the demagnetizing effect of armature reaction, and is given by *de*. The second component, *ab*, is the field current required to send the main flux across the air gap. The third component, *bc*, is that necessary to force the mutual flux through the iron of the magnetic circuit under conditions of no-load saturation. Lastly, there is the added field current, *cd*, to care for the increased saturation caused by the increased field-leakage flux which in turn is caused by the demagnetizing armature current. This fourth component of field current is a function not only of air-gap voltage but also of armature demagnetizing magnetomotive force.

Figure 4 shows a family of field leakage curves plotted in the manner described, where the initial curves have been moved over by the amount of the respective field currents corresponding to the armature reactance voltages. The data for the curves were obtained by test on the 40-horsepower synchronous motor (described later under "Test Results") employing a single-turn full-pitch test coil so placed on the armature surface that it enclosed the main air-gap flux. Because the vector diagram for the

**Table IV. Comparison Between Calculated and Test Values of Torque-Angle and Excitation for the Saturated Salient-Pole Synchronous Machine**

| 277 | 48.4 | 11.62 | 11.62 | 21.9 | 22.0 | 14.37 | 14.30 |

synchronous machine is based on fundamental voltages, harmonics in the air-gap voltage were eliminated by using a wave analyzer, thus giving the values of fundamental voltage directly.

For an overexcited machine at zero power factor, the armature current is wholly demagnetizing and is represented in the vector diagram by a positive $i_d$. Conversely, for an underexcited machine at zero power factor the armature current is magnetizing and is designated by a negative $i_d$. The field leakage curves indicate these relations, the parameter being amperes armature current. The curves are entered with the direct axis component of the air-gap voltage. The horizontal distance between the no-load saturation curve and the interpolated curve for the direct axis component of armature current, also found from the vector diagram, is the field current required to supply the increased field leakage flux caused by that component of armature current.

## Application

The application of the foregoing theory is illustrated by 2 examples. The first is that for the 40-horsepower overexcited synchronous motor operating at 535 volts with a line current of 37.3 amperes at 0.789 power factor. Figure 5 is the vector diagram for this case with all corresponding quantities given in per-unit terms. The torque-angle of the machine is found immediately upon location of the direct axis and is 13.3 electrical degrees, agreeing with the angle of 13.2 degrees obtained by test.

The field current is calculated on the assumption of no saturation, the method following that discussed in conjunction with figure 1. To this value of field current there is added a correction for saturation. Following the method of Doherty and Nickle, the direct-axis component of the voltage behind leakage reactance is carried to the field leakage curves, figure 4. The field current correction is given by the distance between the air-gap line and the interpolated field leakage curve corresponding to the value of $i_d$ in amperes.

The second example, shown by figure 6 is that of the underexcited synchronous motor operating at 535 volts with a line current of 44.5 amperes at a power factor of 0.805. The procedure in determining the torque-angle and excitation is the same as for the first example with the exception that $i_d$ is now negative, indicating magnetizing action of the armature current. It is to be observed that

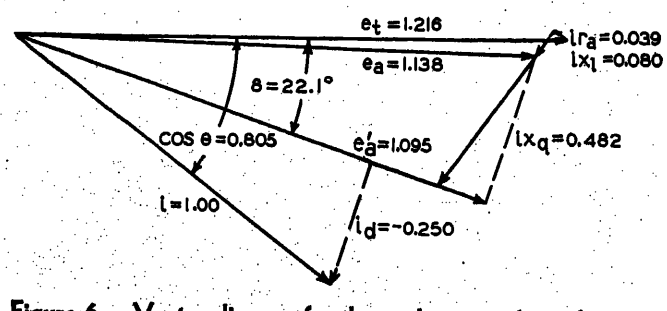

**Figure 6. Vector diagram for the underexcited synchronous motor**

the diagrams of figures 5 and 6 are for purposes of correction, and do not completely represent the unsaturated machine.

## Test Results

Tables I–IV show the comparison between calculation and test of torque-angle and excitation for synchronous machines operating at high voltages under steady load. The data of table I were taken on a salient-pole general-purpose synchronous motor rated 3 phase, 6 pole, 40 horsepower, 1,200 rpm, 440 volts, 44.5 amperes. Tests were taken on the machine, both as a motor and as a generator, over a range of voltages extending from below saturation to 535 volts. All calculations gave the same close agreement with test as shown in the table, but for purposes of comparison only the results of 3 general conditions of load are presented. The curves of machine constants used in these calculations are given by figures 7–9. Motor operation at 535 volts was chosen for presentation because of the high degree of saturation introduced, coupled with the fact that the motor still could carry approximately rated current before reaching the limit on instruments or commutation of the d-c machine connected to it.

Tables II and III show data on a 3-phase 6-pole 7.5-kva 1,200-rpm 220-volt 19.7-ampere alternator designed for operation as a salient-pole generator or as a wound-rotor induction motor by interchanging rotors. Table II gives results for operation of the machine as a salient-pole

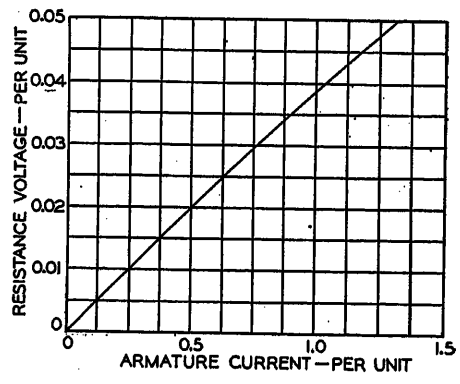

**Figure 7. Effective armature resistance of a 40-horsepower 1,200-rpm 440-volt synchronous motor**

motor. Table III shows data for operation of the machine as a cylindrical-rotor synchronous motor, direct current having been supplied the wound rotor. Due to the fact that saturation was extremely small at rated voltage, tests were carried out at the relatively very high voltage shown.

Table IV gives similar results on a 3-phase 6-pole 15-kva 1,200-rpm 220-volt 39.4-ampere generator. Due to inherent voltage unbalance within this machine, the field current did not check the saturation curve when the machine was connected to an infinite bus with no power exchange. This also accounts for the small discrepancies between calculated and tested field currents at the lower loads.

Zero readings were obtained by adjusting the field currents on both machines so as to give no deflection on the

wattmeters. All constant losses therefore were supplied by the d-c machine. Measurements were taken at those times when the power supply gave balanced voltages because it was found that an unbalance, although very small, introduced errors. Adjustments of the wattmeter readings for desired power factors were occasionally a trifle difficult to make under pump-back operation of the set. Limits on instruments, field heating, and commutation of the d-c machine prevented loading the synchronous motor as highly as was desired.

## Summary

The theoretical discussion given in the paper offers a general method of treating the highly saturated synchronous machine operating under steady load. To as great an extent as possible the mode of attack employs the accepted form of the vector diagram based on Blondel's 2-reaction theory. Torque-angle is obtained by using the saturated quadrature synchronous reactance rather than the unsaturated reactance. Saturation in the interpolar axis affects the displacement angle of the machine, the angle decreasing with saturation, thus leading to a stiffer machine. For accuracy, the effective armature resistance may not be neglected, at least for smaller machines.

While direct axis saturation requires less field current to overcome direct armature reaction, this decrease is more than offset by the required increase in field current to care for increased field leakage flux caused by this direct armature magnetomotive force. The total field current may be thought to consist of several components; one to force the mutual flux across the gap, a second to overcome armature reaction, a third to care for no-load saturation, and a fourth to account for an increase or decrease in saturation due to a change in pole leakage when current is present in the armature. In a manner, the first 2 components are included in the calculation from the vector diagram for the unsaturated machine. The last 2 are obtained from field leakage curves.

The paper is offered as a theoretical analysis on the effects of saturation, and as such should lead to a better understanding on the performance of the synchronous machine. In addition, it should aid in the proper evaluation of empirical methods, and in furthering studies on the saturated machine operating under transient conditions. It is felt that the good agreement between calculation and test results, as shown in the tables, greatly substantiates the theory given in the paper.

## New Bipost-Base Street-Series Lamp

A new type of street-series lamp has been designed especially for use in "high visibility" lighting equipment. The 4,000-lumen lamp, which is 6½ inches in length and which is designed to burn base up, is equipped with a medium bipost base, a relatively small tubular-shaped bulb of clear hard glass, and a horizontal bar filament about one inch long. Application of the bipost method of construction results in the following advantages: reduction of inaccuracies in filament positioning, permanency of lamp and reflector adjustment, a major reduction in size, a rugged straight-sided bulb which is immune to bulb breakage from sudden temperature changes and which is less likely to collect dirt than pear-shaped lamps, and a simplified filament assembly which eliminates several old steps formerly required in lamp making, with economy for both user and maker.

# Discussions

## Of AIEE Papers—as Recommended for Publication by Technical Committees

ON THIS and the following 45 pages appear discussions submitted for publication, and approved by the technical committees, on papers presented at the sessions on communication, electric welding, electronics, instruments and measurements, power distribution, selected subjects, and synchronous machinery at the 1937 AIEE winter convention, New York, N. Y., January 25–29. Authors' closures, where they have been submitted, will be found at the end of the discussion on their respective papers. Other discussion of winter convention papers will be published as it is made available.

Members anywhere are encouraged to submit written discussion of any paper published in ELECTRICAL ENGINEERING, which discussion will be reviewed by the proper technical committee and considered for possible publication in a subsequent issue. Discussions of papers scheduled for presentation at any AIEE meeting or convention will be closed 2 weeks after presentation. Discussions should be (1) concise; (2) restricted to the subject of the paper or papers under consideration; and (3) typewritten and submitted in triplicate to C. S. Rich, secretary, technical program committee, AIEE headquarters 33 West 39th Street, New York, N. Y.

## The Resistance Welding Circuit

**Discussion and author's closure of a paper by C. L. Pfeiffer published in the August 1936 issue, pages 868–73, and presented for oral discussion at the electric welding session of the winter convention, New York, N. Y., January 28, 1937.**

**H. C. Cogan** (nonmember; National Electric Welding Machines Company, Bay City, Mich.): Mr. Pfeiffer's paper "The Resistance Welding Circuit" is very timely. Since the advent of positive cycle control apparatus for resistance welding equipment, and further, since the welding machines themselves have been improved considerably, materials are now being welded by the resistance method that demand close calculation as to their power-demand and welding-circuit conditions.

The welding-machine manufacturers can, through accepted and now standard calculations determine the total impedance of a welding machine circuit (electrodes to transformer) and thereby design a transformer and circuit to deliver a specified current at the weld.

It has not been very easy, however, to calculate the desired current at the weld and thereby specify the fundamental requisite as a starting point for machine and transformer design.

Mr. Pfeiffer's paper is very interesting inasmuch as it shows original methods and a very clear analysis of the possible determination of the voltage-drop and current characteristics at various points in the weld area proper. With the development of methods as outlined in this paper the capacity of resistance welding equipment may be known in time by the maximum current (secondary amperes) that can be delivered at the welding electrodes at a predetermined primary supply, all of which can be definitely put on the name plate of the welding machine, and this alone will be a great step forward in a mutual understanding among the user of the welding machine, the manufacturer of the welding machine, and the power company supplying the power, which supersedes the antiquated and useless kilovolt-ampere rating of resistance welders.

**C. E. Heitman** (Edward G. Budd Manufacturing Co., Philadelphia, Pa.): To those of us vitally concerned with resistance welding and its applications, it is gratifying to note an increasing amount of published information concerning this subject. Mr. Pfeiffer's present paper is noteworthy in that it emphasizes the effect which the electric circuit has upon the successful operation of any resistance welding application. This phase of the problem has been more or less neglected in the past, perhaps because the earlier types of machines did not require such a thorough analysis of the electric circuit as more elaborate machines of today.

The author's discussion of this subject is indeed interesting, although the examples cited apply to a type of welder with which I am not very familiar. All of the spot welding applications with which I have been concerned demand machines having much higher secondary or lead impedances than shown in the vector diagrams of figure 3, due to the physical characteristics of the product being welded. For this reason, I feel that the ratios obtained from these vector diagrams may be misleading if applied to the welding machines used in the average sheet-metal shop.

On various portable spot-welding jobs, wherein the welding electrodes are connected to the transformer by means of cables 5 or 6 feet in length, my experience has been that the voltage drop in these cables alone is approximately 85 per cent of the open-circuit secondary voltage of the transformer, and over 90 per cent of the secondary load voltage. In some cases these figures increase to 90 per cent and 95 per cent respectively. In such cases, little or no difference is made upon the amount of secondary current, whether there is ferrous metal between the electrodes or whether the electrodes are brought together with no metal between them. In the case of the upright stationary machine, the impedance of the leads may be a smaller percentage of the total secondary impedance, depending upon the length and spacings of these leads. In any event, I have found that this lead impedance is practically all reactance, so that this voltage drop must be added at right angles to the almost purely resistance voltage across the weld. For this reason, the impedance of the weld does not add materially to the total circuit impedance. In all such cases the voltage drop across the weld is considerably less than the voltage drop in the secondary leads, even when welding relatively thick sheets of ferrous materials. In cases where the coupling between electrodes and transformer is very close and where the spacing between these leads is small, the values given by the author would no doubt apply, but such machines have comparatively little utility in large sheet metal plants.

I mention these welding conditions as being typical of those with which I have dealt, and which I believe are typical of other manufacturing plants, in the hope that it may shed some additional light upon the problem, and perhaps stimulate further discussion. The field of resistance welding is very broad, and impossible to thoroughly cover in any one discussion.

I wish to express my thanks and appreciation to the author for a most interesting and enlightening discussion of this subject.

**J. W. Dawson** (Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.): The author is most sincerely concurred with in his hope that this elementary paper will stimulate a more thorough investigation of the resistance welding circuit which is so well known and yet so imperfectly understood.

Phenomena occurring in the weld area are very much of transient nature. During the welding period, the electrical, thermal, and metallurgical conditions and even electrode pressure undergo very rapid changes, particularly in so-called "short time" welding. This fact adds to the other practical difficulties in thoroughly investigating this area.

An important part of future study of the resistance welding circuit will undoubtedly concern itself with the adjoining surface layers of the parts being welded, and the transmutation of their contact resistance into the resistance of highly heated metal layers during the weld. The author's discussion of surface film break-down is of interest in this connection.

The author presents data in tabular form showing the voltage drop in various parts of the resistance welding circuit. It is under-

stood that instrument measurements were necessarily made with relatively long welding periods. Mention is made, however, of oscillographic measurements of these quantities and it would be of interest to learn whether the oscillograph showed appreciable changes in weld area voltages during welding.

The author's use of work-body resistance as a criteria in roughly calculating conditions in the weld area, seems to the writer a rather inaccurate basis of approach to this problem. Although less convenient, the all important contact surface resistances are given too little attention. Likewise, Jean's formula $r/4a$ would not seem to apply here. The chief justification for considering the problem in the light of this formula should lie in the fact that resistance is assumed a function of the number of contacting surfaces. Even on the basis of metal-body resistance, this formula should not give correct results since the sheets are of small dimension in the direction of current flow although, as stated by the author, of very large cross section.

Referrring to the 2 vector diagrams, figure 3, it is not clear to the writer how the vector quantity $E_i$ denoting transformer voltage drop has been determined from the measurements given.

The writer cannot entirely agree with the author in that definite energy input to the weld is always the ideal basis for terminating the weld, although in "slow" welding, it would seem a step in the right direction. First of all, the rate of applying energy to the weld area is extremely important, particularly in "short time" welding, one factor being the flow of thermal energy away from the weld through body of the work. Considering the extreme case, a proper total quantity of energy might be applied to the weld but at such extremely low rate as to result in barely warming the weld surfaces. Secondly, and again particularly for the "short time" welding, it is very difficult to terminate the weld excepting at the end of $1/2$ cycle of current. For these reasons, accurate control of all factors would seem the best practice for "short time" welding, which is being much used at present.

**H. A. Woofter** (nonmember; The Federal Machine and Welder Company, Warren, Ohio): Mr. Pfeiffer's excellent paper on resistance welder circuits is one of the best that has been written to date. A few notations and elaborations might be helpful to the reader.

Referring to figures 4 and 5 the layman might take it for granted that because practically any number of projection welds can be made instantaneously from a single circuit as shown in figure 5, that it would immediately follow that practically any number of spot welds could be made instantaneously from a single circuit as shown in figure 4. It is an outstanding fact, however, that only one good spot weld can be made at one time from one circuit with one set of leads. The reason for this is as follows: A spot weld is virtually a short circuit of the secondary of the transformer. Now, when 2 or more points are used, or attempted to be used, the power will not break through all of the points at the same time. One spot will break through under one point first. This as stated above establishes a dead short circuit which knocks down the secondary voltage of the circuit to such an extent that the other points do not have sufficient voltage to make a good spot weld. This, however, can be corrected by bringing out a separate set of leads to each electrode point. It can also be further improved by having individual pressure applied to each individual point, such as a pressure spring, small hydraulic cylinder, air cylinder, or any of the well-known pressure devices.

Referring to figures 6 and 7, especially the latter, when attempting heavy work, requiring large amounts of power, the 3 transformers shown can sometimes be connected to the 3 phases of the power circuit, thus balancing the load on the power line. Under such conditions, however, it is necessary to insulate the 3 heads on one or both sides of the transformer to eliminate the leakage between phases, which on a 3-phase circuit is the square root of 3, which amounts to 1.73 times as much voltage between the phases as there is across the points of the welder.

While perhaps 99.99 per cent of resistance welding is done single phase there are some cases of projection welding, mash welding, wire-mat welding, etc., where the projections or intersections can be grouped into clusters of 3 or multiples thereof, and each cluster welded on a separate phase. This is sometimes done by connecting one side of the transformer to a single lower table with the 3 phases insulated above. At other times it is necessary to insulate the phases on both upper and lower tables.

**L. H. Frost** (nonmember; The Electric Controller & Mfg. Co., Cleveland, Ohio): Mr. Pfeiffer's paper indicates that the electrical circuit involved in a resistance-welding machine is not complicated and that the coordination of 3 principal factors; namely, current, electrode pressure, and time of current application, is essential to proper welding. This is true as a general statement, but it is not generally realized what effect changing values of these factors has upon the total result.

The current which will flow through the welding circuit depends upon conditions as outlined by Mr. Pfeiffer, but the current which is important from the angle of welding is the current which actually flows through the work pieces. Within reasonable limits, this current will be constant for given physical dimensions and electrical characteristics of the welding machine but may vary somewhat due to change of the effective resistance between the work pieces, and the work and the electrodes. In order to show clearly how these factors affect each other, and in general, the amount of heat required to make a weld, refer to figure 1, in which electrodes $E1$ and $E2$ are shown as being of conventional design. $S1$ and $S2$ are the 2 work pieces, in this case indicated as sheets. Between the work pieces and the electrodes are 2 contacting surfaces which have been designated as number 1 and number 3, respectively, and between the 2 pieces there are 2 other contacting surfaces which have been designated as number 2. The area involved in each of these conditions has been termed $A1$, $A3$, and $A2$, respectively.

It will be evident that the point of greatest resistance in this circuit is at the contacting surfaces themselves rather than through the various conducting portions of the circuit,

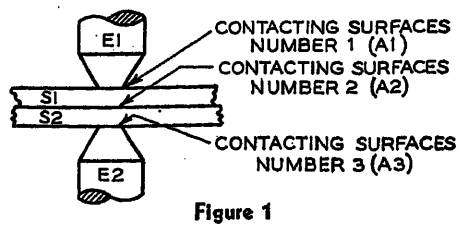

**Figure 1**

$$H_W = (H_D - H_L)t \tag{1}$$

but

$$H_D = I^2R \tag{2}$$

$$R = \frac{r_1}{P} + \frac{r_2}{P} + \frac{r_3}{P} \tag{3}$$

$$r_1 = \frac{C_1(\Omega_{E1} + \Omega_{S1})}{A_1P} \tag{4}$$

$$r_2 = \frac{C_2(\Omega_{S1} + \Omega_{S2})}{A_2P} \tag{5}$$

$$r_3 = \frac{C_3(\Omega_{S2} + \Omega_{E2})}{A_3P} \tag{6}$$

$$R = \frac{1}{P}\left(\frac{C_1}{A_1}(\Omega_{E1} + \Omega_{S1}) + \frac{C_2}{A_2}(\Omega_{S1} + \Omega_{S2}) + \frac{C_3}{A_3}(\Omega_{S2} + \Omega_{E2})\right) \tag{7}$$

$$H_L = K_{E1}V_1 + K_{S1}(V_2 + V_3) + K_{S2}(V_4 + V_5) + K_{E2}V_6 \tag{8}$$

$$H_w = t\left[\frac{I^2}{P}\left(\frac{C_1}{A_1}(\Omega_{E1} + \Omega_{S1}) + \frac{C_2}{A_2}(\Omega_{S1} + \Omega_{S2}) + \frac{C_3}{A_3}(\Omega_{S2} + \Omega_{E2})\right) + K_{E1}V_1 + K_{S1} \times (V_2 + V_3) + K_{S2}(V_4 + V_5) + K_{E2}V_6\right] \tag{9}$$

where

$H_w$ = heat required for weld
$H_D$ = heat developed by current
$H_L$ = heat lost by conduction
$t$ = time
$I$ = current
$R$ = resistance
$r_1, r_2, r_3$ = effective resistance at contacting surfaces 1, 2, and 3
$C_1, C_2, C_3$ = constants for resistivity of contacting surfaces, 1, 2, and 3
$\Omega_{E1}, \Omega_{S1}$ = resistivity
$\Omega_{S2}, \Omega_{E2}$ = resistivity
$P$ = pressure
$K_{E1}, K_{E2}$ = thermal conductivity of electrodes 1 and 2
$K_{S1}, K_{S2}$ = thermal conductivity of sheet 1 and 2
$V_1$ = volume and gradient of electrode 1
$V_6$ = volume and gradient of electrode 2
$V_2$ = volume and gradient of sheet 1 affected by area $A_1$ and electrode 1
$V_3$ = volume and gradient of sheet 1 affected by areas $A_1$ and $A_2$
$V_4$ = volume and gradient of sheet 2 affected by areas $A_1$ and $A_2$
$V_5$ = volume and gradient of sheet 2 affected by area $A_2$ and electrode 2

therefore, heat will be generated at contacting surfaces number 1, and number 3 and also at number 2. It is further evident that the resistance between contacting surfaces number 2 must be greater than between surfaces number 1 and number 2, if a weld is to occur between contacting surfaces number 2. This is a general statement, of course, for there may be a wide dissimiliarity between the fusion points of the electrode material and the work pieces. It is possible to allow the heat to be conducted through from the outside surfaces to the center, but in general, this does not provide a satisfactory welding condition.

Following through the discussion applying to figure 1, we find that the total heat required for welding is equal to the heat developed by the passage of the current minus the heat lost due to conduction into the work pieces and electrodes, times the time required for welding. The heat developed follows $I^2R$, as shown in equation 2. Since $R$ is the unknown and the variable in which we are interested in analyzing, this may be expanded as shown in equation 7. It will be noted that pressure has been introduced into the equation and that the resistance varies inversely with the pressure. This point has been shown in many tests relating to current carrying capacity of contacting surfaces and voltage drop across contacting surfaces and is familiar to everyone.

The heat lost is given in equation 8. The constant designated by $K$ is the thermal conductivity of the electrodes and work pieces expressed in standard units. The factors designated as $V_1$, $V_2$, etc., are a combination of the volume and gradients involved. It will be evident that the gradient will not be linear as in the case of a steady condition, but will be a curve. A mathematical expression of this gradient has not been used as this would unnecessarily complicate the final equation. It should be noted, however, that since heat is being absorbed into the work pieces and into the electrodes at the same time, if there is a high temperature at contacting surfaces number 1, number 2, and number 3, and a low temperature in the electrodes and work pieces, that this gradient cannot be a straight line. The mathematical expression is complicated because of this fact and also because the temperature is increasing throughout the initial portion of the timing period. Therefore, the terminal temperature at the contacting surfaces is variable and that combined with the heat absorbed into the conducting materials makes this a complicated expression.

The final expression for the heat required for a weld is given in equation 9. It will be evident from this equation that the most important single variable in this equation is the time of current application. This is more important even than the amount of current applied since it affects not only the heat developed for welding, but also the heat lost by conduction. It is, therefore, important that the time of welding be controlled. The next most important variable is the current which, as indicated above, is influenced by the resistance of the welding circuit for given physical and electrical characteristics of the welding machine. The third most important variable is the pressure which affects the current inversely. From the equation 9 it will be evident that the relationship between the 3 principle factors of current, electrode pressure, and time of current application, is definite and it is possible to place the proper value in general upon each of these variables. From this equation it is also evident that if the resistivity of the electrodes and the work pieces are the same that the 3 expressions for resistance will be equal and that the heat will be divided in 3 points in equal amounts which will prevent satisfactory welding. This indicates one limit to which electrodes and materials may be changed.

To express this in concrete terms, it would be impossible to obtain satisfactory welds when using steel electrodes for welding steel sheets or by using copper electrodes for welding pure-copper sheets. This, of course, is for electrodes of conventional design as shown. It is sometimes possible, by using a special design, to change the constants $C_1$, $C_2$, and $C_3$.

The constants $C_1$, $C_2$, and $C_3$ must be determined by actual test. Also the effect of the factors $V_1$, $V_2$, etc., may be determined by actual test although in this case a mathematical expression can be obtained. It will be obvious that for various oxides and coatings on the work pieces, different values of $C_1$, $C_2$, and $C_3$ will be required. This will affect the electrical characteristics required in the welding machine to some extent as shown by Mr. Pfeiffer on page 871, but in general the adjustments on the machine permit a reasonably wide range of control for these conditions.

One interesting fact shown by equation 9 is that due to the relationship of current, electrode pressure, and time of current application, it is often possible by increasing the pressure to cause a decrease in resistance which for the given current requires an increased time to make the proper weld. This means that in the case of certain materials where practice has indicated that welds can be obtained only in the shortest possible time, that it may often be possible to increase the pressure and for the same current obtain satisfactory welds in a somewhat longer time.

Mr. Pfeiffer's article is certainly of importance in stimulating activity in the art of resistance welding. In the last few years there has been considerable done to improve means of timing the welds, but there is still much research work to be done in determining what factors influence the welding operation in detail. This work can best be done by educational institutions and engineering foundations, and if Mr. Pfeiffer's article or this discussion can stimulate any such activity, the effort expended in preparing the paper and this discussion will be amply repaid.

**J. H. Zimmerman** (nonmember; The Linde Air Products Company, Newark, N. J.): This simple treatment of the resistance-welding circuit should be of much help to the nonelectrical engineer and to the practical man who does resistance welding. It is hoped that the paper will also serve to stimulate more publications on the same subject, particularly papers dealing more specifically with phenomenal changes in the immediate vicinity of the weld as has been suggested by the author.

For example, little is known of the fluctuations, in electrode pressures during the short time interval of welding. It has been estimated that as much as 60 per cent of the original pressure may be relieved by the surge of current through the secondary. The elastic recoil of the machine following this surge may frequently serve to reverse this effect when the weld metal is in poor condition to withstand sudden overloading. These same pressure fluctuations will naturally produce corresponding electrical disturbances, and a paper embracing this phase of the subject would be valuable.

The title of the paper might better have been "The Spot-Welding Circuit" for much of the subject matter may not strictly apply in the case of flash welding which is also a resistance welding process. Regardless of the title, however, the author is to be complimented for a fundamental addition to the scarce literature on the subject.

**R. H. Hobrock** (nonmember; Bundy Tubing Company, Detroit, Mich.): It is gratifying to see that Mr. Pfeiffer has taken it upon himself to again call our attention to the fact that the resistance-welding circuit as well as the control equipment used in conjunction with resistance welders is in need of further study. Very little has been published on this subject in this country and, although I believe that considerable work is being done in Europe, particularly Germany, not a great deal of the results have as yet found their way into the literature.

The author has mentioned that "the great problem for improvement in resistance welding processes is absolute control of power input to the weld area." This should be emphasized. I have, on several occasions, heard welding engineers describe the ideal control as one which would parcel out exactly a predetermined amount of energy. This is obviously false since the requirement for producing a spot weld is that the temperature of a certain volume of the metal be raised to some value within the welding range of the metal. Whether or not this temperature will be reached is dependent upon the specific heat and specific resistance of the metal, the mass of the metal in the weld area, in some cases on the value of the heat of fusion, and on the temperature gradient between the weld volume and the surrounding metal. The temperature gradient is again dependent upon the heat conductivity of the metal and the shape, size, distribution, and temperature of the electrodes and upon time. Obviously then a given amount of energy, if supplied at low power, may never achieve the fundamental requirement of raising the weld volume of the metal to the temperature required for welding.

The ideal weld control would be some device which permits the current to flow until a predetermined temperature is reached in the weld volume. Two methods have been tried to accomplish this. One method attempts to measure the temperature of the weld volume by measuring the resistance between the electrodes—actually a system of relays opens the primary circuit of the welding transformer when the potential drop across the electrodes reaches a set value. The variable contact resistances between electrodes and sheet as well as between sheets and the variable volume of the material which acts as the electrical conductor are great hindrances to the success of this scheme.

Another method employs the photoelec-

tric cell for measurement of the temperature of the weld spot and through a system of relays controls the flow of current in the welding circuit so as not to exceed a certain predetermined temperature range (see H. Zetzmann, *Archiv f. d. technische Messen*, volume 214, 3, September 1934 and G. Mueller, *Elektroschweiszung*, volume 6, number 1, 1934).

I should like to ask the author why he assumes the volume of the metal carrying the current to be 3 times the volume of the cylinder with bases equal to the diameter of the electrodes and with an altitude equal to the thickness of the 2 sheets, when, from the example of data given, a factor of 2 would be more nearly indicated. Observations made by F. Goldmann (*Elektroschweiszung*, volume 2, page 8, 1931) seem to indicate that the path of the electrical current through one sheet is in the shape of the frustrum of a cone with the smaller diameter equal to the diameter of the electrode. If a cross section of a spot weld is examined and the diameter of the weld spot at the former interface of the 2 sheets measured and if this is assumed as the larger diameter of the frustrum of a cone, the volume of the path traversed by the major portion of the welding current can be calculated. In a few such measurements and calculations made by the author, the factor 2 seemed to be indicated for calculations based on the cylindrical path.

**R. A. Gilbert** (nonmember; General Electric Company, Pittsfield, Mass.): When the article "The Resistance Welding Circuit," by C. L. Pfeiffer, was published in the August 1936 issue of ELECTRICAL ENGINEERING it was recognized as being of considerable fundamental value; in fact, so much so, that photostat copies were made for our files.

The fundamentals of the welding circuit have been thoroughly analyzed by Mr. Pfeiffer and while it could hardly be expected that such a paper would cover all of the ramifications of resistance welding, we feel that he has provided the ground work for more data in a field where little or nothing is available in the current literature.

There is great need for a handbook or textbook on resistance welding, covering not only the fundamental circuit but also other phases of the art such as welding technique, welding machine design, modern tube control devices, electrode materials, etc.

We trust that such a work will soon be available.

**I. T. Hook** (nonmember; American Brass Company, Ansonia, Conn.): Mr. Pfeiffer has brought to our attention some important features of the resistance-welding operation. For instance, he places *electrode pressure* on par with current value and time of heat-on period. For a long time, the importance of maintaining the pressure uniform was under estimated. As a matter of fact, in welding low-carbon plain steels, the pressure may vary greatly without seriously impairing the strength of the connection. Steel is weldable over a long range of temperature and pressure. Since common steel was, for the most part, the material seam and spot welded, little attention was given to the maintenance of a constant pressure.

However, with the fabrication of the stainless steels and copper alloys by resistance welding, more precise control over the 3 fundamental variables became necessary. In the case of the copper alloys, a weld was obtainable only by melting the metal. A slight variation one way or the other in the pressure would cause nonfusion, and consequently no weld, or weaken the connection by squirting the molten metal out of the spot forming troublesome cold slivers between the sheets.

With metals which are inclined to be hot short as is the case of some of the newer copper alloys, it is important that the pressure be controlled to a nicety in order that hot short cracks may be avoided in the welds.

The modern machines with air-weighted electrodes seem to fulfil the requirement of exact pressure control.

Mr. Pfeiffer has made it quite clear that exact timing is also important in spot and seam welding. Short time intervals down to that required for a single wave of a 60-cycle current may be an advantage in the case of the copper alloys for 2 reasons (*a*) it avoids heat losses by conduction into the surrounding areas and (*b*) it minimizes the danger of hot short cracks adjacent to the spot besides restricting heat effects to the spot itself.

Mr. Pfeiffer points out that "the best weapons to combat such variables as surface oxides, heat losses to surrounding areas, etc., are relatively high voltages, high current intensities and short time intervals." We believe that the importance of these electrical and timing desiderata has not been sufficiently emphasized.

What we desire above all things is a definite quantity of energy (electrical at the outset converted to a definite quantity of heat energy at the spot) delivered in a short period of time, say $^1/_{120}$ second. By controlling primary voltage, electrode pressure and time, we are attempting to do this. However, this set-up calls for a source of primary energy capable of overcoming high momentary loads which means a relatively high kilowatt-hour rate.

Studies such as Mr. Pfeiffer has given us help greatly in elucidating the problem. Perhaps we shall see, in the not distant future, some more convenient means of delivering definite quantities of energy in a small fraction of a second of time.

**G. G. Somerville** (nonmember; General Electric Company, Pittsfield, Mass.): This paper presents a very clear and complete theoretical picture of the conditions found in ideal spot and projection welding. The discussion is systematic and straightforward showing a clear understanding of the subject by the author and the writer should be congratulated on his contribution to the art. His attack of the problem and his method of obtaining reliable readings are unique and well worth study by welding engineers.

The practical application of the material presented in the paper by the welding application engineer or welding foreman would present difficulty, however. In practice every welding job is a problem in itself and unless the job is very carefully analyzed the actual voltage, current, and pressure best suited to the problem can be only a guess based on the experience of the supervisor. Many variables enter into the picture such as amount and shape of the material being welded; for example, a steel cylinder extending over one of the welding arms may increase the reactance of the welding circuit to a point where calculated values are useless. Again in practice the ideal spot weld is the exception rather than the rule—generally a great percentage of the welding current is by-passed by previous welds or by the inherent shape of the work. In simple cases the increase in current to compensate for these conditions may be estimated, but in general the proper values of current and time can be determined only by trial.

In a paper such as Mr. Pfeiffer has prepared, it is readily understood that any detailed discussion of problems encountered in practice could not be covered—but it is believed that his paper would be enriched if he included in his summary, a brief paragraph showing where a theoretical attack of some practical welding problems would lead to complications.

**D. I. Bohn** (Aluminum Company of America, Pittsburgh, Pa.): Mr. Pfeiffer is to be commended for presenting his analysis of the resistance-welding circuit.

The rapid changes in resistance-welding technique, as well as the development of suitable equipment for welding nonferrous materials, has required a more intimate knowledge of the electrical conditions actually existing in this type of equipment than has been known in the past.

I am in hopes that this paper will inspire others of a similar nature in the future.

Mr. Pfeiffer mentions that "it is this condition that makes difficult the welding of materials of high electrical conductivity such as copper, brass, or aluminum, because surface conditions often force the use of currents higher than otherwise necessary with the result that the joint is badly burned when the surface resistance between parts or between electrodes and parts approaches zero." I cannot agree with this general statement regarding aluminum, as, with suitable equipment, aluminum is being spot and seam welded commercially with results comparable to those obtained with other materials.

This welding is done without any burning or pitting of the surfaces, and, where desired, one of the surfaces may be welded so that the weld is practically invisible.

**Bela Gati** (Katona Rail Welding Concern, Mount Vernon, N. Y.): The author's comment that "the lack of available literature on this subject inspired the preparation of this paper" is very significant to me since this scarcity is especially evident in European and other countries. I have, in the past, been able to get copies of such papers for a quarter and have found it advisable to send such copies to my boss. It is not considered good practice in the Orient to send an article torn out of ELECTRICAL ENGINEERING, but when I send the whole issue, it gets passed on to a subordinate due to the boss's lack of time and the need to have a subordinate study the other articles contained therein.

The present article is already being studied by the Katona Concern. This concern has arc welded 25,000 rail joints in Hungary and some hundred test joints in other countries. I realize that about 10,000 welded rail

joints have been made in the United States in tunnels and on bridges and that most of these are made by the thermit process and were not made during traffic. I would like to inquire whether the author has had any experience with the resistance welding of rail joints. I would like to make a general inquiry as to whether the Sperry Company could furnish such information and also if any information is available on the mystic infrared X-ray welding of Doctor Longoria.

One hundred million rail joints need to be welded, and this should give work to 100,000 welders for a year. At the present time the battering of steel rail ends in the United States so affects their life as to cause them to last only 5 years and this would be much shorter in case of war. North America might lose such a war because of the failure of her unwelded rails; thus good maintenance of her railroads may be even more important than the acquiring of very costly battleships.

**C. L. Pfeiffer:** I am pleased by the general comments given in all the discussions which emphasize the need for investigating the weld area more thoroughly.

I agree with Mr. Heitman that in most cases the impedance of the leads and transformer is the determining factor in determining the current through the weld and that this is mostly reactance. I also feel that it is usually desirable to have high impedance in the leads and transformer as this acts as a stabilizer and sometimes brings definite rewards in weld quality. The question of electrical efficiency in the weld circuit is often quite secondary to quality in manufacturing operations especially on lower kilovolt-ampere welders. The little data that was given was in connection with relatively low kilovolt-ampere welders having short leads.

Mr. Zimmerman's reference to fluctuations in electrode pressure during the welding interval is an interesting problem for investigation and no doubt would require an ingenious set-up for accurate measurements in short intervals of time.

Mr. Cogan's remarks indicate that he appreciates even an approximate rule-of-thumb method which allows a sufficient factor of safety in determining voltage drop in the weld area and which may be used as a starting point in the design of a welding machine to be used on a specific job. The factor of 3 given in the paper includes a factor of safety for design requirements and should answer Mr. Hobrock's question as to why 3 is used when 2 appears to be more nearly correct.

In connection with Mr. Dawson's comments on oscillographic measurements, not enough data is at hand to say what voltage variations there are in the weld area, although on copper-rod butt welding I can say that no appreciable change was noted on any of hundreds of oscillograms. The references to Jean's formula and related matter are simply suggestions because the whole problem is one of groping around for a possible line of attack. The vector diagrams represent actual vector values for all quantities except $E_T$ which is obtained by subtraction as mentioned and because of the angular relationships can only fit in one way. I agree with Mr. Dawson that definite energy input into the weld area cannot be generally used and only works out in a practical way by the use of ignitron or thyratron control. Because of variable contact or material conditions it is important to know when occasionally a weld or poorer quality is made and this might be accomplished by measurement of voltage drop and current values by an instrument which indicates or reports an off-normal condition. This weld can then be put aside as being questionable. Mr. Hobrock's discussion of energy control into the weld area is correspondingly interesting.

To supplement Mr. Woofter's remarks I wish to point out that figure 4 was made and an example given to show primarily what should not be done, and that the other circuits, figures 5, 6, and 7, are far superior.

In my references to difficulties in welding "materials of high electrical conductivity such as copper, brass, or aluminum" I did not wish to give the impression that there is much trouble in welding aluminum as questioned by Mr. Bohn, but instead that one must be more alert in making machine adjustments and have better welding equipment than in welding low-carbon steels.

Mr. Frost's discussion presents a very clear picture of the input energy and loss factors involved in spot welding and I wish to compliment him in presenting an equation which is a good starting point for nearly any further investigation of the weld area.

I am not in a position to discuss resistance welding of rails or Dr. Longoria's secret process as mentioned by Mr. Bela Gati. Offhand it seems to me that the flash welding of rail ends in the field is a problem of having portable equipment of sufficient capacity available in remote places. Certainly a power supply of perhaps between 1,000 and 2,000 kva to be made available just anywhere along a railroad is a problem by itself.

Further comments on remarks by Messrs. Gilbert, Hook, and Somerville are hardly necessary. Of course I agree with Mr. Somerville that an entirely "theoretical attack of some practical welding problems would lead to complications." At a given voltage the welding machine will duplicate its work time after time providing the parts fed to it are uniform in every respect. One hundred per cent uniformity in fractions of a thousandth of an inch, in surface condition, or contact area is practically impossible. These small variables are not usually of major importance on most jobs but the welding engineer must recognize them, and on critical jobs the design of parts, materials, the type of machine, tools, and control, must be such to reduce possible variations to a minimum.

In conclusion I wish to thank the various discussers for the time spent in examining my paper and preparing their discussions.

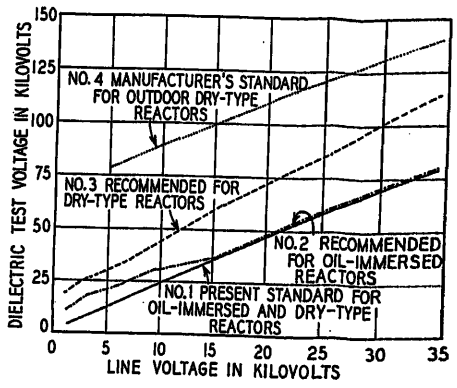

**Figure 1. Standard dielectric test specification for current-limiting reactors**

## Proposed Transformer Standards

**Discussion of a paper by J. E. Clem published in the January 1937 issue, pages 32–36, and presented for oral discussion at the selected subjects session of the winter convention, New York, N. Y., January 25, 1937.**

**S. I. Oesterreicher** (Metropolitan Device Corporation, Brooklyn, N. Y.): I would like to discuss Mr. Clem's paper on the proposed transformer standards and in particular that section which deals with current limiting reactors.

The paper recommends certain insulation requirements for oil immersed and dry type reactors. I believe the values given in table IV are conservative and there should be no difficulty in complying with the suggested requirements.

Up to the rated voltage limits given in table IV, dry-type reactors are used for both indoor and outdoor service. Therefore, it should be made clear whether or not the given values apply to both kinds of service. I believe that for outdoor service we can afford to increase the low-frequency applied voltage tests to higher values so as to be better than the transmission line. To summarize the past and proposed test potentials, I have prepared a diagram which shows the practices followed for the various kinds of reactor services.

However, it is misleading to believe, that due to the new and higher test voltage requirements the reactor will automatically become a superior product. The recommended low frequency dielectric strength requirements are easily met by providing the proper supporting insulators. But this leaves the reactor winding in the same dielectric test muddle as it has been in the past and as stated in the Institute Standards, section # 13, namely: "although it is generally recognized that a test between turns is desirable, no rules have as yet been established." It is not to be thought that because no rules have been set as yet, the designer has an easy task—on the contrary his job is the more difficult. One purchaser specifies a 40-kv high-frequency test for a 13.2-kv line. Another is satisfied with 56 kv on a 24-kv system. One wants a 100-kv impact test with a steep wave front. Not so long ago a 1/4-cycle front on a 60-cycle system was considered steep. Nowadays we speak of wave front in fractions of microseconds, etc. To correct these inconsistencies, I would suggest Mr. Clem and his associates on the transformer subcommittee tackle also this phase of the standardization rules and recommend certain minimum requirements and some uniform procedures which will give us a guide for testing reactors on a more equal basis.

I noticed in the report that the committee changed the classification of the reactors to that of oil-insulated and air-insulated reactors. I would suggest that the present classification namely, oil-immersed and dry-type reactors be retained.

**K. B. McEachron** (General Electric Company, Pittsfield, Mass.): The use of the rod gap as a means of determining the potential to be applied to transformers when undergoing impulse test is not a very satisfactory means of determining test conditions.

The volt-time spark-over curve of the rod gap is very different in shape from the volt-time breakdown curve of transformer insulation. Furthermore, since the transformer insulation strength is not affected by external atmospheric conditions, and the rod gap is so affected, it would appear that the use of kilovolt crest for a given wave shape would be more satisfactory. Thus, the crest value and wave shape without respect to polarity would be specified for each rating of transformer. If it is desired to spark over a parallel rod gap as in test (*a*) of the paper, its spacing would be adjusted to correspond to the existing conditions of humidity, air density, and polarity.

The change from inches of gap to kilovolt values should not now be difficult, since data agreed upon by the various American laboratories are available for both polarities, and corrections for atmospheric conditions are pretty well agreed upon. It seems to me that there is no very good reason for continuing the use of inches of rod gap as a standard, when kilovolt crest values are much more fundamental and can be regarded as a true standard.

For other wave shapes than the standard $1^1/_2$x40, sufficient data concerning the volt-time breakdown curve of transformer insulation are becoming available, so that the proper kilovolt value can be readily chosen. I would like to recommend to the transformer subcommittee that serious consideration be given to the use of kilovolt values rather than inches of rod gap.

In making the impulse tests which have been called for, upon transformers, one rather serious difficulty has arisen, which has increased both the time and cost of making the required tests. I refer particularly to transformers having more than 2 windings, in which case one winding will be utilized for excitation at normal frequency and potential. The winding under test will have one terminal grounded, the impulse being applied to the other end of the same winding while any other windings (and there may be several, particularly if the transformer is 3-phase) will have an air gap connected across each terminal to ground. Quite often these gaps spark-over, and the sudden change of constants affect the wave shape of the impulse applied to the winding under test in an unpredictable degree, and at the same time power follow may take place across the gaps. To prevent such power following, lightning arresters are frequently connected to ground from the terminal of each winding not under test. This is not a complete answer, however, partly because of the multiplicity of arrester ratings required, and partly because the arrester's resistance is nonlinear, being infinite until the gaps spark over, dropping to a low value which increases as the current decreases.

A considerable improvement in testing technique would result if a resistance of proper ohmic value could be connected between each terminal of windings not being tested and ground. This, however, is impractical as long as the power-frequency excitation is a required part of the test, since the energy loss in the resistors is very high. This situation is somewhat improved by the use of a high voltage fuse in series with the resistance and having a series gap just great enough to prevent the normal-frequency excitation potential from putting the fuse into the circuit until the arrival of the test impulse.

A solution of this problem, it seems to me, would be to make the 3 tests as now outlined in Mr. Clem's paper, without the use of power excitation, and follow with a fourth test with normal excitation with the applied impulse reduced to a level just below the spark-over values of the gaps in parallel with the terminals of the winding or windings not being tested. For this last test, the resistor which had been bridged across the bushings for the 3 previous tests would have been removed. Such a procedure would greatly facilitate the test, since the proper impulse-generator constants can be set up in advance using the transient analyzer (The Oscillograph Electric Transient Analyzer, N. Rohats, *G. E. Rev.* volume 39, 1936, page 146), since the transformer constants would not change due to the flashover of gaps connected to windings not being tested.

**I. W. Gross** (American Gas and Electric Company, New York, N. Y.): I am sure we very much appreciate the efforts of Mr. Clem in studying in detail the proposed transformer standards and pointing out those features which are outstanding, so far as suggested changes or revisions are concerned, before they are written into the standards with which we may be tied up for some period of time in the future.

There are several comments I would like to make on this paper: first, in regard to the rated circuit voltages listed in the first columns of tables I and VI, I think the setup of both tables would be much simplified by omitting voltage classifications where no data is given, such, for example, as voltage ratings of 120, 240, 480, 2,400, 4,160, and 4,330. It is not clear why these have been included in the table and it would seem to be a very simple matter to footnote this column to indicate that transformers to be used at rated circuit voltages which were not listed would fall in the class of the next higher voltage class.

In table VI, also, the voltage rating of 2.5 kv is given but data are not given for bushings in this voltage class. Either this voltage rating should be omitted or proper data should be inserted in the table.

Another point which has continually come up for consideration is the designation of impulse strength of transformers. I note that specifying impulse strength in terms of inches of gap is still retained to the exclusion of any other method. In table I, the value of the impulse characteristics of transformer insulation would be very much enhanced if the so-called "basic insulation level" were given in kilovolts. This does not mean that the tabulation of gap spacing need be omitted, but I feel very strongly that the kilovolt values should appear. At the present time, there is no tie between the inches of gap spacing given in table I and the impulse strength of the transformer without searching the literature for the corresponding impulse strength of the gap levels indicated. Such an omission in "Standards" is going to be decidedly burdensome to those who have frequent occasion to design a protective system in conjunction with either lightning arresters or gaps in their various forms.

It cannot be too strongly emphasized that the gap is only a test device for applying voltage under specified conditions and has impulse characteristics quite different from fibrous transformer insulation. For example, the gap spacings given in table I are suitable only for positive waves; for negative waves the spacing must be changed. For fast rising waves, the gap permits higher voltages on the transformer, even to the point of exceeding the transformer ultimate strength. To adopt such a test device as a basic insulation level for transformers seems fundamentally unsound.

Commercial impulse tests on transformers have now been made for a period of several years, and in our own company such tests are usually made on all large high-voltage transformers. In this connection, I wish to point out that the procedure indicated on page 33 under "Impulse Test on Transformers" is, at present, rather confusing. Apparently, the intent is to apply 3 impulse waves; one, a full wave; one chopped on the tail (by gap flashover); and one chopped near the crest (by bushing flashover). If these waves were definitely specified as to the crest kilovolts, with tolerances for time at the instant of flashover, I believe the situation would be fully covered. It seems the logical way to define a test voltage is by magnitude and duration, leaving to the test code such problems as type of equipment to use for the test and the conditions under which they are to be made. Another point in connection with items (a), (b), and (c) referring to the application of the test wave, shows that 2 voltages are applied under the existing conditions of humidity, and air density, and another test under standard conditions. Under these conditions, therefore, the transformer winding will receive a voltage test depending, to some extent, upon weather conditions, and there seems to be no justification for this. I would suggest that all impulse tests be made under definite standard conditions. This again would be accomplished if the test voltages were specified in terms of volts and time rather than in terms of the device used to make the test.

I believe this section on the impulse test data on transformers could be, and should be, very much clarified before being written into the permanent standards.

## A New Electrostatic Precipitator

**Discussion and author's closure of a paper by G. W. Penney published in the January 1937 issue, pages 159–63, and presented for oral discussion at the selected subjects session of the winter convention, New York, N. Y., January 25, 1937.**

**R. E. Hellmund** (Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.): The rather brief reference in the paper to the beneficial effects of the electro-

static precipitator upon those suffering from allergic conditions conveys very little idea of the very important part which this device may play in the relief of such suffering. An allergic condition as referred to in the paper simply means a supersensitiveness which some persons have to certain substances which they eat or with which they come in contact in other ways. If these persons breathe air containing substances to which they are supersensitive and which in the majority of cases seem to be of an organic nature, it results in the irritation of the nose, throat, or eyes so familiar to victims of hay fever. If the bronchial tubes are sensitive, the result will be astlima, either of the hay-fever type caused by pollen in the air, or of a type caused by other substances. It is claimed that even certain skin irritations, such as eczema, are caused by similar conditions. Asthma, in particular, seems to be caused to a great extent, although by no means exclusively, by something emanating from moulds or fungi growing in damp places. One method of cure consists in innoculating the patient by hypodermic injections of the particular substance to which he is supersensitive. However, the number of cures claimed by this method is small because so few of the substances likely to cause these allergic conditions are known at this time. In view of this, it is at once evident that this electrostatic precipitator offers relief to a great many people. It is claimed that about 15 per cent of the population (about 20,000,000 in the United States) are suffering from some allergic condition or other, and it seems that only a small percentage of these are affected by substances other than those conveyed by the air.

In view of the prevalency of asthma in Holland, a chair for the study of it was created in the University of Leyden several years. Dr. W. S. van Leeuwen, following some original work done in America, obtained some very excellent results. He was the first one to experiment with means for cleaning the air to bring about relief. He arranged for air intakes a considerable distance above the ground and used large amounts of cotton as filtering material. In some cases this yielded very good results to those who spent their nights in these rooms and went about their regular duties in the daytime. However, in other cases he failed to get results, though his analyses had shown that they were also due to substances conveyed by the air. It is well known that air even at considerable height contains particles of organic materials, and from Mr. Penney's investigation it is evident that the cotton was effective in removing only some of the larger particles; as a consequence, those sufferers affected by the smaller particles naturally did not obtain relief. It is in this connection that the electrostatic precipitator is likely to be of great value. As indicated in the paper, some astounding results have been obtained with it and comparative experiments on patients have definitely proved its superiority over the mechanical filter; in fact, it seems to give almost 100 per cent results in cleaning the air.

There are some persons, however, who are affected by dust or other irritating substances located in wearing apparel, bedding, etc. Dr. van Leeuwen has, for instance, established as a cause certain moulds growing on the feathers in pillows in damp localities. Such substances can, of course, reach the breathing organs through air which immediately surrounds the sleeper and which has not been passed through the precipitator. Again, such substances as face powder, dandruff, and the like have been suspected as possible causes, and here it is again impossible to accomplish complete filtering before the particles enter the patient's breathing organs. However, with the many substances eliminated which can be filtered out by the electrostatic precipitator, the remaining possible causes are narrowed down to a very few, thus making it relatively easy to determine what they are and to eliminate them from the living quarters of the sufferer. Dust particles, in addition to causing allergic conditions, are quite generally assumed to carry certain bacteria, and therefore their elimination may also lessen the danger of contagious diseases caused by germ-laden air.

**Myron Zucker** (The Detroit Edison Company, Detroit, Mich.): Mr. Penney calls it a precipitator, but its real meaning would be brought home better if he called it a filter.

Mr. Penney's development is of great interest because of the fields it opens. The 2 major contributions seem to be the practical elimination of ozone (which is now considered an active poison), thus permitting the use of the cleaner for air conditioning; and increased economy. Since no costs are given, however, it is difficult to imagine just how widespread the precipitator's use might become. Would the author give some orders-of-magnitude for initial cost, power demand, and power consumption for sizes ranging from his window air filter up through 500,000 cubic feet per minute in plants?

Also, similar figures for physical size of the units, and the corresponding gas velocities to be used for satisfactory filtration would help orient the field for this precipitator.

Have any tests been made for ionization remaining in the cleaned air? It might be a favorable by-product in case researches now being conducted show that ionized air is healthful.

**E. M. Strong** (Cornell University, Ithaca, N. Y.): The author has produced a very commendable improvement in the technique of electrostatic filtering. A really effective dust remover has enormous possibilities in many fields and in large quantities. I am interested especially in the field of hay-fever treatment which the author mentions. While this is an allergic affliction and therefore concerned with food and other factors in addition to dust and pollen, it is true that removal of these particles is a major preventive. The author may very well initiate a humane service in this field which involves a large share of our population.

There are 2 major objectives indicated by the author in the development of his precipitator:

1. Reduction of power and space required
2. Reduction of generation of unhealthful products

It is regrettable that more definite quantitative data are not given in the paper to show just how well these objectives were realized. I would inquire what power is used by the models now built and how it is proportioned between ionizer and precipitator.

The generation of unhealthful products seems to me a matter of major concern and one which demands thorough investigation before the apparatus is made available to the general public. So far as I am aware, our knowledge of the effects on the health of humans, exposed for long periods to the products of corona in confined air, is very meager.

One very logical application of the apparatus illustrated by the author is in the air circulating system of the modern air conditioning unit for home or other use. With customary high percentage recirculation it is conceivable that the "very low generation" of unhealthful products may well accumulate to sizeable and definitely dangerous proportions.

If the author has as yet any data on this aspect of the application of the precipitator, surely they are of major importance; if not, I would urge that a careful study be made into the consequences of long-time living with the apparatus before it is put on the market.

**G. W. Penney:** Mr. Strong and Mr. Zucker asked for definite figures on the size of the unit and the reduction in size as compared to the previous precipitation practice. This is frequently given in terms of precipitation time. The precipitation time which we have used varies from 0.12 seconds to 0.6 seconds, depending on the application. In other words, a precipitator to handle 3,000 cubic feet per minute would occupy a volume of 6 to 30 cubic feet. From published figures I believe that the precipitation time in older practice has been of the order of 5 seconds, which would correspond to a precipitator volume of 250 cubic feet to handle 3,000 cubic feet per minute. These volumes refer to the actual volume occupied by the precipitator proper and does not include any space occupied by ducts.

The high-voltage power consumption is approximately one watt per 100 cubic feet per minute. For the 3,000-cubic-foot-per-minute unit referred to above, the transformer and tube losses amount to about 30 watts so that the total power consumption is about 60 watts.

There is apparently no disagreement as to the harmful effects of the amount of ozone present in the air from the older precipitators. However, I believe that the danger from minute quantities of ozone is frequently exaggerated. There are many things which are essential to life in certain concentrations but which are very harmful in excessive concentrations. In discussing this question with a number of doctors, they have all agreed that ozone is probably beneficial and certainly not objectionable as long as it is present only in a concentration not exceeding that found in outdoor air.

The generation of ozone is controllable over a considerable range, although a unit for very low ozone generation is somewhat more expensive. The ozone generation which we have regarded as the allowable limit is based on the same premise as that suggested by Mr. Strong, which is that when used in a house with full recirculation,

the natural infiltration and the decomposition of ozone must keep the ozone below any objectionable limit. We assume that the ozone is not objectionable provided that its concentration does not exceed that present in outdoor air in bright sunshine. Our measurements give the ozone generated as less than one part in 300,000,000 parts of air. However, methods for measuring such minute quantities of ozone may not be entirely reliable in giving the absolute concentration, but at least the comparison between outdoor air and the air from the precipitator should be reliable.

Mr. Zucker asked for cost figures. This device has been produced in relatively small quantities to date so that manufacturing costs are not stabilized, so that for the present we can only quote prices on specific applications. However, when manufacturing methods are developed for quantity production it is expected that the cost of equipment for cleaning the air in a house should be comparable with the cost of the household refrigerator.

In reply to Mr. Zucker's question as to the ionization remaining in the cleaned air, there is some residual ionization and this can be varied over a wide range but our present viewpoint is that this ionization probably does not have any noticeable effect.

## Studies of Stability of Cable Insulation

**Discussion and authors' closure of a paper by Herman Halperin and C. E. Betzer published in the October 1936 issue, pages 1074–82, and presented for oral discussion at the selected subjects session of the winter convention, New York, N. Y., January 25, 1937.**

T. B. Jones (The Johns Hopkins University, Baltimore, Md.): At The Johns Hopkins University studies are in progress dealing with the nature of the radial variations of power factor as affected by oxidation of the compound and by the type of metals used as electrodes. By varying the amount of oxygen in the compound it is possible to obtain rising power factor-time curves with very high values of power factor at elevated temperatures in the vicinity of 80 degrees centigrade. However, when the specimen has cooled down and radial power factor measurements are made it is found that the average of the radial curves does not differ greatly between good specimens and deteriorated specimens. This is in agreement with the authors' table I. Since the radial measurements indicate the degree of "solid" loss then the difference between the average value of the radial tests and the final over-all value of power factor of the sample before dissembling should give an indication of the interlayer or ionization losses. I would like to know if the authors have made any determinations of this nature and if such results correlate with the ionization factors of the complete samples.

The ionization factors in table I are taken at room temperature. Is there any change in ionization factor with increase in temperature? Our results indicate ionization factors as high as 0.006 at 80 degrees centigrade whereas when the temperature is reduced to 25 degrees centigrade the ionization factor is zero. Moreover the final over-all values of power factor at room temperature do not differ greatly among good and poor samples, this would seem to indicate that the high losses occurring in samples with oxidized compound can in all cases be associated with elevated temperature.

W. A. Del Mar (Habirshaw Cable and Wire Corporation, Yonkers, N. Y.): Load cycle life tests are the penultimate tests of cables, the ultimate tests being, of course, actual service under proper supervision.

The company with which I am associated has used and continues to use such tests for comparing different cable oils, papers, and designs. Formerly the criterion of these tests was the number of cycles until failure occurred. Tests on this basis often lasted for several months and as the capacity of the equipment was necessarily limited, the number of tests that could be made per annum was not very great. Thanks to Messrs. Halperin's and Betzer's work, this condition has been changed and a great many more tests can be made in a given time. This is accomplished by establishing a number of arbitrary test limits and stopping the test when any one of these has been reached. These test limits include power factor, temperature, and ionization, as well as life. The limits are chosen by experience to distinguish a cable that is practically stable from one that is unstable.

Messrs. Halperin and Betzer choose a test voltage of $2^1/_2$ times the working voltage. I think that it would be more revealing if they said that they use a maximum stress of 234 volts per mil (calculated by the simple logarithmic formula). Using this stress it is possible to practically parallel Mr. Halperin's results using cable of different design, for instance, thinner walls at lower voltages and indeed, this is what we do in our standard tests, using 220 mils of insulation.

Mr. Halperin's tests were made on horizontal cable, whereas some tests by Detroit Edison Company were made on vertical loops. We have made tests both on vertical U's and horizontal lengths and find that quite different results are obtained. There is some question as to which type of test gives the more reliable results, i.e., results most consistent with operating conditions. However the test is made, it seems important to have the ends horizontal, so that the oil in the end paper (where there is no lead sheath) will not drip into the remainder of the cable.

There is difficulty in obtaining consistent results on a number of apparently identical cables and until this has been removed, some suspicion attaches to the validity of all these tests. We have made series of 4 cables of apparently identical materials, given identical and simultaneous treatment under the most carefully controlled laboratory conditions and yet the cables, on test, will show different results. Dr. Whitehead's voltage-time tests on laboratory prepared cables showed similar divergencies. In those tests only 15 layers of paper were used, so that differences in paper density might not have been averaged out, but in our tests, there are normally at least 36 layers of paper, so that the probability of many low-density spots being superimposed is rather remote. Nevertheless, we find that the variance is much less with high than with low-density paper.

Mr. Halperin has spoken of the better results given by cables impregnated with rosin-blended oils. We have found that such cables exhibit better adhesion of compound to the paper and are less subject to excessive drainage. The use of rosin, however, is advantageous only with certain types of oil, instability resulting from its use with certain naphthene base oils now advocated for cables.

G. M. L. Sommerman (American Steel & Wire Company, Worcester, Mass.): The results presented by Halperin and Betzer show that cables made under identical conditions of fabrication, but with different saturating materials, possess widely differing values of stability and life. This leads to the general conclusion that the problem of finding stable impregnating compounds is fully as important as the problem of reducing deteriorating influences by the use of improved methods in the manufacture of cables.

Load cycle life tests indicate whether one cable is better than another, but, in themselves, give little information as to why it is better. Various methods of diagnosis, such as the dyeing of tapes and the radial power factor test, indicate reasons for superiority more clearly. The authors are to be commended for their discovery of a correlation between life and the quantity: inch-hours of vacuum maintained by the cable. In order to determine the ultimate basis of superiority, however, the materials used in cables must be subjected to various simplified tests, each determining some isolated characteristic. The results of these simplified tests must then be correlated with the observations covering load cycle life tests. As an illustration of this, it has been found by simplified tests made in our laboratory that there are at least 3 advantages accruing from the use of rosin in impregnating compounds, in addition to the obvious effects arising from the increased viscosity of such compounds.

It is now being more generally recognized that the stability of insulation and the properties after some service are more important than the initial properties. This should have an effect on the choice of cable saturants. The use of rosin in the saturating compound is a case in point. Many cables made 5 to 10 years ago contained from 5 to 15 per cent rosin in the saturant. Because the rosin then in use was relatively crude in form, these cables had maximum power factors of the order of 2 per cent (at 85 degrees centigrade), while cables containing no rosin had lower power factors. Although it was realized in a general way that rosin stabilized the insulation, there has been a general trend away from its use during the last 6 years—mainly because of the lower initial power factors obtainable by the use of straight oils. The load cycle life tests made prior to several years ago were so accelerated (employing voltages from 3 to 10 times the rated values) that differences in dielectric loss were greatly magnified. Because of these exaggerated conditions, the probability of thermal instability in test was high for the rosin-containing

cables, and these cables consequently showed up rather poorly. The load cycle life test has, from its inception, enjoyed such prestige that the results were allowed to subordinate the results of electrochemical stability tests and cable operating records.

In the last few years, 2 things have occurred. One has been the development of improved rosins and the use of these rosins in cable saturants, with the result that the cables so made have power factors little if any higher than those of cables made with straight oils. Another has been the improvement of load cycle life testing procedures which are less accelerated in character, and which yield cable failures approximating those occurring in service. The work of Halperin, Betzer, and their associates is an important contribution to this latter field. As a result of these developments, both of which have made thermal instability improbable in the life tests, the more stable characteristics of rosin-containing cables have become manifest. In view of this, it would not be surprising to see a trend back to the greater use of rosin or similar addition agents in the saturants of paper-insulated cables.

**M. G. Malti** (Cornell University, Ithaca, N. Y.): Various writers,[1,2,3,4] on dielectrics have ascribed the breakdown of dielectrics to heat, asserting that electric breakdown is essentially a heat phenomenon. Over 9 years ago, in a paper,[5] I asserted that the absence of valuable data on the nature of dielectric breakdown with alternating potentials renders the formulation of a theory, or even a definition thereof, a matter of wild conjecture. I further disagreed with the propounders of the so-called pyroelectric theory of breakdown on the following grounds:

(*a*). The energy dissipated in the period from the time of voltage application to the time of breakdown, does not raise the temperature sufficiently to account for a breakdown due to heat

(*b*). Actual temperature measurements[6] show that no temperature rise exceeding 10 degrees centigrade does occur in glass before rupture.

The results of the present paper[7] furnish excellent evidence against the pyroelectric theory. Indeed that the breakdown of a solid dielectric cannot be a heat phenomenon is shown by the following facts brought out by the paper:

1. The fact that power factor is sometimes lower at high temperatures than at room temperature (see reference 7, figure 1).

2. The fact that breakdown is always accompanied with a change in the physical condition and chemical composition, and that no breakdown occurs except where such a change shows up (see reference 7, figure 5).

3. The fact that breakdown sometimes takes long paths (over 5 feet as shown by reference 7, figure 7). Indeed if breakdown were simply a heat phenomenon, it would occur where heat would be concentrated, that is, over short paths.

4. The fact that breakdown sometimes starts at the sheath (reference 7, figure 7) where presumably the cable is coolest.

5. The fact that it takes "ageing" to reveal weakness and that different samples presumably subjected to the same heat show no failure unless chemical and physical changes occur (see figures 1 and 5 and conclusion 13 of reference 7).

6. The fact that the authors have observed (see conclusion 6, reference 7) that *ionization* not heat is the cause of deterioration which ultimately results in failure.

7. The fact that stability of the impregnating compound (not heat) is a primary factor in insulation deterioration (see conclusions 5 and 10).

**R. J. Wiseman** (The Okonite Company, Passaic, N. J.): In stability tests on cables we are largely concerned with small movements or migrations of the free oil, that is, the oil between the paper tapes, in the gaps between the paper edges, and the oil between the strands of the conductor. For this reason, the amount of oil which flows longitudinally into or out of the joints is of importance in determining the life of the cable. However, because this is such a variable factor, and because the section of a long cable farthest from the ends is the most isolated, and usually the most liable to breakdown on stability test, it appears to be preferable to seal the ends of the cable as completely as possible. The authors' cable joints were designed to prevent longitudinal flow and this was "closely approached," but not "completely achieved." What tests were made to check the amount of longitudinal flow?

If this lengthwise flow is eliminated, then stability tests on 50 foot lengths of cable, or even somewhat less, are practical. The cable should be long enough to include in a representative way those slight irregularities which are the reason for breakdown initiation at one point rather than another, and so that the effect of the inevitable loss of a few drops of oil at a splice or insulating joint is insignificant.

If the length of cable under test has the ends perfectly sealed, the only oil movement when the cable is heated is a radial movement, which expands the sheath. If the sheath expansion is measured at different points around the circumference, and at intervals along the length, very considerable differences will be found in sheath expansion. Even with pressures of 40 or 50 pounds per square inch inside the sheath, there may be a decrease in diameter along one axis. The differences in sheath expansion probably account for the unequal stability of samples 60 and 61, which were identical except for being sheathed separately and with different kinds of lead.

The difficulty of predicting failure by making periodic power factor tests is well illustrated by the radial power factor tests made on a few inches of cable involved in incipient failures. Take the case of curve *H*, figure 3, where the carbon extended about 30 per cent of the distance from the conductor to the sheath. The radial power factor curve shows the remainder of the wall to be in good condition. It is easy to estimate approximately the effect of the high power factor of this short section on the average power factor which would be measured on a reel length of cable. Suppose 50 per cent of the insulation was broken down completely, then this whole section would be at conductor potential and except for the increased stress on the good 50 per cent remaining, its power factor would remain unaltered. So that if 50 per cent of the insulation was completely broken down, there would be no appreciable change in the average power factor of the cable.

If this 50 per cent, instead of being completely short-circuited, had its power factor increased 40 times, the power factor of the short section under consideration would be about 10 times what it was before. If this section was about 6 inches long, this effect would be lost in a 500-foot length, for it carries only 1/1,000th of the total capacity current, and the power factor would only be increased by 10/1,000th or 1 per cent of its previous value. Such a small increase is completely masked by temperature changes and other effects.

On this account, the authors have made their power factor measurements on 25-foot sections, but the introduction of insulating joints is open to objection, chiefly because it disturbs the cable. A better method for locating incipient failures and testing longitudinal uniformity is to measure the temperature rise along the sheath with thermocouples at points located 2 or 3 feet apart. If the power factor of a few inches of cable increases 10%, the heat generated in that section will increase 10 per cent and the sheath temperature would increase 10 per cent were it not for heat conduction along the cable. If a 66-kv cable is held at say 115-kv with a similar dead cable alongside for use as a temperature zero level, then the heat of dielectric loss will give a temperature rise of something like 3 degrees centigrade for a 66-kv cable with a 0.0035 power factor. A one-degree-centigrade rise above normal at a point on the sheath represents a "hot" spot, and by making careful measurements the point of failure of a cable has been predicted a month before breakdown occurred. This would have been impossible with power factor measurements.

It is important to decide whether the quality of a cable is to be judged by the interval between the start of test and the time when instability sets in, or if the time to failure is to be used to make comparisons. Figure 4 shows that class *A* and class *B* cables could easily be distinguished from the other classes by the small increase in power factor at elevated temperature. The actual time to failure, once failure has set in, does not seem so important, for conditions might be very local at the fault. Probably the best way to compare cables on stability tests is to make sheath tempera-

ture or "hot spot" measurements at 2-foot or 3-foot intervals along the sheath, and to use the curves of sheath temperature rise versus length, obtained after a standard interval of say 2 or 3 weeks to grade the cables. Whereas figure 4 shows that grade *B* cables had similar average power factors to grade *A* cables, the local deterioration which was found in grade *B* cables, and which is evident from figure 5, would become apparent from sheath temperature measurements.

It is quite possible that simultaneous voltages and load cycles are not necessary. The power factor of the cable could be tested with no more end preparation than is used for routine tests at the factory. Load cycles could be applied, followed by a final high-voltage test for making sheath temperature measurements. The oil movement caused by the load cycles is responsible for the formation of the ionizable voids and consequent increase in power factor, and the authors have shown in figure 3 that the carbonized areas created by the high voltage, contribute very little to the power factor in the earlier stages of the test.

The difficulty of correlating power factor tests with cable condition is increased by the difficulty of controlling the ambient temperature. A change of a few degrees in the room temperature may change the oil pressure in some cables from a good vacuum to a few pounds above atmospheric and this will have an important effect on the measured ionization. It is also tied in very closely with the effect of previous heat cycles on sheath stretching and it may be that a hot spot or local deterioration originates at a point where the sheath expansion is abnormal. The sheath stretches most where, measured around the circumference, there are the longest sections of thin lead.

The improved stability resulting from the use of paper and oil which are gas free, is well illustrated in the authors' paper. The reason for this is not as obvious as it might seem, but it is probable that in a highly degassed cable, the oil returns radially inward on cooling in a continuous unbroken column, and the voids are created near the sheath, where the stress is lower. If this is the case, we should expect that in class-*A* and *B* cables, failure would initiate at the sheath, whereas it would commence at the conductor in the poorer classes. An examination of figure 7 shows samples 24 and 64 (in class *B*) apparently do belong to the sheath failure class, whereas in samples 97 and 114 (in class *D*) the breakdown evidently initiated at the conductor.

It is said that the primary cause of failure is the bombardment of the compound by ionization in gaseous spaces. Is not the primary cause rather the production of ionizable spaces? The most effective method of improving high voltage cables is not in finding a compound which will withstand bombardment, or evolve a minimum of gas, but to prevent or minimize the formation of these ionizable voids in the first place, or else to restrict their formation to a part of the cable which is not under stress.

When a sheath failure occurs which is not accompanied by insulation breakdown, repairs are made in the manhole or shop. The cable insulation is removed until all traces of moisture is eliminated. It is difficult to decide whether a tape is moist or not by its appearance, and power factor tests are not practicable under such conditions. However, high-voltage d-c tests on paper tapes are said to be a good indication of the presence of moisture and are easily carried out on portable apparatus.

The article proves the value of stability tests to determine the ability of the cable to operate satisfactorily in service. Some manufacturers have been making these tests for a long time, and have found them invaluable in arriving at the operating characteristics of new types of cable.

**Herman Halperin and C. E. Betzer:** In reply to T. B. Jones' question, the results of power-factor measurements of individual tapes when properly averaged give the power factor of the cable as a whole at sufficiently low voltage to avoid ionization providing that conducting paths have not formed in the insulation. Such paths do not necessarily have the same effect in the test of individual tapes as in the test of the complete cable.

We have noted in a previous series of aging tests of 66-kv cable that in most cases ionization factors increased with increasing temperature but in a few cables the reverse was true. We have no explanation for this phenomenon. In the tests covered by this paper ionization measurements were made at room temperature only.

Although the point is not emphasized in the paper, we are pleased to have W. A. Del Mar point out again the fact that aging tests need not be continued to failure.

His suggestion that the test voltage be expressed in terms of maximum stress is in general agreement with our statement that for cables to operate at less than 66 kv the ratio of test voltage to operating voltage might be more than $2^1/_2$ on account of the relatively low operating stresses. Voltage tests in general are based on average stresses instead of maximum stresses in the insulation and probably the same should apply to aging tests.

In connection with the differences in test results for apparently identical cables it should be noted that such cables often differ widely in service. Sometimes a few lengths fail in service in a few weeks or months while other lengths have normal lives.

We agree with Sommerman that service performance is the all-important consideration. The aging test is the only known method of determining the performance in a shortened time. We have endeavored also to obtain all available information from auxiliary tests and service.

As emphasized by Malti, deterioration and failure in these tests resulted primarily from ionization, and this has been the weakness in insulation that has caused service failures in our 66-kv cables made in 1927 and later. We do not consider the test results proof, however, that breakdown by thermal instability is impossible. In one series of aging tests at $1^1/_2$ times normal voltage, 66-kv cables were immersed in oil. One 1926 cable deteriorated until its power factor at 70 degrees centigrade was 0.23 and then it remained stable for over 2 weeks. When the cables were removed from the oil, this cable soon failed in test. Apparently the failure was due to a pyroelectric effect which could not develop while the oil was conducting the heat away from the cable. It appears that failure can develop by ionization or by thermal instability and that increasing the voltage to accelerate the aging, hastens mainly the ionization action.

In reply to Wiseman's question, some of the joints had small standpipes in which loss of compound, if any, during the tests could be observed. When the joints were dissected, examinations were made for compound movement.

That differences in sheath expansion may have caused the differences in stabilities of samples 60 and 61 appears to be supported by the results of measurements of the gaps between insulation and sheath measured after the aging tests. These gaps were about 0.003 inch in sample 60 and 0.012 to 0.021 inch in sample 61. In general, however, no consistent relation was found between the sheath expansion and stability.

In these tests sheath temperatures were observed by means of thermocouples and by means of 2 stripes of heat-sensitive paint applied over the entire lengths of all samples. Information of this kind has been found to be helpful, but in all cases approaching failures were predicted by increases in power factor of the cable samples.

Concerning the suggestion that voltage and load cycles need not necessarily be applied simultaneously, failures have in some cases developed during the cooling period of our aging tests. Ionization effects are most pronounced during cooling when the greatest internal vacuum exists. In time after cooling, improvement in ionization factor and decrease in vacuum takes place. It appears important, therefore, that the voltage be on during the load cycles which simulates service conditions.

The theory that failure in class-*B* cable should start at the sheath does not agree with the test results. In 2 cables of class *B* failure started at the sheath while in three cables of this class failure started at the conductor.

We agree that the ionizable voids in cable insulation should be at a minimum. In cable of the ordinary type, however, some voids appear to be inevitable and therefore it is important that the compound be able to withstand bombardment at least to some extent.

## Electronic Transient Visualizers

**Discussion and author's closure of a paper by Herbert J. Reich published in the December 1936 issue, pages 1314–18, and presented for oral discussion at the selected subjects session of the winter convention, New York, N. Y., January 25, 1937.**

**N. Rohats** (General Electric Company, Schenectady, N. Y.): This paper presents some very interesting work on circuits for use with the cathode-ray oscillograph. The idea of repeating a transient in exact co-ordination with the oscillograph time axis so that a standing wave on the fluorescent screen is available for visual observation or permanent photographic records has already been used in a number of prac-

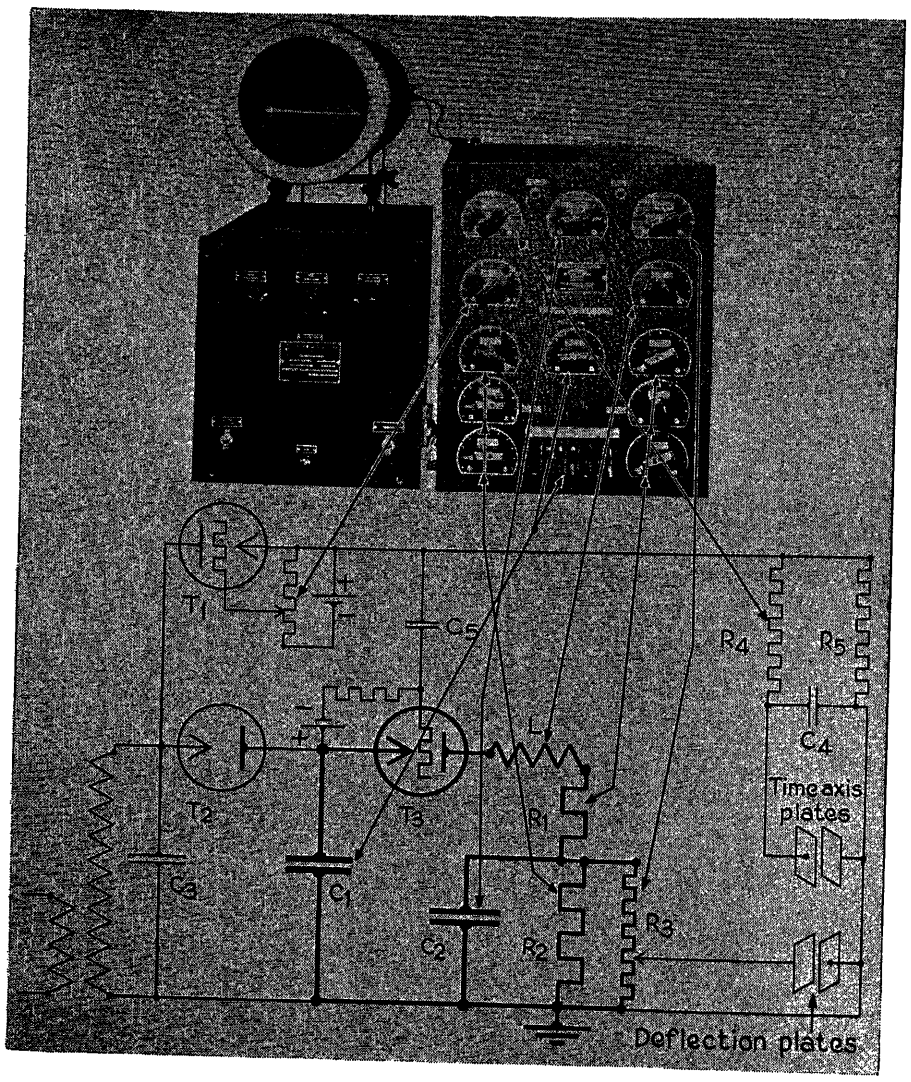

Figure 1

tical commercial applications. As the author points out, an arrangement which accomplishes this by mechanical switches has serious limitations for all but slow transients. Considerable objection may be found to the author's statement (quotation) "The device should not possess inductance, capacitance, or resistance—and this requirement prohibits the use of devices in which a capacitor or inductor charge or discharge is inherently associated with the action of that part of the switching device through which the transient flows" (quotation closed). The circuit arrangement which has been found most useful in general engineering work is one wherein the transient energy is originally stored in a capacitor and then released through a mercury-vapor tube to flow into an inductance and resistance discharge circuit. Presumably, this does not meet the author's requirements that the visualizer should be an ideal switching device. This requirement considered in the light of every day testing problems in transient work seems to have very little practical significance.

A more realistic general requirement is that such a device be capable of generating and imposing on circuits and machines, definite waves of a wide range of shapes. This requirement is met by the oscillograph electric-transient analyzer. The circuit arrangement is shown in figure 1. The complete analyzer consists of a set of variable capacitors, inductors, and resistors, a sweep circuit for a cathode-ray oscillograph time axis and the required means for properly co-ordinating these 2 so that a standing wave is visible on the oscillograph screen. Such a device from a testing standpoint is definitely related, as to type and use, to surge or impulse generators. When connections are arranged to give one output surge for each cycle of a power frequency supply voltage, it becomes a repeating type surge generator. It differs from the usual surge generator only in that it is low in voltage (1,000 volts), has a tube in place of the usual sphere gap, and is portable.

The miniature impulse generator is shown in figure 1 in heavy lines. Operation proceeds as follows: On the negative half cycle of the supply transformer $C_1$ receives a negative charge through rectifier $T_2$. On the positive half-cycle $T_1$ begins to conduct at the crest voltage, thereby sweeping the beam of the oscillograph at a speed determined by $R_4$ and $C_4$. The grid of tube $T_3$ receives an impulse through $C_5$ at the start of the sweep and becomes conducting thereby initiating the discharge of $C_1$ through $L$, $R_1$, $R_2$, $R_3$, and $C_2$ and producing the required wave shape across $C_2$.

The practical usefulness of such a device in the field of impulse testing is apparent. Many of the tests previously made with the single-discharge surge generator are now performed with a great saving in time over the old method.

For instance, in the adjustment of circuit constants of high-voltage surge generators to give standard waves such as the 1x5 or $1^1/_2$x40 for commerical impulse tests, such as for transformers, the analyzer is connected directly to the transformer and the circuit elements adjusted until the required wave is obtained on the oscillograph screen. The numerical values of circuit constants required are read from the dials of the analyzer and the high-voltage surge generator circuit constants set to correspond. This saves many hours of work.

The distribution of voltage across windings of transformers and generators is readily determined by applying output surges of the analyzer to one end of the winding and recording wave shapes at several tap points. This is a very important application because maximum surge-voltage strength is obtained only when the design is such as to cause uniform surge voltage distribution from one end of the winding to the other.

By connecting the output surges to a circuit or to machine windings and studying voltage and current reflection conditions for a range of values of resistance at the terminal end the surge impedance can be readily obtained.

These are all practical applications which have been made in many instances and through which valuable design and test information has been obtained.

Other uses such as demonstration of transient phenomena, study of induced voltages, and location of faults in circuits and windings are also of importance.

Returning to consideration of the visualizer and keeping in mind its conception as purely a switching device, it seems to be limited to special applications, particularly demonstrations of transients associated with switching phenomenon. Would the author comment on the limitation of current by the gas discharge tube itself? Also, does not the tube current controlled by the grid potential affect the shape of the transient? Also, does not tube voltage vary with current sufficiently to depart from a true switching device and to affect voltage distribution in the circuit?

The author is to be commended on the progress made in the design of visualizer circuits. It is hoped that his work will continue as the field is considerably unexplored and new factors of usefulness are quite certain to be obtained.

**H. J. Reich:** In discussing the limitation of my circuits to special applications Mr. Rohats seems to confine himself to the types of visualizer shown in figures 4 and 7 of my paper. This criticism also applies, however, to my circuits of figures 11 and 12 and to his own. Is it not generally true that the best instruments must be designed for specific fields of application?

I believe that the questions regarding the limitation of current by the tube and the effect of grid voltage upon the transient have been answered in my paper (paragraph 3, page 1314; paragraph 2, page 1317). So far as I have been able to determine, these factors do not affect the form of the transient.

In the type of visualizer shown in figure 7 the variation of anode voltage of an 885 gas-discharge tube affects the form of a starting transient to a certain extent when the supply voltage is low. The anode-voltage *vs.* anode-current curves of individual 885 tubes differ and are likely to change somewhat with tube age. The voltage of a typical tube falls from 17½ volts to 17 volts in the range from 40 to 6 milliamperes; at 1½ milliamperes it is 16 volts, and below 1½ milliamperes it falls to zero nearly linearly with current. A discontinuity of a volt or a volt and a half, accompanied by a change in the form of the discharge may occur at about 25 or 30 milliamperes, but its effect has not been observed in the transients, probably because of the rapidity with which the current changes during the transient. Distortion decreases with increase of supply voltage and with increase of average current. With a 45-volt supply and an average current of 40 milliamperes, the distortion is small. The distortion which results from the rapid fall of voltage below 1½ milliamperes can be prevented in most studies by shunting the transient circuit with a resistance of such size that the current does not fall below 5 or 6 milliamperes during the life of the transient. In the work referred to in reference 4 of my paper, Mr. Bennett showed that circuit parameters could be determined with considerable accuracy from oscillograms obtained with a transient visualizer of the type shown in figure 4 of my paper, using thyratrons. When transients are initiated by the interruption of current the tube does not conduct during the life of the transient and so cannot affect the form except as the result of its small inter-electrode capacitance. If the life of the transient is extremely short, some distortion may result from the finite deionization time of the tube, but this may be safely neglected in the study of transients whose life exceeds 1,000 microseconds.

Mr. Rohats' circuit is beautiful in its simplicity. It should prove to be valuable in many applications.

## An Electronic Regulator for D-C Generators

**Discussion and author's closure of a paper by F. H. Gulliksen published in the August 1936 issue, pages 873–5, and presented for oral discussion at the electronics session of the winter convention, New York, N. Y., January 27, 1937.**

**B. G. Ballard** (National Research Council, Ottawa, Ont., Canada): Those of us who have requested prices from manufacturers for electronic regulators will appreciate the development of a unit which sells at a price comparable to that of electromagnetic regulators.

The regulator described in Mr. Gulliksen's paper appears to possess particularly desirable features. It has dispensed with the amplifier usually employed and it apparently does not require a specially wound field. If a constant a-c input is assumed a sensitivity of 0.1 per cent is claimed which is equal to that of any precision regulator of which I am aware. In view of these desirable features I have been wondering if it would not be possible to adapt this regulator to a-c generators. It would seem feasible to heat the cathode of the diode with alternating current and feed the resistance in series with the cathode from a small filtered rectifier with a relatively short time constant. Since the alternating current supplied to the thyratrons should now be constant the over-all sensitivity of the unit should approach 0.1 per cent. I should appreciate the author's comments on this point and also I would like to know if the diode was specially developed for this application. Is it provided with a tungsten filament or a coated filament?

**Russell Ranson** (Duke University, Durham, N. C.): It is understood from Mr. Gulliksen's paper that the compensating or compounding rheostat in the filament circuit of the diode must be adjusted to suit the needs of the particular generator with which the regulator is used. This adjustment is similar to the adjustment of a diverter which is used in parallel with the series field of a compound generator to give flat compounding. It follows that a different adjustment of this rheostat is necessary for every voltage for which the regulator is set by the voltage-adjusting rheostat. This means that in order to change the regulated voltage from one value to another 2 adjustments must be made.

According to Mr. Gulliksen's curves the generator voltage varies in a straight line from no load to full load, either with or without the regulator. If this be true, why not pass the generator load current through a very low resistance similar to an ammeter shunt and impress the voltage drop across this resistor on the grid circuit to obtain the necessary phase shift? This will eliminate one electron tube, the diode. It is generally believed that a reduction in the number of electron tubes is desirable. Again referring to the curves given, the voltage change as given by the diode might be equaled by a voltage drop across a very low resistance as suggested with a loss of power that will be negligible.

Even if this plan were followed, it would still be necessary to provide adjustable resistors to match the generator characteristics and to provide for generator voltage adjustment.

**F. H. Gulliksen:** Mr. Ranson raises the question whether it is necessary to change the compensating adjustment if the regulated voltage is varied. Theoretically this assumption is correct, i.e., if the regulated voltage is varied the regulator will not have a flat characteristic from no load to full load, but the variation in regulated voltage will be so small (approximately $\pm 1/10$ of one per cent or less) that it will not be necessary to change the compensating adjustment. This is apparent from the curves *B* in figure 6 and 7 which show the regulator characteristic without compensation giving a drooping characteristic of 3 per cent and one per cent, respectively. If the characteristic in figure 6 is used it is apparent that the compensating adjustment may be varied 10 per cent without giving more than 0.3 volt error in regulated voltage from no load to full load. This is well within the guaranteed sensitivity of the regulator which is ±0.5 volts.

Mr. Ranson's suggestion to eliminate the diode may not be practicable because in that case voltage $E_2$ must be reduced considerably in order to obtain sufficient regulator sensitivity. If this be done the regulated voltage will vary with the changing grid-voltage characteristics of the arc discharge tubes caused primarily by varying tube temperatures.

In reply to Mr. Ballard's question, the author wishes to state that regulators for a-c generators operating on a somewhat similar principle are commercially available. In a-c generator applications a d-c exciter is usually needed and for this reason anti-hunting means must be added to the regulator circuits to obtain stable operation. The diode was specially developed for this application, and is equipped with a tungsten filament.

## Sealed-Off Ignitrons for Welding Control

**Discussion and authors' closures of a paper by David Packard and J. H. Hutchings published in the January 1937 issue, pages 37–40, and presented for oral discussion at the electronics session of the winter convention, New York, N. Y., January 27, 1937.**

**Bela Gati** (Katona Rail Welding Concern, Mount Vernon, N. Y.): Three little questions: Have you tried to weld nickel with aluminum? If so, did you preheat the nickel? Aluminum melts at 659 centigrades (Celsius), nickel at 1,452. Did you use your ignitron in rail-welding process?

**J. H. Cox** (Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.): The authors have done a creditable piece of work in working out to a satisfactory conclusion, the numerous problems involved in manufacturing a sealed-off metal tube for use with a mercury arc. The paper could have been made more valuable by a discussion of the degassing processes essential in this type of device.

Limiting temperatures of 50 to 125 degrees centigrade are given. Our work indicates that the minimum temperature for satisfactory operation is a great deal less than 50 degrees centigrade, and a maximum of 125 degrees centigrade sounds impracticably high for a water-cooled device. Possibly Fahrenheit degrees were intended.

Unless more water is used than is usually necessary, a water jacket design results in a low water velocity, deposit of sediment and inefficient cooling. Cooling coils permit more flexibility in design and, for the above reasons, may supersede the jacket.

This paper provides additional confirmation of the contention made by Dällenbach several years ago, that it is impossible to build a sealed-off metal tube with a corrosive cooling system, since corrosion of iron in water produces hydrogen ions which diffuse through steel walls.

The authors mention peak currents of 7,000 amperes and 250-ampere average currents at lower peaks. I would like to ask

what average currents they are able to carry with 7,000 ampere peaks, and how large the tubes are that carry these currents.

I think that the list of advantages given is misleading, since most of them are characteristics of ignitrons in general and not limited to sealed-off designs. In general, there is an economic division between the field for sealed off tubes and continuously pumped tubes. At the lower ratings, the tube cost is low and the assembly does not justify the expense of a vacuum pumping equipment. At the higher ratings, the replacement cost of tubes would be prohibitive and the cost of a pumping set a small percentage of the total. The dividing point will be influenced by what proves to be the average life of the sealed-off tubes in service. It is quite likely that it will be greater than we are used to in the case of thermionic cathode tubes.

**W. C. White** (General Electric Company, Schenectady, N. Y.): In connection with the life of this form of ignitron, it is important to differentiate clearly between elapsed time and actual operating time. Unlike a tube with a thermionic cathode, it is absolutely as "dead" as an insulating bushing when not actually passing current. This is particularly true of these sealed-off tubes incorporating only one anode, as there is no holding arc or pump in operation. In normal industrial welding operating schedules, the tubes are actually "alive" only a relatively small part of the elapsed time. It is believed, therefore, that in this service tube failures will be from accidental causes traceable to use or manufacture rather than any normal deterioration factor in the ignitor or other parts of the tube.

As regards choice between sealed-off and pumped ignitrons, there is an additional factor. This is the number of years assumed for the write-off period of the investment in the welding equipment as a whole. In the resistance welding field, it is relatively short compared with, for instance, the central-station field. A short write-off period, in combination with the aforementioned intermittent operation, is favorable to the sealed-off tube. Another favorable factor is the inherent feature of this type of tube to be ready to operate the instant power is applied regardless of the time it may have been shut down.

**R. E. Hellmund** (Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.): In addition to the previously mentioned advantages of the ignitron over other types of tubes for welding purposes, it has the further advantage that it can be built either "sealed off" or for operation in connection with pumps; this, of course, would not be practicable with gas-filled tubes. The question as to which way the ignitron should be built is then purely an economical one. The sealed-off tube has a somewhat limited life, which means either complete replacement from time to time or retreatment of the tubes. This maintenance cost has to be weighed against the carrying charges resulting from the higher initial cost of tubes designed for operating with pumps. It is at once evident that the smallest tubes mentioned in the paper will prove more economical as sealed-off tubes. It is also quite certain that the very large and high-power tube arrangements will be more economical under present-day conditions if equipped with pumps. Somewhere between these 2 extremes there is a dividing line, above which the one arrangement will prove more economical and below which the other will work out best. It will probably be some time before the dividing line can be definitely determined, and furthermore, as the design, manufacturing practice and treatment of the sealed-off tubes are improved, the dividing line may shift to a higher level. However, in order to establish even a preliminary dividing line, it will be necessary to know something about the life to be expected from the sealed-off tubes in their present state of perfection. While I appreciate that it is rather early to raise this question, it would be of assistance if the authors could give an approximate idea of the life of the larger sealed-off tubes having stainless steel walls, as described in the papers.

It is very gratifying to note that in the papers presented and the discussions relating to them, the same nomenclature was used for the various tubes mentioned. After the igniter principle had been discovered in the Westinghouse Research Laboratories and practical tubes had been designed, it was of course necessary to find a fitting designation for these tubes. The name "ignitron," signifying an igniting device, was chosen, and in accordance with the established practice, trademark rights were secured. While this is a perfectly legitimate commercial practice, it became more and more evident as time went on that such practice was resulting in great confusion in the establishment and application of a proper nomenclature for electronic devices. Therefore, at the suggestion of the General Electric Company, the interested manufacturers relinquished their trademark rights, thus permitting anybody to refer, for instance, to the gas- or vapor-filled, hot-cathode, grid-controlled tube as the "thyratron" or to call the pool-type tube with an igniter an "ignitron."

In talking about the life of tubes, from an engineering point of view it is of course logical to express this in the number of operations or load cycles performed by the tube. On the other hand, the purchaser of welding equipment in choosing between the pumped and sealed-off arrangement, is accustomed to calculate his carrying, maintenance, and replacement charges on an annual basis for his particular application. It may, therefore, be necessary for manufacturers eventually to determine the life of tubes for a number of selected and typical types of service on an annual basis. While in the previous part of my discussion reference was made to a dividing line between different ratings, it is quite possible that over a certain range of ratings the sealed-off tube may prove more economical for relatively light and infrequent service, and pumped tubes of the same rating may be preferable for continuous and heavy service.

**David Packard:** The question of where to draw the dividing line between the application of sealed-off tubes and continuously pumped tanks is one which cannot be answered definitely at this early stage of ignitron use. As was brought out in the discussion, there is no question but that the smaller tubes have the field to themselves, and as we pointed out in the paper we have not yet encountered an application which required higher welding currents or greater duty cycle than can be handled by the largest sealed-off tubes now developed. If it appears undesirable to make sealed-off tubes for higher currents, there is, of course, the possibility of going to higher voltages in which case tubes of essentially the same size might be extended to higher power.

The life which will be obtained from tubes now in the field will also be an important consideration in determining how much further sealed-off tubes may be extended. In the development of the sealed-off tubes we have had every indication that they will give very long service. Our experience with tubes in the field has substantiated this belief although they have not been in use long enough to determine just what the life will actually be. There have been failures, of course, but in general the failures have been traceable to either misuse or to manufacturing defects which have showed up when the tubes were first put into service or shortly thereafter. To state a typical case; one user of the water-cooled ignitrons with 50 tubes in service under severe conditions has been operating about 7 months with no failures other than manufacturing defects which became apparent due to transportation or when the tubes were first installed. Some of the smaller tubes have been installed for approximately 2 years. Although the life of the sealed-off tubes has been entirely satisfactory thus far, the users of the tubes are protected against excessive cost in 2 ways. In the first place, the tubes are supplied on a policy which assures the user that the tube cost per month will not exceed a certain maximum amount when the tubes are used within the specified ratings. In the second place, losses which might result from a shut-down in a production line because of tube failure are kept at a minimum with sealed-off ignitrons because they can be replaced quickly and are ready for service instantly.

In closing, it might be of interest to know how many sealed-off tubes are in the field. The total number of tubes now in service is about 500. Of these about 150 are water-cooled metal ignitrons, some of which have been in service nearly a year. The remainder are the air-cooled tubes, and some of these have been in service about 2 years.

**J. H. Hutchings:** In regard to the temperature range in which ignitrons will operate, work done by the authors and their associates has netted results in agreement with those expressed by Mr. J. H. Cox. As Mr. Cox points out, ignitrons are able to operate at quite low temperatures (far below 50 degrees centigrade). Reasonably reliable operation has been obtained, in fact, with tubes so thoroughly chilled as to solidify the mercury. The absence (for all practical purposes) of any minimum operating temperature limit for ignitrons is attributed to the fact that evaporation of mercury from the cathode spot supplies the vapor pressure necessary for conduction of the arc current.

The limiting temperature range of 50 to 125 degrees centigrade mentioned in the paper is a range of maximum temperatures for the 6 tubes under consideration, the variation being due mainly to circuit con-

ons. Fifty degrees centigrade applies as a imum where high voltage and peak cur- are encountered and the period of current duction is of long duration. Some air- ed tubes will operate reliably at 125 rees centigrade when voltage and cur- are low and the conduction period short. Mr. Cox asks how large a sealed-off igni- is required to pass peak currents of 7,000 peres and what average current can be ducted at this peak. Size: 5½ inches liameter. Average current rating: 110 peres at 550 volts, 160 amperes at 220 ts.

n answer to Mr. Bela Gati's 3 questions, have never attempted to weld nickel aluminum. Stainless steel and alumi- n, however, have been welded satis- torily, in which case it was not necessary preheat the stainless steel. We are not iliar with any attempt to use ignitrons ail-welding processes.

The matter of tube life has been discussed others. However, Mr. Hellmund in- res into life of tubes "having stainless el walls" and so brings the thought that miting factor in tube life may be gas ac- nulation through the process of hydrogen fusion. Preliminary tests recently com- ted indicate that many years would be uired for vacuum to be impaired through s mechanism.

## Watt-Hour Meter Bearings

**scussion of a paper by I. F. Kinnard and H. Goss published in the January 1937 ue, pages 129–37, and presented for oral scussion at the instruments and measure- nts session of the winter convention, New rk, N. Y., January 28, 1937.**

**. B. Brooks:** See discussion, page 880.

anley Green (Duncan Electric Manu- cturing Co., Lafayette, Ind.): In this per a great deal of work has been sum- arized leading toward a better watt-hour- eter bearing. The demand for such a aring which will last up to 20 years with- it replacement under the recently imposed nditions of outdoor operation with attend- nt variations in humidity and temperature as been insistent. The bearing problem rtainly is one of the most acute of any in e watt-hour-meter art today. During the ast few years I have followed with interest nd some concern the work outlined in much the bibliography appended to this paper nd also want to commend the authors on heir industry and thoroughness with respect the material in the paper.

Personally, however, I feel that we shall ot attain the object of our search until il is totally eliminated in bearings. Alloys must be obtained which will run on a jewel ry without being harmed. With the de- elopment in the field of alloys progressing s it is, I feel that there is more possibility long this line than that a perfect oil will ever e developed. Even if a perfect oil were vailable, there are still operating incon- eniences and uncertainties attached to its se.

**A. R. Rutter** (Westinghouse Electric & Manufacturing Company, Newark, N. J.): The authors have prepared an excellent paper which will be used by meter engineers as a reference on the subject of meter bearings. While most of the data deals with the pivot type of bearing, the ball type is mentioned a number of times in the paper. Some additional information on the ball bearing might be of interest to anyone studying the problem.

The ball type of meter bearing has been manufactured in America for over 35 years, during which time a large percentage of the meters manufactured have been equipped with this type of bearing. The functioning of the ball bearing is described in Mr. Lenehan's article in the November 1929 *Electric Journal*.

The performance of the ball bearing has been recognized by the utility companies because of 3 important fundamentals. These are:

1. Sustained meter accuracy
2. Long life without lubrication trouble and wear
3. Low maintenance cost

The ball bearing satisfies these outstanding characteristics because the ball turns between 2 jewels and acts as an infinite number of pivots, with the result that the wear of the parts is distributed over the entire surface of the ball and over a large portion of the jewel area. Since a double jewel is used and the ball rolls in the jewels, the jewel surface used is much greater than in the pivot bearing. For all practical purposes the ball has a rolling action and does not require lubrication. The action of the ball bearing is such that dirt does not interfere seriously with the bearing.

The radius of the ball used in American meters is 0.031 of an inch. The data in the paper, particularly figures 3, 4, and 12, confirm the reason for the very good results in service that have been obtained with the ball type of bearing.

A large amount of study has been given to the question of material for the ball, but, to date, no commercial materials have been accepted and approved as being superior to carbon steel.

**A. J. Allen** (Consolidated Edison Company of New York, Inc., New York, N. Y.): The paper "Watt-Hour Meter Bearings," by I. F. Kinnard and J. H. Goss is very commendable as it indicates an endeavor toward an end that is very much desired by meter engineers.

For a long period of years watt-hour meter lower bearings have consisted of natural or synthetic sapphire jewels with glass-hard steel pivots or balls. The use of steel in meter bearings has proved undesirable because if the steel rusts rapid failure of the bearing follows: Rust or ferrous oxide is most abrasive and forms readily unless some protective coating is maintained: for this purpose oil has been used. The oil also provided lubrication which is necessary for steel pivots but not for steel balls; in fact its presence in a ball bearing is undesirable from a lubrication standpoint.

The need to find or develop a substitute for high-carbon steel that would not form an abrasive oxide has been foremost in the minds of meter engineers and at their urgent request several meter manufacturers have given the development serious attention. The increasing practice to install watt-hour meters on the outside of buildings further intensifies the need, and it injects into the problem temperature range requirements for bearing lubricants not necessary for meters installed indoors. There is a well substantiated belief that oil is not necessary or desirable in a meter bearing. The authors state "the provision of a good lubricant is not a simple matter," this has been true ever since the first oil was placed in a meter bearing. The sad experience which followed the use of fish, vegetable and mineral oils and various oil compounds has well established the hope to eliminate the need for oil in meter bearings. As to this, the authors hold out a ray of hope when they state "While all tests definitely show that proper lubrication increased the life of bearings, it has also been shown that cobalt-tungsten performs exceptionally well even without oil."

Table I—"Properties of Pivot Materials" indicates in the second column whether the materials were corrosive or not. Cobalt-tungsten is shown as not being corrosive yet it oxidizes when exposed to air. If the oxide is nonabrasive that fact is naturally the most important. Beryllium alloys, as indicated in the table, may have some possibilities. I have experimented with a beryllium-nickel-copper alloy that has proved superior to beryllium alloyed with nickel or copper alone in respect to non-abrasive oxide.

The matter of shock resistance of pivot materials is most important. It appears that reducing the contact area to an area as small as possible has been responsible for considerable damage to jewels. The advantage of a larger area is apparent from the tests made in comparison with steel and cobalt-tungsten pivots. It appears that a cobalt-tungsten pivot should have a contact area equal to that created by the shock of the short-circuit test on the assumption that a short-circuit shock would not cause deformation of a pivot having this area.

Accelerated life tests, while necessary, do not prove entirely the serviceability of a material, they do, however, indicate a trend that can be expected. A meter bearing that has a life of 20 years and does not require oil is not far away.

## Amplification Loci of Resistance-Capacitance Coupled Amplifiers

**Discussion and author's closure of a paper by Anatoli C. Seletzky published in the December 1936 issue, pages 1364–71, and presented for oral discussion at the electronics session of the winter convention, New York, N. Y., January 27, 1937.**

**Dale Pollack** (nonmember; RCA Manufacturing Company, Inc., Camden, N. J.): In the form in which the author writes the vector amplification of a resistance-coupled amplifier, (2) of his paper, it appears that the locus is not a single circle, but is the vector sum of 2 different circles. However, the equation is easily manipulated to show

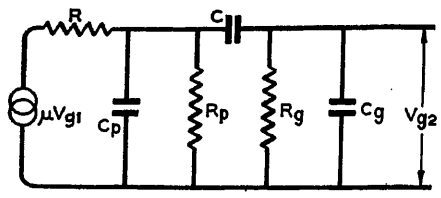

Figure 1

that it may, in fact, be represented by the locus of a single circle, and that the author's 2-circle representation is unnecessarily complicated. Consider the author's (2),

$$A = \frac{-jK\omega}{\omega^2 - jb\omega - c} \qquad (2)$$

dividing through by the numerator gives

$$A = \frac{1}{\frac{1}{k}\left[b + j\left(\omega - \frac{c}{\omega}\right)\right]}$$

Making the substitution

$$m = \omega - \frac{c}{\omega}$$

yields

$$A = \frac{1}{\frac{1}{k}(b + jm)} \qquad (2a)$$

where $m$ is now the parameter instead of $\omega$. (2a) is the locus of a single circle, which is evident by comparison with the author's (4), or from the following:

$$\frac{1}{A} = \frac{1}{k}(b + jm) = \frac{1}{|A|}e^{j\theta} \qquad (2b)$$

then

$$\frac{1}{|A|} = \frac{1}{k}\sqrt{b^2 + m^2} \qquad (2c)$$

and

$$\frac{m}{b} = \tan\theta \qquad (2d)$$

Substituting (2d) into (2c)

$$\frac{1}{|A|} = \frac{b}{k}\sqrt{1 + \tan^2\theta} = \frac{b}{k}\sec\theta$$

and, inverting,

$$|A| = \frac{k}{b}\cos\theta \qquad (2e)$$

(2e) is the polar equation of a circle passing through the origin with its center on the horizontal axis.

This same conclusion is reached by Luck in his paper "A Simplified General Method for Resistance-Capacity Coupled Amplifier Design," IRE *Proceedings*, volume 20, page 1401, 1932, when he states, on page 1403, "... there is a simple fixed relation between gain magnitude per stage and phase displacement per stage, the former being proportional to the cosine of the latter."

The author's ingenious algebraic solution is correct, except that the resulting locus is erroneously called a bicircular quartic instead of simply a circle. By starting with this single circle, instead of taking the sum of 2 circles as the author does, the computation is simplified. The writer has been using a graphical design method based upon the simple circular locus, and it may be of interest to present it. Using Luck's notation and analysis (see figure 1) which differ slightly from the author's,
let

$$\frac{1}{R_s} = \frac{1}{R} + \frac{1}{R_p} + \frac{1}{R_g}$$

$$\frac{1}{R_1} = \frac{1}{R} + \frac{1}{R_p}$$

$$w = \left(1 + \frac{C_g}{C}\right)\sqrt{\frac{R_g R_1 C}{R_s^2\left(C_p + C_g + \frac{C_p C_g}{C}\right)}}$$

then

$$A_0 = \frac{S_m/R_s}{1 + C_g/C}$$

is the maximum gain occurring at a frequency $f_0$

$$f_0 = \frac{1}{2\pi\sqrt{R_1/R_g(C_p C + C_g C + C_p C_g)}}$$

$S_m$ is the mutual conductance of the tube. Also let

$$y = \frac{f}{f_0} - \frac{f_0}{f}$$

be the frequency parameter. Then

$$|A| = A_0 \cos\left[\tan^{-1}\frac{y}{w}\right]$$

where

$$\phi = \tan^{-1}\frac{y}{w}$$

is the phase angle of the vector amplification. The only assumption made, aside from those from linearity and freedom from feed-back, is that

$$\frac{C_p - C_g}{C} << 1$$

This assumption does not affect the shape of the amplification locus but it does simplify some of the equations.

The general locus for any resistance-capacitance amplifier may now be sketched by drawing the circle on polar-co-ordinate paper, as in figure 2. By plotting the frequency determining parameter $y/w$ linearly along the vertical line, as shown, and projecting from the origin through the vertical line to the circle the frequency determining points on the circle are found. Knowing the constants of the amplifier, its gain and phase shift can be found very rapidly with the aid of the circle diagram. It is only necessary to calculate $w$ and $y$ for the desired frequencies from which the value of the vector gain may be read from the diagram. The converse process, for obtaining the circuit constants from a known frequency and phase characteristic, may also be carried out. The process is very similar to the one suggested by Luck, except that the circular locus on polar paper replaces Luck's generalized gain and phase curves. This reduces the labor involved and improves the accuracy of the method.

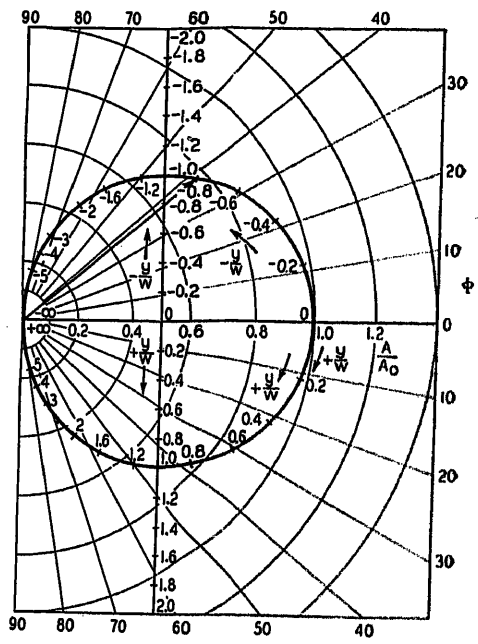

Figure 2

I. Rotkin (United Transformer Corporation, New York, N. Y.): This paper presents an interesting and convenient solution of the problem of calculating the complex response of a resistance-coupled amplifier from its circuit constants.

To the extent that grid-to-plate capacity in the vacuum tube is neglected the final result is, however, only an approximation. This is the case even in what Mr. Seletzky calls the exact equivalent circuit. The amount of error introduced by omitting consideration of the grid-to-plate capacity depends on the circuit constants, and it increases with frequency. There are 3 discrepancies introduced by this approximation.

When the grid-to-plate capacity is taken into account, the exact equivalent circuit of a resistance-capacitance stage of amplification becomes like the circuit of figure 3, where $C_{gp}$ is the grid-to-plate capacity of the amplifier tube, and $R_g'$ and $C_g'$ are, respectively, the effective input resistance and input capacity of the following tube. The other symbols are the same as those in the paper.

Except for very high frequencies $R_p\omega C_{gp}$ is much smaller than $\mu$. Hence the error introduced by neglecting the imaginary term, as the author has done, is negligible.

Very small, though not in general negligible, is the error introduced in the paper by neglecting the $C_{gp}$ term in the output capacity.

The third error is the most serious. It may be so large as to limit the author's method to the low audio frequencies for certain types of tubes. Mr. Seletzky assumes the input impedance of the following tube to be constant and to consist of the grid resistor and grid-to-cathode capacity of the following tube. Under actual condi-

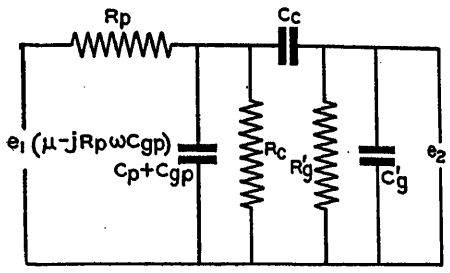

Figure 3

tions, however, the plate circuit of this tube is reflected back into its grid circuit through its grid-to-plate capacity. As a result the values of $R_g'$ and $C_g'$ vary with frequency.

I have calculated this effect for 2 types of tubes, the 6*F5* high-mu triode and the 6*J7* pentode, both of which are very commonly used in resistance-capacitance coupled amplifiers. A 6*F5*, with a one-megohm grid resistor, a 250,000-ohm plate-loading resistor, and total grid-to-cathode and plate-to-cathode capacities of 20 micromicrofarads including socket terminals and wiring, when used at 8,000 cycles, will have an effective input resistance of only 155,000 ohms and an effective input capacity of 162 micromicrofarads. In short, the effective input resistance is only 15.5 per cent of the one-megohm grid resistor, while the effective input capacity is 800 per cent of the grid-to-cathode capacity. At higher frequencies the error is even larger.

Even the 6*J7*, which has an extremely small grid-to-plate capacity (only 0.005 micromicrofarads), gives effective values of $R_g'$ and $C_g'$, respectively, of 0.99 megohm and 21.2 micromicrofarads. This represents an error of one per cent in resistance and 6 per cent in capacity. Here, too, the error would be greater for higher frequencies.

Mr. Seletzky's method is, nevertheless, a very valuable one. If care is used in its application, it should yield results of sufficient accuracy for most purposes with a minimum of effort. It will be especially useful in problems which involve phase shift.

**A. C. Seletzky:** Mr. Pollack in his discussion brings out several valuable comments on the design of resistance-capacitance coupled amplifiers. It should be noted, however, that throughout the entire paper, the angular velocity $\omega_1$ is treated as the scalar variable. *With respect to the scalar variable* $\omega$ the general equation for amplification as given by (2) remains a bicircular quartic, because it consists of the sum of 2 circles, which sum does not reduce to the canonical expression of the circle,

$$\frac{a + b\omega}{c + d\omega}$$

inasmuch as it involves higher powers of $\omega$, as may be seen from equation (2), namely

$$A = \frac{-jk\omega}{\omega^2 - jb\omega - c} \qquad (2)$$

In the author's opinion, the opening line of the paragraph in the paper following equation 6, "The variable scalar in the present case is the angular velocity . . . ." should make it reasonably clear that the variable scalar treated in the problem is the angular velocity.

Mr. Pollack throws the amplification equation into the form of a circle by changing the scalar variable from $\omega$ to

$$\omega - c/\omega$$

which is $(\omega^2 - c)/\omega$

and by this artifice considers the amplification to be circular in form. It is, but the scalar variable in the transformed equation is not the angular velocity $\omega$, but a new function of angular velocity, involving higher powers of $\omega$. Thus instead of using a linear scale line in units of $\omega$, Mr. Pollack is using a linear scale line in units of

$$(\omega^2 - c)/\omega$$

It should be evident, therefore, that Mr. Pollack, instead of contradicting any statements made in the paper, is merely introducing a new scalar variable of higher order. Thus the general equation of amplification may be considered to be either (a) a bicircular quartic, i.e., the sum of 2 circles, each component circle having a linear scale of $\omega$ or (b) a single circle with a linear scale in units of

$$(\omega^2 - c)/\omega$$

Mr. Pollack's modification of Mr. Luck's method applied to the single circle is very interesting and helpful. The author is gratified in observing the increasing use of the circle diagram to eliminate time-consuming computation. It is difficult to judge as to which particular method involves the minimum of time and effort. Generally speaking, however, it has been the experience of the author, that what is eliminated from the drawing board is merely transferred to the slide rule and tables of functions, and that best results are obtained from a judicious balance of the 2.

Mr. Rotkin's comments on the variation from linearity of the general circuit are greatly appreciated. This paper was written on the basis that the "exact" equivalent circuit as shown in figure 1, was sufficiently exact to be valid for the great majority of resistance-capacitance coupled amplifiers, and Mr. Rotkin concurs with this viewpoint in the closing paragraph of his discussion. Designers encountering the somewhat special conditions described by Mr. Rotkin should be guided by his observations. The author hopes that Mr. Rotkin will formulate the proper expressions of circuit coefficients, expressed as functions of the frequency, and incorporate them into a general method of determination of amplification loci.

## Development of a Modern Watt-Hour Meter

**Discussion and authors' closure of a paper by I. F. Kinnard and H. E. Trekell published in the January 1937 issue, pages 172–9, and presented for oral discussion at the instruments and measurements session of the winter convention, New York, N. Y., January 28, 1937.**

**Stanley Green** (Duncan Electric Manufacturing Co., Lafayette, Ind.): Performance of the new meter described in this paper is better than has been considered acceptable previously and the fact that it is now proposed indicates that there may be a demand for it by the utility users of meters. In general, such improved characteristics in a meter will cost more to manufacture—but not much more. The idea has been advanced by some utilities that by concentrating production in one size, this small cost increment can be overcome. Under these conditions, the low-capacity type would become rare and production would be concentrated in only 2 sizes, domestic and commercial, with the former greatly predominating. This view appears constructive and even if the future domestic meter were increased in cost slightly, the increased range could be worth it to the utilities, not only from simplification of operations but because it will give ample margin for the vitally important load building activities of the future.

The authors have accurately expressed the elementary design limitations in equations 1, 2, and 3 and the discussion relating thereto. On these, most designers should be in agreement. Unfortunately, space available has apparently not permitted a more detailed exposition of subsidiary design factors and their interrelationships, although some of these are mentioned by the authors. Relative gap lengths and proportions, pole configurations and proximity, relative flux density in interrelated parts and characteristic curves of the magnetic material entering into parts of the structure all so complicate the problem that many solutions instead of only one unique one are possible. This is where the skill and judgment of the designer are utilized and if it were not for this, there could be only one good meter design. Instead, there have always been many designs and generally each is a little better than its predecessors. A paper such as the present one is useful in a high degree as it supplies still another step in that stimulating chain of advances which is ever-lengthening because of changing requirements in the electrical industry.

The short mean length of potential-coil turn mentioned by the authors is a useful expedient. The recognition that load compensation is necessary to give linear performance at the heavy-load end of the registration curve is constructive. Better methods of controlling this form of compensation have been developing in the last few years and precision load compensation in any reasonable amount can now be obtained by several forms of compensators all working on the same "saturable bridge" principle. It has been recognized by designers for some time that the load compensator modifies the shape of the registration curve at light loads and I think we can look for continued beneficial effects from the compensator on this end of the curve in future designs.

In modifying the design of a given meter to meet the new long-range performance more than one path can be taken. It would be interesting to describe more than one avenue, but for brevity and clearness, I mention only one simple scheme:

In a paper in the October 1935, issue of ELECTRICAL ENGINEERING, I described a new watt-hour meter which has been manufactured in 5-, 15-, and 50-ampere nominal ratings. The 3 ratings in this meter could be modified easily to duplicate the new performance now proposed. In this modification the 15-ampere rating would become

the "domestic" meter. Its torque would be raised from 46 to 62.8 by increasing the potential-element ampere-turns. This would give the same torque at 12.5 amperes as the new watt-hour meter and would, of course, allow the same light-load performance as such performance is basically a function of torque available. The increased potential excitation would be accomplished at the expense of raising the potential watts loss from 0.9 watt to about 1.25 or the same as the meter of the paper under discussion. The increased ratio of potential to current flux makes it easy to compensate the modified meter so that the performance is straight line to 400 per cent load or 60 amperes since before modification the droop at this point was only 1.5 per cent. Increasing current-coil copper and providing a stronger damping magnet are details easily accomplished.

Since a stronger damping magnet would be used, the watt-hour constant would not be changed and for the 15-ampere 2-wire "domestic" meter would be one, which is also a desirable constant for use with all types of rotating standards now in use.

**H. B. Brooks** (National Bureau of Standards, Washington, D. C.): The papers by Kinnard, Goss, and Trekell are gratifying examples of the modern trend away from the old policy of secrecy. If the design of electrical measuring devices is to progress as it should, designers must be allowed a reasonable degree of freedom to publish the principles which guide them, the results of their experimental studies, and the particular structures which form the end result of their work. It is to be hoped that those who control the policies to which the designing engineer must conform will discern the advantages which will accrue to all concerned as a result of such co-operation in the advancement of the art.

Referring to the analysis chart, table I of Kinnard and Trekell's paper, I suggest that it would be interesting to have for comparison the corresponding figures for the meters now being produced by the other American manufacturers. Most of the data for one of these other meters was given in Mr. Green's paper in volume 54 of the TRANSACTIONS.

The suggestion of Kinnard and Trekell that modern watt-hour meters should be rated in terms of the nominal and the maximum current rating deserves consideration with a view to general adoption. The retention of the present nominal rating (i.e., 5 amperes for a meter with a maximum continuous rating of 15 or 20 amperes) is a necessity for calibration and comparison purposes for the present and for the immediate future. The straight-line accuracy characteristics over a large portion of the load curve raises an interesting question in regard to what shall be eventually taken as the nominal test point. If individual treatment of meters were practicable, the average load of the installation would be the logical one at which tests and adjustments would be made. Since this is not feasible, and since tests of modern meters at the maximum current would require that the testers should carry larger and heavier equipment, it seems logical to adopt the present values of calibrating current for the new meters.

Table II of Kinnard and Trekell's paper does not include a meter of 2.5 amperes nominal, 7.5 amperes maximum rating. This meter would differ from the authors' "low-capacity" meter only in having 20 turns on each current pole, and would be preferable to the nominal 5-ampere meter for use in connection with current transformers. I understand that meters of 2.5 amperes nominal rating are being used for this purpose. It seems advisable to recognize this formally as a fourth standard rating.

**F. C. Holtz** (Sangamo Electric Company, Springfield, Ill.): The authors are to be complimented on their very clear and concise presentation of a subject which, while fairly clear to the designer of watt-hour meters, may not have been fully appreciated by the user.

By a careful and systematic analysis it has been possible to greatly extend the useful range of a meter by the introduction of various types of compensating means. In this way the manufacturer has kept pace with the increased demand of the user until now it seems possible that we may be able to further limit the number of types or capacities required for a more diversified application.

From a manufacturing standpoint, I believe we agree with the choice of ampere-turns which will simplify our problems. In doing so, however, it should be on a basis which fully recognizes the requirements of the user as to convenience of testing and the use of testing equipment.

I doubt if the time is right for us to forget meter ratings in volts and amperes and merely refer to them as "domestic," "commercial" or other meters.

There is also some question as to the advisability of changing ampere rating from the series toward which the industry has been striving. This may be of no great importance or it may readily be modified by advancements which as in this case would definitely tend toward the elimination of one or more of the present types. The advantages in this case would lie in simplification of stocks which is a great benefit to producer and user alike.

In the present instance we may find ourselves in a dilemma. If the author's meter were to be rated at 15 amperes and given a watt-hour constant of 1.5, this would not agree as to constant with existing meters of similar manufacture. If it is given a rating of $12^1/_2$ amperes with the same constant, then the capacity is out of line with the present accepted standards. Of these 2 the choice should probably rest with the change in capacity in order that the constants may remain in line with present practice.

**E. D. Kane** (The Detroit Edison Company, Detroit, Mich): This paper is a worthy contribution to the art of metering, in that it presents a comprehensive discussion of the elements affecting watt-hour meter design. The watt-hour meter holds a unique position as an instrument for measuring a quantity from which revenue is derived because it is subjected to so many variable factors as a result of its operating location in the field. Also, the accuracy requirements must be more stringent than other forms of commercial measuring apparatus, with a minimum amount of attention.

Perhaps the nature of the problem and its importance has acted as an incentive for improvement in the art, so that now the most scientific methods of design and analysis are employed together with pure scientific research to determine the underlying theories of operation.

The contents of this paper graphically illustrates this fact and the treatment of analysis deserves special mention. Table I may well serve as a criterion for meter acceptance with perhaps some other constants added. Such a table allows uniform presentation of the data in a concise practical style. The determination of meter constants to establish performance characteristics might reduce the labor in making acceptance tests and reduce operating parameters to a more equal basis. Information concerning additional factors may prove desirable. Suggestions from designers as to the best parameter which could be used as a relative index of over-all performance would be interesting. No doubt such a value will be found in the future as the investigations are carried further into the problem to which this investigation has contributed so much.

It is to be hoped that the bibliography of meter research will continue to grow and the literature will be as productive of progress as that of other scientific and engineering fields.

The proposed rating discussed for new watt-hour meters appears to offer considerable advantage as is pointed out in the paper, namely;

(*a*). Reduced stock of meters and parts
(*b*). Meets field requirements to better advantage
(*c*). Offers improved standardization in test methods

The question of the test constant value of the "long range" domestic, namely; 1.5, may cause confusion but that condition can be easily overcome by proper run selection.

**I. F. Kinnard and H. E. Trekell:** Doctor Brooks has suggested that the 3 self-contained ratings be augmented by a meter of 2.5 ampere nominal current rating for use with instrument transformers. With a 5-ampere-secondary current transformer, the use of a 2.5-ampere meter provides greater insurance of accuracy of registration, especially at light loads, since the meter works at double torque. From a thermal standpoint, current transformers will not operate continuously at loads above 7.5 amperes in the secondary winding. A 2.5-ampere meter is the best choice for the actual operating range of the transformer. The burden of the current circuit of a watt-hour meter is sufficiently low that the increased burden of the 2.5-ampere meter is usually not objectionable.

Mr. Green has proposed an interesting modification of a present meter design. However, it has been found from experience that a small inherent error can be compensated much easier than a large error. Furthermore, due to variations in materials and manufacturing tolerances, attempts to compensate large, inherent errors usually result in considerable variations in the performance of the device.

As pointed out in the paper, any design

can be readily analyzed and its merit judged by a tabulation of data as shown in table I, page 178. It would be interesting, as suggested by Doctor Brooks, to give complete data of this nature for suggested alternate designs.

While it is true, as Mr. Holtz points out, that when rated in accordance with present established constants the "domestic" meter described is in reality a 12.5-ampere size, yet it might be called a 15-ampere meter. In this event, however, the relation between watt-hour constant and ampere rating is different from any established standard. If this is done in order to meet present rating classifications, the inherent, nominal full load of 12.5 amperes should also appear on the nameplate to prevent confusion.

Mr. Kane's discussion is very much to the point, and as he points out, meter design and operating constants can be rationalized and guided by scientific analysis.

# Impulse-Generator Voltage Charts for Selecting Circuit Constants

**Discussion and author's closure of a paper by J. L. Thomason published in the January 1937 issue, pages 183–9, and presented for oral discussion at the instruments and measurements session of the winter convention, New York, N. Y., January 28, 1937.**

**C. F. Harding** (Purdue University, Lafayette, Ind.): This paper provides a much-needed rapid method of adequately determining and standardizing surge test results as they are undertaken in the various laboratories wherein some difficulties have been experienced in the past in securing comparable data. Demands on the part of prospective customers for surge tests to be made in independent laboratories are becoming more numerous and therefore any developments, such as are outlined in this paper, looking toward the co-ordination of results obtained from surge generators of varying capacitance and discharge constants represent a distinct contribution to the pioneer work of our profession.

In the accompanying discussion, which I shall present with my endorsement, from Mr. C. S. Sprague, who is in charge of the surge testing of our high-voltage laboratory at Purdue University, a further simplification of the standard calculations of the paper which are applicable to the frequently used $1^1/_2$x40 wave will be evident.

**J. H. Hagenguth** (General Electric Company, Pittsfield, Mass.): Mr. Thomason has presented a paper which should prove very useful in laboratories where impulse work is being done. Especially in those laboratories, where cathode-ray oscillographs are not available the charts and curves presented should save considerable time as compared to the more laborious methods of actual calculations to obtain accurate information of the wave shape used for a particular impulse circuit.

Where accuracy required is within ±5 per cent of actual values some rather simple

**Table I**

| Constant | By Test | By Chart | By Equations |
|---|---|---|---|
| $K_1$ | 0.30 | 0.30 | 0.30 |
| $K_2$ | 0.057 | 0.057 | 0.057 |
| Front (microseconds) | 1.9 | 1.9 | 1.88 |
| Duration (microseconds) | 40 | 39 | 37.7 |
| Crest (per cent) | 72 | 71 | 73.2 |
| $K_1$ | 0.128 | 0.128 | 0.128 |
| $K_2$ | 0.073 | 0.073 | 0.073 |
| Front (microseconds) | 1.4 | 1.5 | 1.35 |
| Duration (microseconds) | 44 | 44 | 43.3 |
| Crest (per cent) | 81 | 80 | 82.5 |

equations are available as follows using the same notations as the paper:

$$\text{Wave front: } 3R_1C = 3R_1C_2\frac{1}{1 + C_2/C_1} \quad (1)$$

$$\text{Wave duration: } 0.697(R_1 + R_2) \times (C_1 + C_2) = 0.697R_2C_1(1 + R_1/R_2) \times (1 + C_2/C_1) \quad (2)$$

$$E/E_0 = \frac{1}{1 + R_1/R_2}\,\frac{1}{1 + C_2/C_1} \quad (3)$$

These equations yield remarkably good results if $R_1$ is equal to the critical resistance as explained in the paper.

Applying these equations to the 2 examples presented the values of table I are obtained.

It can be seen that the equations give numerical values which check closely the test results and the values obtained by means of the charts. Often it is desired to have a higher crest than that obtained with the circuit of figure 2 but maintaining the same wave duration. In such a case it is an advantage to insert another resistance $R_3$ from the junction of $C_1$ and $R_1$ to ground. In that case the equations 1 and 3 remain unchanged, while the equation 2 changes to

$$\text{Wave tail: } 0.697R(C_1 + C_2)$$

where

$$R = \frac{(R_1 + R_2)R_3}{R_1 + R_2 + R_3} \quad (4)$$

For transformer testing more complicated charts would have to be used to take care of the inductance to ground of the transformer. It is also relatively difficult to determine the impulse capacitance of the transformer winding, which with any additional load capacitance determines the wave front. Although these voltages, wave fronts, etc., can be calculated, it would be a rather time consuming task to do so, when a large number of transformers have to be tested. Fortunately the electrical transient analyzer is available, with which the circuit constants required for any particular transformer can be determined rapidly and accurately.

**C. S. Sprague** (Purdue University, Lafayette, Ind.): Although the use of charts and curves for quickly determining the impulse generator constants for producing a specified wave is not new, the author, by the use of *ratios* of circuit constants, and of wave front and duration times, presents a method whereby the circuit constants may be determined for producing practically *any* wave shape, or conversely the wave shape produced by a given set of constants may be determined.

For a wave, such as the $1^1/_2$x40, which is in sufficiently general use to warrant the procedure, the use of the curves can be considerably simplified by plotting, in figures 4*b* and 4*B*, $K_1$ *vs.* $K_2$ for the constant value of $t_1/t_2$ representing the $1^1/_2$x40 wave. Likewise in figures 4*a* and 4*A*, the value of $C_1R_2$ may be plotted against $K_2$ for the particular wave front time $t_1 = 1^1/_2$ microseconds. This procedure would reduce figures 4*a*, 4*A*, 4*b*, and 4*B* to a single curve each, and avoid interpolation between a family of logarithmically spaced curves on a logarithmic scale. In the more general nature of the data as presented by the author, these simplifications could not be obtained; however, it might be well to indicate the advantages to a particular laboratory of limiting the variables to those representing conditions in that laboratory.

The author indicates the growing need for specification not only of the time constants of the impulse but also of the circuit constants of the generator producing the impulse.

The above seem to be the principal contributions of this paper.

As is well known a particular wave shape can be obtained from a variety of circuit constants. However, the actual test results obtained, particularly in flashover tests of equipment having considerable time lag, will depend upon the series impedance or the rate at which energy can be supplied to the test piece. This is particularly true at short flashover times or flashover on the rising front and is a further argument for specifying, at least the permissible range, of the generator constants.

On page 185 under circuit II, the author calculates a necessary inductance of 58 microhenrys and states that if this value cannot be obtained, or if the actual $L_1$ = 40 microhenrys, that the values of $R_1$ and $R_2$ can be adjusted on a straight line basis. Will not this change the duration of the wave? Why not add 18 microhenrys to obtain the calculated value of 58 microhenrys? Theoretically the limitation on $L_1$ is the minimum value of the inherent self inductance of the generator circuit.

In chart II the author states (page 5) that

$$L_1 = \frac{R_1^2C}{4}$$

or in other words

$$R_1^2 = \frac{4L}{C}$$

so that oscillations of the generator inductance and the effective series capacitance cannot occur. Three values of $W$ are denoted by asterisks as indicating real roots, presumably meaning a unidirectional impulse, which the author designates (page 6) as a "smooth wave." Are all other waves oscillatory, and if so, cannot a damped oscillatory wave be smooth? From the conditions

$$L_1 = \frac{R_1^2 C}{4}$$

superimposed oscillations could not occur. Perhaps the author's definition of a "smooth wave" might clear up this point.

On page 188 a value of 1.4 microseconds is given for the wave front as determined from the oscillogram of figure 7. With the slow sweep used in figure 7 the accuracy of determination of the wave front time seems somewhat questionable.

**P. L. Bellaschi** (Westinghouse Electric & Manufacturing Company, Sharon, Pa.): The impulse generator came into engineering prominence about 5 years ago. At that time the basic circuits and generator characteristics when testing electrical apparatus were analyzed and carefully studied.[1] Since then the literature on the subject has grown both here and abroad.[2] Some of these contributions relate to the experience acquired, others pertain to further refinements in the analysis or method of calculation.

The present paper is of a character that should be helpful in reducing labor where charts similar to those in figure 4 may not be available. The calculation of these or similar charts is based on circuit analysis, on methods where terms are expressed as ratios between similar circuit constants and on plotting the results conveniently and effectively in terms of the time constants of the circuit—all of these having been developed and applied some 5 years ago. The usefulness of such methods is well demonstrated in the present paper.

Reference is made by Mr. Thomason that the circuit diagram of figure 2 has been recommended as basic by the International Electrotechnical Commission. This statement should not be misconstrued perhaps to the effect that this circuit represents all circuit conditions encountered in present-day testing. For example, this is not necessarily the basic circuit when testing transformers for such apparatus may introduce other elements into the circuit, such as low inductance to ground, substantial energy drain from the generator into the transformer circuit proper and also into the circuit from which the transformer may be excited at normal-frequency voltage. A consideration of the work by the IEC covered in the report in question will bring to light that this circuit representation is really intended, when such loads as insulators, gaps, bushings, and similar equipment are connected to the generator.

A good number of impulse generators have come into existence both in this country and in Europe since 1932. These generators have for the greater part been built to generate a smooth impulse voltage of a 1½x40-microsecond duration or thereabout. When we compare for example the half-a-dozen impulse generators built hereto for 3 million volts, particularly those for testing equipment of relatively large capacitance, we find that the generator capacitance, the self-inductance, the stray capacitance, the damping resistance, and the load resistance for each generator are respectively of the same order of magnitude as the corresponding constants of the other generators. Thus in practice for a given voltage rating of the generator the part of the circuit charts, such as in figure 4 of the paper, which would be used is rather localized. Considering the various voltage ratings of generators even then only certain "practical" regions in the charts would really be used.

2. In addition to the works by P. L. Bellaschi, J. L. Thomason, and C. S. Sprague presented to the AIEE, there have been contributions elsewhere in recent years by Roys (Purdue University), Lewis (Bureau of Standards), Angelini (Italy), Goodlet (England), Elsner (Germany), and others both in this country and abroad.

**J. L. Thomason:** In their discussions of this paper Dr. C. F. Harding, and Messrs. C. S. Sprague, J. H. Hagenguth, and P. L. Bellaschi have extended the art of impulse-voltage testing by adding new and qualifying information.

Mr. Sprague has asked for the author's definition of a smooth wave. It can be stated thus: "In impulse testing the voltage wave applied to the test piece will be considered smooth and when its mathematical expression for a circuit of five constants (figure 2 in paper) takes the form

$$e = Ae^{-at} + Be^{-bt} + Ce^{-ct}$$

and conversely the voltage wave will be considered oscillatory when its mathematical expression takes the form

$$e = Me^{-mt} + Ne^{-nt}(\cos \omega t + Q \sin \omega t),$$

where all the symbols are constants except $e$ and $t$. While the smooth-wave form of the equation could express a wave that would cross the zero-voltage axis, this does not usually occur in a circuit of 5 constants (figure 2 in paper) for ordinary values of the circuit constants." This definition of a smooth wave was used in the paper. For practical purposes the wave could be considered smooth even though the part

$$Ne^{-nt}(\cos \omega t + Q \sin \omega t)$$

in the oscillatory form amounts to one per cent or more of the voltage at its crest. This idea also was used in the paper to allow for the rigorous use of the relation

$$L_1 = R_1^2 C/4$$

because even when using this relation the oscillatory form of impulse-voltage test wave does generally result as indicated in the paper. This also falls in line with Mr. Sprague's thought of increasing the inductance to the value of $L_1$ demanded by this relation. In general this is a good idea but normally increasing $L_1$ increases the wave front, and depending upon the wave shape desired, it might be better to juggle the values of $R_1$ and $R_2$—this gives a minimum wave front with a maximum economical crest for a practically smooth wave.

There is one idea in this paper that I believe should be emphasized again and that is this: Considering the mathematical expression of the voltage wave applied to the test piece, as long as the ratios $K_1$ and $K_2$ are constant and

$$L_1 = R_1^2 C/4$$

all test waves will be identical throughout.

Mr. Hagenguth has presented some very useful approximate equations and has shown their accuracy with examples. Such equations should be very helpful in reducing the time required to select circuit constants. Mr. Hagenguth has also referred to the usefulness of the electrical transient analyzer[1] which is a valuable adjunct to any laboratory doing impulse work.

Mr. Bellaschi has brought out a point which may have been overlooked in the paper by some readers—that is, that figure 2 in the paper is for only a capacitance load. In his discussion Mr. Bellaschi apparently overlooked the fact that the original investigators, Steinmetz and Peek, had analyzed the behavior of the impulse generator considerably earlier than 5 years ago.

Dr. Harding has indicated the need of co-ordinating the data obtained in various impulse-voltage laboratories and to this I will add that there is the ever present need of reducing the time and cost of making tests.

## Short-Time Spark-Over of Gaps

**Discussion and author's closure of a paper by J. H. Hagenguth published in the January 1937 issue, pages 67–76, and presented for oral discussion at the instruments and measurements session of the winter convention, New York, N. Y., January 28, 1937.**

**C. S. Sprague** (Purdue University, Lafayette, Ind.): The shielded resistance divider described by the author seems to be the first real attempt to make this type of divider suitable for fast fronts and very short times. With regard to this divider the writer wishes to ask what length of resistance wire is used to obtain the 7,000 ohms employed in the divider. The voltage applied to the entering end of the cable arises, in part, from the current flowing through the resistor, and in part from the induced charges due to the shielding and ground capacitances. With very steep waves the latter must form a reasonable percentage of the total, especially on the rising wave front; if not, then there would be no need for shielding. That portion of the voltage at the entering end of the cable, arising from the capacitance effects, is presumably applied simultaneously with the rising voltage at the top end of the divider, while that portion resulting from the surge current flowing

through the resistance is not applied until the wave has traveled over the length of resistance wire between the top end of the divider and the cable connection. There is also the fact that the induced charges are continually leaking to ground during the short interval before the current wave has traversed the entire length of the resistance wire. The argument becomes complicated and will be carried no farther, however, it seems remarkable that the resistance dividers when used for such fast fronts are as satisfactory as they are stated to be.

With reference to the author's figures 4*a* and *b* the writer agrees with the author as to the elimination of $L_g$ in so far as possible. However, where some $L_g$ must be tolerated, it appears that the impulse generator and oscillograph grounds could be made to the circuit at the lower end of $R_d$, providing the voltage drop across $L_g$ was not too high so as to damage charging equipment, etc.

For some time the writer has contended that short-time flashover and breakdown values are considerably affected by the amount of series resistance and inductance in the generator circuit. It is gratifying to have this confirmed in the author's figure 5 and thus lend further support to the suggestion that surge generator constants, or at least their range, should be specified as well as the wave shape.

**K. B. McEachron** (General Electric Company, Pittsfield, Mass.): There appears to be a real need for a high-voltage divider, to be used in laboratories where impulse testing is carried on, which will successfully reproduce steep-fronted waves and still be compact in design and uninfluenced by surrounding fields. Such a divider Mr. Hagenguth has described, and should prove to be very useful indeed. Additional tests are of course necessary in connection with this divider, so that all of its uses are completely understood, but the data presented by Mr. Hagenguth appeared to indicate quite clearly that it gives results which may be relied upon. It is, of course, unfortunate that no standards exist in this field of measurement when times shorter than a microsecond or so to breakdown are considered.

I hope that this paper will not be interpreted in any sense as being intended to propose steeper and still steeper waves for impulse testing of apparatus. From my experience relating to surges due to natural lightning, either at the point of inception or elsewhere, there seems as yet to be no indication that waves having an over-all steepness much in excess of 1,000 kv per microsecond need be considered.

It is true that much of our information along this line is deductive and based to a considerable degree upon the effects observed of direct strokes on apparatus and structures of one sort or another. These observations are, of course, coupled with results of tests made in the laboratory where wave shapes are known, and there does not seem at this time much justification for further increase in the rate of rise of test impulse waves.

From the point of view, however, of being certain of the accuracy of the results for the steepness of waves expected in practice, it is quite desirable that our measuring equipment be so designed and operated that measurements can be taken at rates of rise considerably in excess of those expected. These additional data points will lend support to the accuracy of those points within the expected lightning range, and help to appreciably increase our confidence in the results obtained. It would seem, therefore, in the absence of data to indicate these ultrasteep waves, that we would do well to confine our co-ordination studies to waves not exceeding 1,000 kv per microsecond at least, until such time as field data indicate that still steeper waves are to be encountered in practice.

There is one situation in which waves may appear whose steepness compares with that found in the laboratory, and this is the case of flashover between one conductor and another where the time to breakdown would be of the same order as observed in the laboratory for the same distances.

In Mr. Hagenguth's paper, mention is made of the difficulties involved in describing the front of the wave in those cases where sufficient prespark-over current is drawn to cause the applied voltage wave to depart from its normal expected rise. It seems to me that the best answer to this situation, from the point of view of the testing laboratory, is to so proportion impulse-generator capacitances, and load capacitances and series resistance that this turning over characteristic will be so small as to be negligible. If this result can be obtained, then the kilovolts at breakdown divided by the time to breakdown would give a correct rate of voltage rise, assuming of course that the zero of time was determined by the intersection of the line drawn through the 10 and 90 per cent point on the front of the wave and its intersection with the time axis. To get such a rate of rise with a sharp breakdown when testing on the front of the wave may require some modification in some of the impulse generators now in use, but it certainly would prevent considerable confusion with respect to the meaning of the data obtained.

**H. L. Rorden and P. M. Ross** (Ohio Brass Company, Barberton, Ohio): In surge-voltage testing, the accuracy of recorded waves and voltage calibration has been the object of much discussion and question. The voltage divider is a necessary part of surge testing and its accuracy might well be questioned, since with high voltages an accurate means of calibration or check is lacking. When the new laboratory of the Ohio Brass Company was put into operation in 1934, one of the major items of consideration in the design of the surge generator was to obtain an electrostatic field which, inherent to the design, would be substantially uniform throughout the height of the generator, illustrated in figure 1. The divider is placed in the field adjacent to the generator structure, which is built in the form of a helix. In each revolution of the helix a capacitor is close to the divider and maintains a voltage proportional to its physical height above ground. This results in a uniform voltage distribution throughout the length of the divider and is a desired condition for accurate reproduction at the oscillograph.

At the several available junctions of the divider the potential differs by less than 3 per cent from a uniform distribution. For further check, volt-time characteristics of

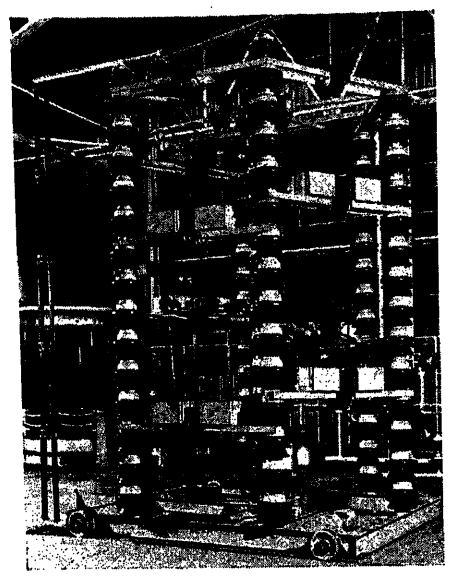

**Figure 1. The Ohio Brass Company surge generator**

spheres were obtained, the results of which are in close agreement in the $^1/_4$-microsecond region with Mr. Hagenguth's figure 15.

In many of its features this generator fits the description suggested by Mr. McEachron in his discussion as being desirable. Due to the helical design it is compact; it has a substantially uniform voltage distribution; the entire generator including the divider is portable. The divider and other circuit resistors are enclosed in porcelain, also the supporting insulation is porcelain. The generator may be used outdoors without damage in the event of inclement weather.

In his figure 5 showing the change of wave shape with a change in circuit constants, we believe Mr. Hagenguth has touched upon an item which should receive serious consideration in setting up standards of surge testing. Other investigators directly familiar with surge testing have undoubtedly observed this phenomenon. It seems very evident that considerable energy is required to charge corona and ionization streamers prior to complete breakdown. Insertion of damping resistors in surge generators is very necessary, since otherwise it seems impossible to obtain uniform waves. The damping resistance so limits the available energy at the test that prior to breakdown the voltage across a gap falls appreciably from that of its normal wave shape. This becomes increasingly greater with overvoltages and appears to be present in all cases where flashover is dependent upon the completion of corona streamers.

An outstanding example of the inability of surge generators to maintain their wave shape before spark-over is illustrated in figure 2. This illustration, with additions, is reproduced from the March 1936 *Journal* of the British IEE. The limitations mentioned are very evident. It may be observed that the final flashover of the overvoltages occurs below the wave of the minimum flashover. These authors have proposed to set up British standards of testing on the basis of their results, which would seem to be of questionable accuracy.

We have also noticed this phenomenon to be present, although to somewhat lesser degree, if the damping resistance is removed. Also it is greater with generators of low energy, such as were used by early investigators when the so-called 1x5 wave was proposed as a standard for testing. It is now generally recognized that with the

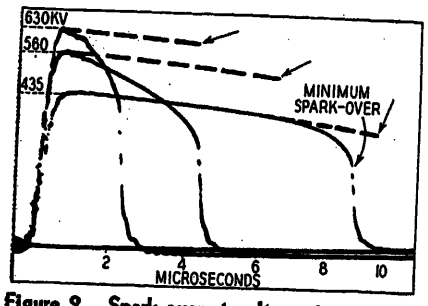

**Figure 2. Spark-over at voltages in excess of minimum impulse spark-over**

generators of higher energy in use, the 1x5 wave so limits the available energy and voltage for test, due to the necessary high damping resistance, that it is undesirable for test purposes. This wave was readily obtained in generators of low energy but imposes a serious handicap on present methods.

Surge testing is complicated by several such limitations and we wish to stress the importance of this point which Mr. Hagenguth has touched upon.

**P. L. Bellaschi** (Westinghouse Electric & Manufacturing Company, Sharon, Pa.): The paper by J. H. Hagenguth is a further contribution on the short-time spark-over of gaps and to the technique in obtaining such data. In attempting to compare his results to data published in the past few years, the first question which arises is one on method of scaling oscillograms and plotting data.

It has been and is the common practice in testing with impulse voltages chopped on the front to specify the steepness of the front in kilovolts per microsecond and the crest voltage. In table I the results from typical oscillograms are given. In the first column the steepness of the front is determined according to established definition, that is drawing the line of the slope through the 2 points on the oscillograms at 10 per cent and 90 per cent the crest value. Circuit conditions present in practical testing often result in some superimposed oscillations on and distortion of the main component of the rising front. Some judgment is necessary in applying the 10 per cent–90 per cent definition and this is best done scaling the steepness of the front along the major component. The second column of table I gives the values determined from the application of this practical method. It shows that the results in general are in substantial agreement with those applying the 10 per cent–90 per cent rule. In the third column the time-to-breakdown has been employed to calculate the rate of voltage rise (average). It is apparent that the results from this third method are not in general comparable to those from the first 2 methods.

The values in column 3 are 10 to 20 per cent lower than those in column 2. Considering the different methods, it will be seen that the data for the rod gaps in figure 9 (by the author) are in better agreement with the previously published data (ELECTRICAL ENGINEERING, June 1934, page 870 and ELECTRICAL ENGINEERING, September 1936, page 985) than it may appear from a superficial comparison. The data in the paper and those reported by the writer for bushings, insulators, and similar equipment

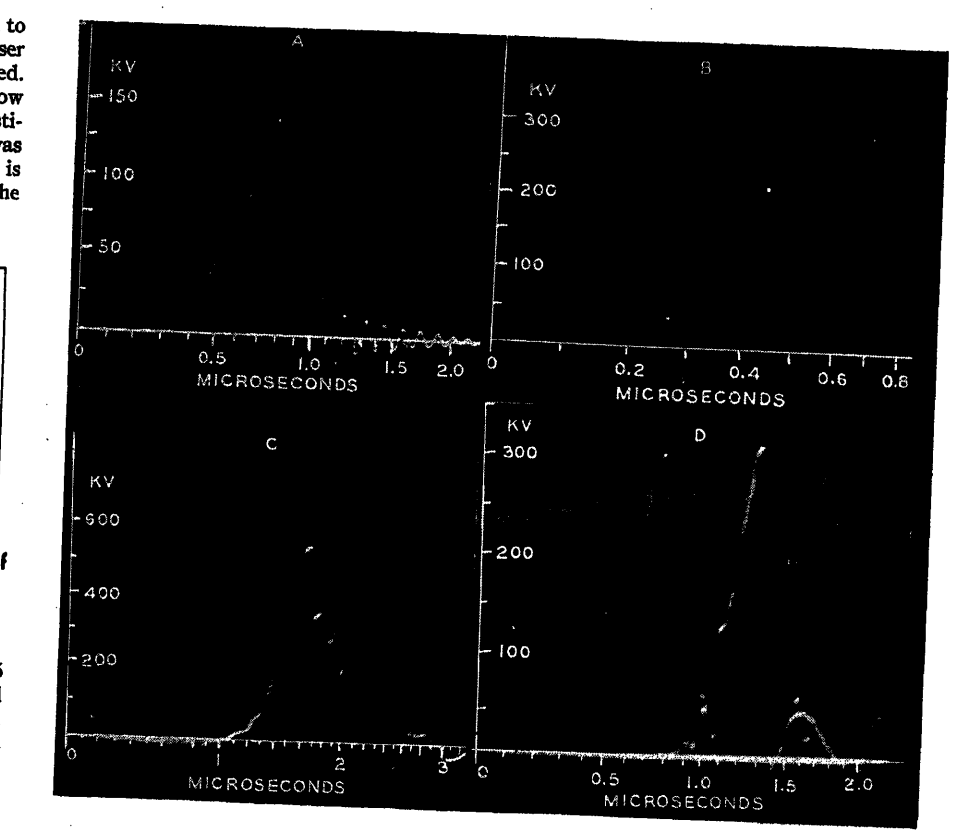

**Figure 4**

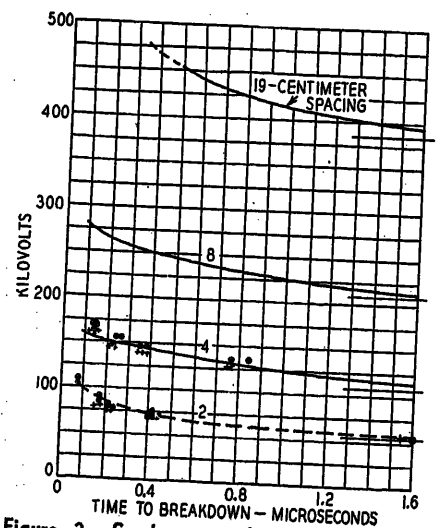

**Figure 3. Spark-over voltage of 25-centimeter sphere gap on positive impulse**

Crosses represent resistance-divider measurements (recent data)

Circled crosses represent capacitance-divider measurements (recent data)

Curves in solid lines are from figure 6 of "Sphere Gap Characteristics on Very Short Impulses," *Electric Journal*, volume 32, March 1935, page 120

(*Electric Journal*, June 1936, page 274) are substantially in the same order considering the character of the tests. It would have been well had the author called attention that his data for solid and for the combined solid and liquid insulation applies for single or a limited application of tests.

Table II gives data for rod gaps which were taken recently in the course of ordinary tests. These data have been scaled according to the established technique (method in column 2 of table I) from such oscillograms as *C* and *D* of figure 4. A comparison of these sample data with those first presented to the AIEE (ELECTRICAL ENGINEERING, June 1934, page 874, figure 6) shows adequate agreement from a practical standpoint. This shows that the methods and technique used can give practically good results. In this connection it is well to note that departures from the average of some ±10 per cent for the voltage and about ±20 per cent for the rate of rise are to be expected and such variations should be considered permissible at the present. That these and even greater variations are present and inherent in work of this kind will be evident also from a close study of the data in figure 8 of the paper. The smoothness of this curve at the short times is more apparent than real.

There are a number of points which come to the attention in studying this paper:

(*a*). According to the author, the method of measuring steepness in terms of time to breakdown comes into the picture because of the flattening effect on the crest of the wave when a high series resistance (2,000 ohms) is used in the generator. Judging from the experience in a good many laboratories the series resistance more commonly used is about 400 to 500 ohms. Besides, as the author suggests, this resistance could

be removed partially or altogether to get the steep fronts when the load is of high capacitance. Because of this the flattening effect would not be expected in any great amount in the more common test arrangements.

(*b*). While the steeper fronts are obtained by the removal of the series resistance there are disadvantages entailed from this practice. For example, it is often convenient or desirable to have an identical setup of the generator to test the same gap or apparatus with either the $1^1/_2$x40 microsecond wave or a steep-fronted impulse. Another disadvantage would be that the effects of leads are accentuated upon complete removal of the series resistance.

(*c*). The scheme in figure 4 (*b*) of the author in attempting to reduce the effect of voltage drops in the ground discharge circuit has been recognized. There are physical limitations to the degree this method can actually be applied. There are other possibilities and approaches possible to minimize the ground effects such as the following. Good results are obtained keeping the cable of the divider away from the discharge circuit or insulating it from ground. It should also be possible to ground at the test piece and connect this grounded end directly to the generator by means of cables so as to confine the discharge currents in a definite known path.

The data on the short-time spark-over of the 25-centimeter sphere gap in figure 15 of the paper are substantially in disagreement with the results obtained by the writer and W. L. Teague from tests on this size of sphere gap at exactly the same spacings (*Electric Journal*, March 1935, page 120). For example the data for 4-centimeter spacing at a time to breakdown of 0.2 microsecond is 40 per cent higher in figure 15 than in the corresponding data plotted essentially on the same basis which appears in figure 6 on page 122 of *Electric Journal*, March 1935.

Since taking the data in the *Electric Journal*, check tests have been made from time to time with substantially good agreement. Recently a series of check tests have been made in a different laboratory from the one where the original data were taken. Results of these tests for the 2- and 4-centimeter spacings are plotted in figure 3. Approximately half the measurements were recorded at the cathode-ray oscillograph with the resistance divider having a resistance of 3,300 ohms and with a short cable (surge impedance equals 44 ohms). The other half of the tests were recorded with a capacitance divider. Figure 5 shows the test and measuring setup. Oscillograms recorded are given in figure 4 (*A* and *B*). A study of these data leads to the conclusion that the 2 dividers are in good agreement. It further shows that the use of these 2 methods of measurement has the great advantages of confirming results and establishing confidence in measurement.

At the same time these check tests were made on the 25-centimeter sphere gaps data were taken also on the 12.5-centimeter sphere gap for spacings of one centimeter, 2 centimeters and 3 centimeters (plotted on figure 6). On this same figure are also plotted data obtained by A. K. Nutall (*Journal* Institution of Electrical Engineers, February 1936, page 229) on the 12.5-centimeter sphere gap for these same spacings by means of a cathode-ray oscillograph of such construction that the measurements are directly recorded at the oscillograph plates. The agreement between data obtained from the 3 methods of measurement (figure 6) is amply close for all practical purposes. Because of this good agreement there are good reasons to question the data of figure 15 in Hagenguth's paper.

In conclusion it is gratifying to note the progress that has been made possible through the application of the resistance divider. The resistance divider has come into wider use in the past few years and in greater favor. A good number of laboratories in the country are now also using the capacitance divider. Experience has shown that the judicious use of these 2 methods of measurement can fulfill most if not all practical requirements, in impulse voltage measurements.

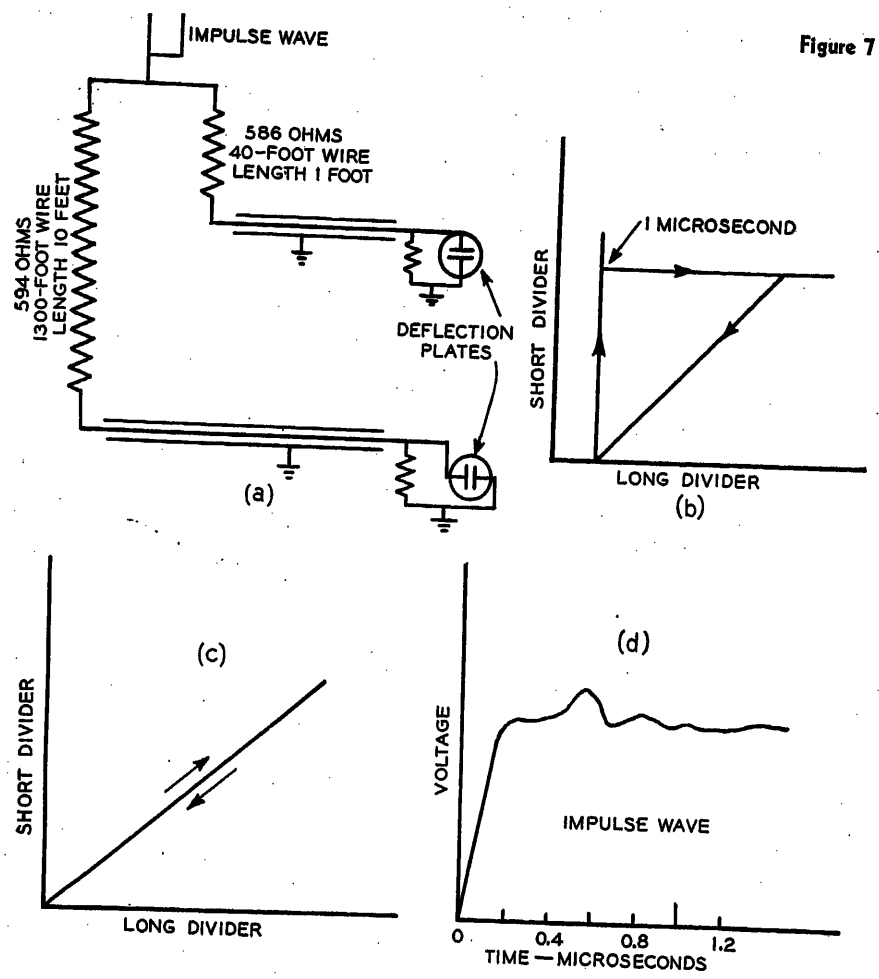
**J. H. Hagenguth:** The discussions are principally related to the divider, effect of circuit constants, and the steepness of waves and will be taken up in that order.



In answer to Mr. Sprague the length of wire used in the divider described is approximately 850 feet. However, the total physical length of the resistance elements is only 6 feet. A brief attempt was made several years ago to determine the velocity of wave propagation on an ordinary resistance divider, using 2 dividers of approximately equal resistance (see figure 7*a*) but of different physical length both as regards actual length of wire and length of divider. The ends of these 2 types of dividers were connected through cables of equal lengths to the 2 pairs of plates of the cathode-ray oscillograph.

If, as expected the current must be established in a divider of this type by traveling along the wire only, the pattern obtained should have been of the form shown on figure 7*b*, i.e., the voltage at the plates connected to the short divider should have increased first and approximately one microsecond later, assuming a velocity equal to the speed of light, the voltage at the other pair of plates should have increased. However, the actual oscillogram obtained was of the form as shown on figure 7*c*. The wave used for this test is shown on figure 7*d* and had a front of approximately 0.2 microseconds.

This test seems to indicate that the voltage transmission on a divider of this type is a wave phenomenon of somewhat the nature of a space wave traveling along the divider. An exact physical interpretation of this phenomenon has not been attempted on account of the more urgent problem of finding a divider which could be used with confidence to measure impulse voltage with steep fronts. It is, however, an intriguing problem and well worth while of study.

Standards for determining the accuracy of dividers for measuring steep wave fronts are not available, as pointed out by Mr. McEachron. Three methods have been used to obtain proofs for the correctness of the

Figure 7

solution: First, the use of the spark-over of a sphere gap strongly irradicated (figure 1 of paper) represents a relative proof, since the actual wave front is not known. The fact, that a spark-over of the sphere occurs after the crest, which is reached in 0.1 microsecond, shows that the divider will be suitable for measuring fronts of 0.4 microsecond or longer, which represent the output of large high-voltage generators. Second, a comparison between a calculated wave and waves measured with 3 different resistance dividers as shown on figure 8. The calculated waves measured with shielded and the low resistance divider check fairly well. The third method consists in checking the input and output voltages of the shielded divider by means of the electrical transient analyzer, and comparing the result with other types of dividers such as a small capacitance divider. The waves applied during such tests have fronts of approximately 0.05 microsecond.

Messrs. Rorden and Ross show a divider shielded by the impulse generator and claim that the voltage distribution along the divider is practically uniform. It is gratifying to know that the author's results on sphere gaps are checked with this arrangement. Without knowing how this distribution was measured and with what type of wave, it is not possible to interpret this result correctly.

There are several objections: (1) The divider has to be used in this one position requiring relatively long leads between divider and testpiece; (2) the shielding cannot be checked conveniently and the divider may be under- or overcompensated.

For elimination of inductance $L_g$ in the ground leads compromises have to be made, since for spark-over tests on the range of 0.5 microsecond or less voltages of the order of 1,000 kv will occur across a wire of 30-foot length.

All are agreed that it is well to arrange discharge circuit to obtain an essentially straight voltage rise, thus eliminating one of

the variables of the problem of front of wave testing. Mr. Bellaschi shows in his table I the values of rate of rise of several oscillograms obtained by 3 methods. Differences between method 1 and 2 are of the order of 10 per cent while differences between 1, 2, and method 3 as proposed in the paper are as much as 30 per cent. The reason for the large differences is the bending over of the wave near the crest. In the cases where 1, 2, and 3 agree the front is probably straight, in the other cases bending over occurs. This bending over is,

however, not as confusing as it appears as is shown on figure 9 of this discussion. Curves $A_1$ and $B_1$ were plotted using conventional methods of definition of kv/μs rise, for $A_2$ and $B_2$. The method proposed in the paper was used. Spark-over without series resistance ($A_1$ and $A_2$) took place partly on the tail of the wave at about one microsecond, while at short times to spark-over (0.25 microsecond) the voltage rise was straight with a sharp breakdown point. The waves

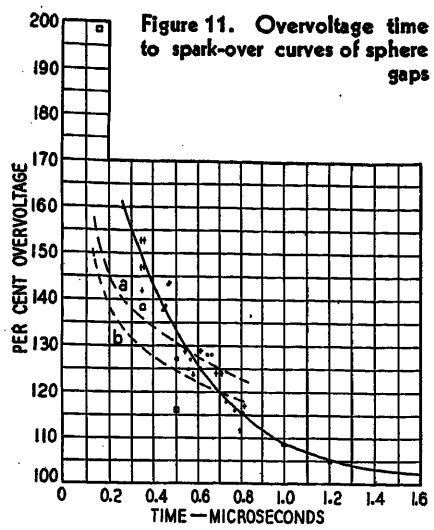

**Figure 11. Overvoltage time to spark-over curves of sphere gaps**

Solid curves—Average for 25-centimeter and 100-centimeter spheres; tests with shielded divider
+—Positive polarity; 50-centimeter sphere; 16.7-centimeter spacing
•—Negative polarity; 50-centimeter sphere; 16.7-centimeter spacing
o—Average of 100-centimeter sphere; 23- to 40-centimeter spacing
Nuttal (*Journal* of the Institution of Electrical Engineers, February 1936), direct measurements without divider
Dotted curves—Bellaschi; 25-centimeter sphere; 4-centimeter spacing

(*b*)—Resistance divider

of curves $B_1$ and $B_2$ showed the bending-over effect shortly before spark-over occurred. In spite of the different nature of the waves used to arrive at these curves, curves $A_2$ and $B_2$ practically fall together, and are checked with waves having straight voltage rise at all rates of rise. It appears therefore that the method of average rate of rise would produce more consistent results.

Neither definition, however, seems to fit conditions for spark-over on the front of the wave, when spark-over takes place at a time in excess of one microsecond. Figure 10 shows spark-over of a 20-inch rod gap when waves with slow exponential fronts are applied. Two limits appear to exist: (*a*) spark-over due to a rectangular wave (or practically speaking a 1.5x40 wave) and (*b*) the spark-over due to straight line rise of voltage (or practically curve *a* with a time constant, $RC$ = 12 microseconds). That waves with such slow rates of voltage rise cause arc-over on transmission system has been shown by Berger (Lightning Investigation During 1932 and 1933 in Switzerland, K. Berger. ASE Bulletin No. 9, April 27, 1934). For slow wave front tests it appears desirable to indicate rate of rise by the time constant of the wave front to permit comparison between results obtained by different investigators.

Concerning comparison of results published by Mr. Bellaschi and his associates and in the paper, it appears that the differences of rod-gap spark-over obtained are of the order of 10 to 20 per cent for larger spacings, i.e., spark-over values obtained with the shielded divider are higher by about that amount, when compared on the same basis (average rate of voltage rise). The values obtained with the shielded divider usually check within 10 per cent under entirely different test conditions, with different generators, oscillograms, and operating personnel. That the differences in results between the 2 laboratories is not greater than 10 to 20 per cent is undoubtedly due to the fact, that Mr. Bellaschi uses a 1.5x40 wave. For a front of such relatively slow rise the distortion effect of the nonshielded resistance divider is relatively small. However, as pointed out in the paper, the 1.5-microsecond front cannot economically be used for front-of-wave tests on gaps in excess of 30 inches and it should, therefore, be expected that results for the larger gaps should show greater differences.

It is not quite clear why it should be desirable to use an identical generator setup for both the 1.5x40 wave and the steep-fronted impulse. A standardized front is desirable for full-wave test and expecially the elimination of oscillations superimposed on the crest of the wave is of great importance; for front-of-wave tests, however, limitations on the actual front used should not be imposed except to specify the rate of voltage rise, or the time to spark-over. The removal of the series resistance does not materially increase testing difficulties provided the divider is connected directly to the testpiece.

Much greater differences in results, are found when comparing the spark-over of sphere gaps, as pointed out by Mr. Bellaschi. From figure 3 and figure 6 obtained by Mr. Bellaschi using a resistance type and capacitance divider it appears that spark-over voltages obtained with the capacitance divider are consistently higher than those obtained with the resistance divider which seems to indicate that even a resistance divider of as low a value as 3,300 ohms will not reproduce correctly the true rate of rise. In figure 5 of this paper is replotted an average curve obtained recently on a 50-centimeter sphere gap with 16.7-centimeters or 33.4-per cent spacing with points indicating negative polarity and crosses positive polarity. The large circles on this curve represent average values obtained from tests on a 100-centimeter sphere gap with spacing varying between 23 and 40 centimeters. Other recent data obtained with a 25-centimeter sphere gap fall within 10 per cent of the plotted curve. The squares indicate the points published in Mr. Nuttal's paper similar to those in figure 6 of Mr. Bellaschi's discussion. Finally the 2 dotted curves represent values of figure 3 of Mr. Bellaschi's discussion for 4-centimeter spacing. A comparison of the overvoltage values of the 50-centimeter and 100-centimeter sphere seems to indicate that the characteristic spark-over curves of the 2 sizes of gaps agree very well, also Nuttal's results obtained on a much smaller gap of 12.5-centimeter diameter indicate the same general trend. The curves of figure 1 of Mr. Bellaschi's paper, especially the values obtained with the capacitance divider agree fairly well in the region for spark-over times of 0.4 microseconds and longer. In the region of short-time spark-over the curves do not check, which possibly is due to the distorting effect of the resistance divider and possibly due to the effect of the resistance divider on the field in the capacitance divider, which apparently were placed quite close as shown in figure 5 of Mr. Bellaschi's discussion.

In conclusion the author wishes to emphasize the point brought out by Mr. McEachron that the paper should not be interpreted as advocating the use of increasingly steeper fronts for impulse testing. It is merely intended to discuss the problem of voltage measurement and to show the effect of steep wave fronts on the spark-over of the component parts of transmission systems.

A much greater amount of field data would be required to justify testing with fronts having rates of rise in excess of 1,000 kv per microsecond.

## Currents and Potentials Along Leaky Ground-Return Conductors

**Discussion of a paper by E. D. Sunde published in the December 1936 issue, pages 1338–46, and presented for oral discussion at the communication session of the winter convention, New York, N. Y., January 25, 1937.**

K. L. Maurer (Bell Telephone Laboratories, Incorporated, New York, N. Y.): The earth as a conductor of electricity has long been a puzzling and troublesome subject because of its great extent, its amorphous structural arrangement, and its general lack of homogeneity. The tendency upon the part of the engineer dealing with practical problems involving the earth as a conductor, has been to get around the uncertainties either by ignoring them or by idealizations often more consistent with convenience than with the facts. Fortunately, in many types of circuit problems, propagation rates are slow enough to admit rather sweeping idealizations of the electrical behavior of the earth. In other types of circuit problems, some of which are mentioned in the paper, and in particular, those involving differences in potential between points on the ground itself, recognition of what actually takes place in the earth cannot be avoided. In the past 10 years or so, a great deal of work

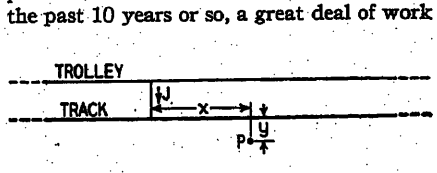

**Figure 1**

on this subject has been done by a number of investigators, as a result of which many of the difficulties have been resolved, and to this work Mr. Sunde's paper is an important contribution.

The formidable appearance of the expressions for voltage and current may, at first glance, give the impression that the formulas are too unwieldy for practical use. As a matter of fact, in most practical applications it will be found that the expressions can be considerably simplified without overstepping the limits of engineering accuracy, because it is rarely if ever that all of the factors in a circuit problem involving the earth can be determined with enough assurance to justify carrying out all of the steps called for in the formulas. The main factor of uncertainty, of course, is the character of the earth in the locality in question. As may be seen from the formulas in table II, the earth resistivity, although of secondary impor-

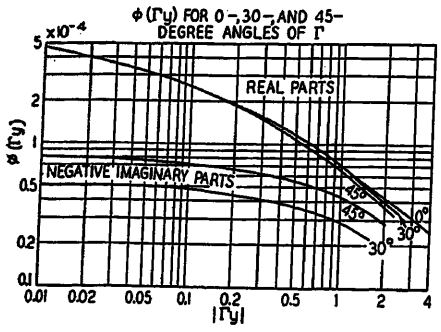

Figure 2

tance in the expressions for the conductor current and voltage, is an extremely important factor in determining ground potential since the latter is almost directly proportional to the resistivity. Since it is known by experience that the earth, particularly at the surface, usually is far from homogeneous, and since it is practically impossible to determine the variations in resistivity over the entire area involved in a particular problem, the question of the reliability of the formulas in practical work naturally arises.

To answer this question, a rather extensive series of tests was undertaken in the summer of 1935. The leaky ground-return conductor for these tests consisted of a single electrified railway track, and particular attention was given to the investigation of ground potentials, such as might affect communication circuits in the vicinity. From the results of these tests, which are described in another discussion of this paper, and from several other experimental checks, it appears that in the average case, a reasonably good fit between the formulas and the experimental data can be expected with relatively simple hypotheses as to the earth's structure.

As an example of the extent to which the formulas in the paper can be simplified for engineering use, consider the expression on page 1343 for ground potential produced by an electrified railway, as at point $P$ in figure 1 of this discussion. Since ground potentials are largest close to the track, it is of practical interest to examine this formula for small values of separation. By means of the expressions in table II, the ground potential for small values of $y$ may be written (using the notation of the paper):

$$V_e(x, y) = \frac{J\rho\Gamma}{4\pi}(1 - \mu) \times \left[K(x) + 2e^{-\Gamma x}\log_e \frac{1.12}{\Gamma y}\right] \text{volts} \quad (1)$$

in which $K(x)$ is a quantity, independent of the separation which is found to vary only slightly over the practical range of values of $\Gamma x$. In obtaining the difference in ground potential between 2 points at a given value of $x$, the quantity $K(x)$ cancels out and in obtaining the difference in ground potential between 2 points at different values of $x$, the difference between the 2 values of $K(x)$ is small compared to the difference between the 2 values of the remaining term, since the latter varies exponentially with $x$. Therefore, for close separations (up to about 500 feet in the average case), it is permissible to ignore $K(x)$.

Since the largest values of ground potential at a given separation occur opposite the current source or the load, it is also of practical interest to examine the formula in the paper for small values of $x$. In this vicinity, the ground potential may be written as

$$V_e(x, y) = J\rho\Gamma(1 - \mu)e^{-\Gamma x}\phi(\Gamma y) \text{ volts} \quad (2)$$

For convenience in practical work the terms of equation 2 are defined as follows:

$J$ = trolley current, amperes

$\rho$ = earth resistivity, meter-ohms

$\mu = M/Z$ = ratio of mutual impedance of trolley and return system to return system self-impedance, both on an earth return basis

$x$ = distance along track from point opposite electrode at which ground potential is taken, to point at which current enters tracks, miles

$y$ = separation, normal to track, between electrode and track, miles

$\Gamma = \sqrt{G \cdot Z}$ = track-return-system propagation constant, per mile

$G = (g \cdot g_1)/(g + g_1)$ = track-return-system leakage conductance mhos per mile

$g$ = leakage conductance of ties, track ballast, and other leaks, such as catenary structure footings, etc. For tracks, this quantity has been found to vary between 0.5 and 2 mhos per mile per track for dry and wet weather conditions, respectively. One mho per mile per track is frequently used as a representative value

$g_1$ = "leakage conductance" relating to the earth in the vicinity of track. This quantity may be taken as $1{,}000/\rho$ mhos per mile, regardless of the number of tracks

$\phi(\Gamma y)$ = a function of the return-system propagation constant and electrode separation, containing factors for conversion of distances from meters to miles. This function is shown in the accompanying figure

At $x = 0$ equation 2 is valid for a large range of values of $\Gamma y$. As $x$ increases, however, the range of values of $\Gamma y$ for which the equation is accurate becomes narrower. For $\Gamma x$ larger than about 2 in the average case, the equation is restricted to separations about the same as those for equation 1. At large values of $\Gamma x$, however, the ground potential ordinarily is so small compared to that at small values of $\Gamma x$, that its accurate determination is of less practical importance.

The ground potential produced by current leaving the track, as at a substation, is calculated in the same way, but has reversed sign. The total ground potential produced by current entering the track at one point and leaving at another, as in a section between a load and a substation, is the algebraic sum of the potentials calculated for each point separately. The difference in ground potential between 2 electrodes is the difference between the ground potentials calculated in this way for each point independently.

**P. Goldstone** (Gibbs & Hill, Inc., New York, N. Y.): In the preceding discussion reference was made to certain tests to obtain experimental checks on the analysis given in the paper. In these tests, in which I was interested from the railroad viewpoint, in addition to the study of ground potentials, measurements were also made of track currents and potentials, which are of interest to the railroad engineer.

The test arrangements are shown in figure 3. The circuit, which represents the trolley-track circuit of an electrified railway, consisted of a single overhead wire with return in a single bonded track. The tests were made at one end of the circuit and circuit lengths of 1, 2, 3, and 4 miles were used.

Figure 3 shows observations of the following quantities as the length of the energized section was varied: (*a*) track potential measured between the track and a ground rod located at the edge of the ballast, (*b*) difference in ground potential between the ground rod at the edge of the ballast and a ground rod situated about 9,000 feet away on a line at right angles to the track, (*c*) track current flowing away from the energized section. (This current is of course equal to the earth current at the end of the section.) The results indicate that all 3 quantities vary in substantially the same manner as the section length is changed. It will be seen that the track potential changed considerably with weather conditions due to the fact that the moisture increased the track ballast leakage conductance. The effect of weather conditions upon the ground potential, however, was negligible. The ground potentials at points near the track are seen in this case to be of the same order of magnitude as the track potential.

On figure 4 are shown observed differences in ground potential measured between the ground rod at the edge of the ballast and ground rods at various separations from the track along a right angle line. The energized circuit in this case was 4 miles long. Three calculated curves also are shown on this figure. Curves *A* and *B* were calculated by methods described in the paper assuming homogeneous earth having values of resistivity of 1,600 and 200 meter-ohms, respectively. Curve *C* was calculated for a resistivity variable with depth. Comparison of the experimental with the calculated curves brings out the effect of nonhomogeneous earth upon the variation of ground potential with separation. Measurements of earth resistivity by the usual d-c method in the vicinity of the end of the energized section indicated roughly a 2-layer earth structure, in which the resistivity of the upper layer was on the order of 1,600 meter-ohms, while at greater depth the resistivity was on the order of 200 meter-ohms. This condition required extending the formulas given in the paper, which are based on homogeneous earth, to correspond to the case of re-

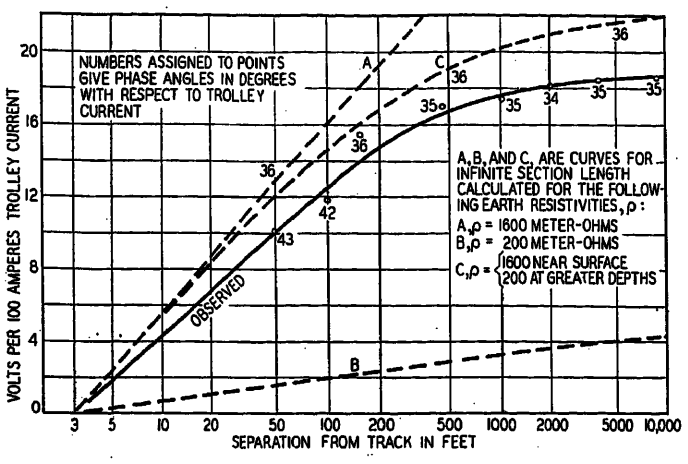

**Figure 3. 28-cycle tests on single-track railroad; earth potentials at end of 4-mile section referred to a ground near track**

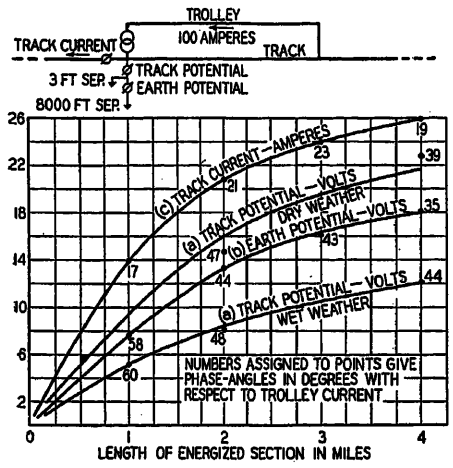

**Figure 4. 28-cycle tests on single-track railroad**

sistivity variable with depth and curve *C* on figure 4 is based on this assumption. The calculated curves are based on the assumption of infinite length of the energized circuit whereas the actual circuit was only 4 miles long. This fact accounts for some of the difference between the observed results and the calculated curve *C*.

Curve *C* was calculated by the author of the original paper in the following manner. Assume the variation in apparent earth resistivity $\rho'$, with electrode separation $r$ to be given by the formula:

$$\rho' = \rho(1 + ke^{-\beta r})$$

where $\rho$ is the earth resistivity measured for large electrode spacings, $(1 + k)\,\rho$ the earth resistivity for small spacings and $\beta$ a properly chosen constant. The earth potential is then approximated by calculating the earth potential for homogeneous ground of resistivity $\rho$ for 2 separations $y$, and

$$y' = y\sqrt{1 + \left(\frac{\beta}{\Gamma}\right)^2};$$

where $\Gamma$ is the propagation constant of the track for the unit length used for $r$. The latter earth potential is multiplied by $k$ and added to the first. It was found that the earth resistivities measured in these tests could be approximated by taking $\rho = 200$ per foot, $k = 7$, and $\beta = 0.015$ per foot, and curve *C* of figure 4 is based on these assumptions.

The following conclusions may be drawn from the experiments:

1. Ground potentials, track potentials and earth current at one end of a traction circuit (at which point the potentials normally are largest) vary with the circuit length $s$ nearly as $1 - e^{-\Gamma s}$ and decrease with distance $x$, along the track from one end of the section toward the center nearly as $e^{-\Gamma x}$
2. If the earth is not homogeneous, but has a resistivity decreasing with depth, the ground potential difference between 2 electrodes, one of which is near the track, increases less rapidly, as the other electrode is moved away from the track, than if the earth is homogeneous
3. With the track energized across a track break (as in case 1 of the paper) the track current propagation is nearly exponential for a considerable distance. This was found to be the case over the entire section (3 miles) used in the tests.

# Inductive Co-ordination of Common-Neutral Power-Distribution Systems and Telephone Circuits

**Discussion and authors' closure of a paper by J. O'R. Coleman and R. F. Davis published in the January 1937 issue, pages 17–26, and presented for oral discussion at the communication session of the winter convention, New York, N. Y., January 25, 1937.**

**Sidney Withington** (The New York, New Haven and Hartford Railroad Company, New Haven, Conn.): The co-operation which has been accomplished between the power and telephone interests, implied in this paper, I believe should be emphasized.

Reference is made in the paper to the co-ordination between the National Electric Light Association and the Bell Telephone system. Attention is called to the joint effort of the Edison Electric Institute and Association of American Railroads, resulting also in general agreement as to principles and practices, which should avoid a great deal of unprofitable controversy in the future.

Work of this kind which insures that decisions will be based upon engineering principles, is incomparably more desirable than permitting contests in the courts, where decisions by nontechnical individuals may be based upon cleverness of presentation by brilliant lawyers, regardless of engineering merits or economic factors, rather than upon logical analysis founded upon facts.

Instances of this kind have unfortunately occurred in the past, and it speaks well for the engineering profession that means have been taken to keep such discussion out of the courts in the future.

**T. A. Taylor** (Bell Telephone Laboratories, Incorporated, New York, N. Y.): The paper by Messrs. Coleman and Davis discusses the factors which must be considered in the inductive co-ordination of common neutral power distribution systems and telephone circuits operating in urban areas. As pointed out in the paper, there has been a recent trend toward the use of multigrounded or common-neutral systems in rural areas and in view of this trend, it may be of interest to compare briefly the co-ordination problems presented in rural areas with those discussed in the paper. This discussion is based upon the results of field studies of this problem carried out during the past 2 years by the joint subcommittee on development and research—EEI and Bell system. A comprehensive report on this work is now being prepared.

As the authors have indicated, rural power circuits are generally longer, operate at lower load densities and frequently at higher voltages than those in urban areas. As a result, it has been found, particularly in the case of rural lines operating at the higher voltages, that the ground-return charging current components are apt to be more important in contributing to their inductive influence than either the load current or transformer exciting current components, which generally control the influence of the lower voltage urban circuits. These "capacitive" or charging-current components return, at least in part, in the ground, regardless of whether the circuit is operated isolated, or with a single-grounded or multigrounded neutral. The results of tests in a number of locations indicate that while multigrounding the neutral of these longer circuits increases the 60- and 180-cycle ground-return components, it, on the average, makes no substantial change in the components of higher frequency, although in individual cases they may be increased or decreased. Measurements of noise on rural telephone circuits exposed to these power circuits have shown that these higher frequency components tend to control the noise whether the power circuits are unigrounded or multigrounded. On the average, therefore, on circuits exposed to rural power lines operating at 7,600 volts and above, the noise is not materially different whether the power circuit neutral is uni- or multigrounded.

In the case of short low-voltage rural power lines, the charging currents are of relatively small importance compared to the transformer exciting currents and load components. The behavior of such circuits, when multigrounded, is therefore similar to that of the urban circuits discussed in the paper, although differences in the influence under the unigrounded and multigrounded conditions may not be as great.

The studies of the committee have disclosed no new co-ordinative measures which may be applied to rural power and telephone circuits but indicate that certain of the measures outlined in the Coleman-Davis paper are applicable in rural areas. Since the ground-return charging current components are of particular interest, measures which tend to limit their magnitudes are relatively more important than those which primarily affect the transformer exciting current or load current components.

Experience has shown that the magnitudes of the charging currents may be affected in either the unigrounded or multigrounded cases by resonant conditions and propagation effects which occur in the longer circuits used in rural areas. The importance of these effects depends upon the voltage wave shape impressed on the circuit. The charging currents may therefore be reduced by improvement in the wave-shape conditions. The ground-return components of the charging currents on 3-phase lines may also be reduced by maintaining the greatest practicable degree of balance-to-ground of the system, by equalizing the lengths of single-phase extensions connected to each phase.

Since most of the rural telephone plant is of open-wire construction, the use of adequately co-ordinated telephone transpositions and the avoidance of severe unbalances in the open-wire conductors may often be a practicable and effective co-ordinative measure.

The method of co-operative planning of routes by both parties to avoid severe exposure conditions, which has been found effective in urban areas, is sometimes more difficult to employ in planning rural extensions, since the power and telephone circuits frequently must be carried along the same highways. Therefore, co-operative advance planning must usually be directed toward limiting the influence of the power system and the susceptiveness of the telephone system.

The paper points out that in many cases desirable magnetic shielding effects may be obtained by grounding the sheaths of exposed telephone cables. The joint subcommittee has found from tests in 2 urban areas that such grounds may often be practicably provided by bonding the cable sheath to the multigrounded neutral of the power-distribution system. Since the neutrals in these urban areas were very well grounded the degree of shielding so obtained was found to be comparable to that observed with other low-impedance grounds.

**J. J. Smith** (General Electric Company, Schenectady, N. Y.): This paper illustrates well the benefits to be derived from co-operative studies by power and telephone engineers of the mutual problems which arise between their respective systems. My recollection is that in the days when the use of the common-neutral system was first considered on a large scale, some engineers thought that it would considerably increase the influence of power circuits on paralleling telephone systems while other engineers felt that it would not. In order to arrive at the facts, experimental studies were undertaken which over the succeeding years brought forth the results given in this paper. The results described indicate that while the use of the common-neutral system without any reference to inductive co-ordination might give rise to noise difficulties, these can largely be avoided by co-operative procedure with regard to certain features of both the power and communication systems.

The experimental studies led to the breaking down of the over-all noise into its component parts. The tables given in the paper show well the effects of the wave shape of the power system and of the unbalances on the telephone system. The section on inductive coupling, however, refers only to factors which generally influence the type of construction used, whether the systems use the same pole jointly or are at highway separation. I feel that a table or curve giving a comparison of the effects of these types of construction in an average case would be a worthwhile addition to the paper. I should also like to suggest the inclusion in the paper of a comparison of open-wire and cable telephone circuits showing the results to be expected on each in some typical average case.

At the bottom of page 24 it is stated that "direct metallic-circuit induction can be greatly reduced by systematic transpositions in the telephone circuit." This agrees with the results in table 9 where variations of 5 to 1 up to 20 to 1 are given for the contributions to the noise from open-wire sections. These variations are attributed to the effectiveness of the transpositions. On page 24, however, the further statement is made that "due to the physical limitations in a practical layout of telephone transpositions the reduction in metallic-circuit induction is on the average from 60 to 80 per cent on nonpole pairs and about 90 per cent on pole pairs." These reductions, ranging from 2 to 1 up to 5 to 1, do not seem to agree very well with the previous statement or with the result given in table 9. I should like to have the authors clarify this point.

**Coleman and Davis:** On the first page of the paper reference is made to the start of this system in Minneapolis. Although this was the first extensive use in this country the system was developed and installed in Toronto, Canada by Mr. Hood prior to its installation in Minneapolis.

Mr. Smith raises 2 technical points that appear to require slight elaboration to answer.

Effectiveness of transpositions in exchange lines cited on page 24 are average values based on tests made by the joint subcommittee on development and research on several lines and published in volume 2 of "Engineering Reports," table IX, page 102. Under favorable conditions greater effectiveness than the average can of course be obtained. In table IX, page 25, the lower values of the noise contributed by the open wire is for a transposed nonpole pair and the higher value is for a nontransposed pair. Consequently the range shown is greater than that obtaining for a particular pair when transposed and nontransposed.

"Engineering Reports" 13 and 17, (volume II and III) show complete information on coupling and since there are many factors such as direct metallic and longitudinal coupling for both the balanced and residual components of both current and voltage each varying differently with separation it does not seem feasible to prepare a summary curve.

For distribution circuits induction from residual currents and voltages is frequently the controlling factor. The table I shows the order of magnitude of the ratios between joint use and roadway separation for residual coupling.

Table I

| Type of Telephone Construction | Component of Noise | Relative Noise: Joint Use About 6 Feet Separation | 40 Feet Separation | 75 Feet Separation |
|---|---|---|---|---|
| Open wire | Direct Metallic | | | |
| | 1. From voltages | 100 | 20 | 7 |

## Calorimetric Measurement of Dielectric Losses in Solids

**Discussion and authors' closure of a paper by H. H. Race and S. C. Leonard published in the December 1936 issue, pages 1347–56, and presented for oral discussion at the communication session of the winter convention New York, N. Y., January 25, 1937.**

**P. M. Lincoln** (Cornell University, Ithaca, N. Y.): The paper by Messrs. H. H. Race and S. C. Leonard, describing calorimetric measurement of dielectric losses in solids is an interesting one.

The general theory of the procedure is perfectly sound. This theory is that a certain known power applied to a given mass of material during a given time will raise that material to a certain determinable temperature at the end of that time. The temperature at the end of the power application is inferred from the cooling rate, details of which are fully described in the paper. If then power is applied to a similar mass of material at an unknown rate, the power can

be inferred by determining the temperature elevation after a given short time.

The method is perfectly sound in theory, but there are a number of discrepancies which appear in the data submitted in this paper which I believe deserve further explanation.

In the first place the points at which the wattage is applied to the samples under test, and to the calibrating sample are quite different. In the test samples the wattage is applied presumably at a uniform rate throughout the mass of the material. In the calibrating sample, however, the wattage is applied to the exterior surface of the sample, and it is an open question whether or not the temperatures measured by the method indicated are a true relative measure of the energy input in the 2 cases. In the case of the calibrating sample there must necessarily be a flow of heat from the point of generation to the point of measurement, and it is highly questionable whether or not the heat is uniformly distributed throughout the sample at the end of the short time of the calibration sample test run.

The method of measuring temperature of both the calibrating sample and the test sample is such that it gives essentially the temperature gradient at the surface of the piece under test. This temperature gradient is in turn a measure of the cooling rate. One of the things in this paper, for which I see no explanation, is the decided difference in the cooling rate for the calibration sample, as compared to the test sample which presumably is identical in every respect, except that the calibration sample is covered with a thin coating of conducting material. An analysis of figure 8, for instance, showing the cooling curves taken during the d-c calibration on the fused-quartz calibration sample, shows that the rate of cooling is such that the temperature falls to $^1/_2$ the initial temperature in approximately 100 seconds as a minimum and 150 seconds as a maximum. These cooling rates are shown by the slope of the cooling curves. The slopes of all curves in figure 8 are not the same. The slope of the curve starting at the maximum temperature is approximately 50 per cent greater than that of the curve which starts at the minimum temperature. This is as might be expected, since it is well known that the rate of cooling due to natural convection decreases with temperature elevation, and the above result might have been anticipated. However, when we come to compare the rates of cooling shown in figure 8 on the calibration sample, with the rates shown in figure 13 on a test sample, which is presumably a duplicate of the sample of figure 8 except that it has no surface conductor, we find a rate of cooling entirely different. In figure 13 the rate of cooling is such that $^1/_2$ the initial temperature is reached in from 220 to 250 seconds, or, in other words, the rate of cooling is only about $^1/_2$ of what we find on the calibration sample. I should like to ask Mr. Race if there is any known reason for this rather remarkable difference in the cooling rates of the 2 presumably duplicate samples.

If now we compare figure 10, which shows the cooling curves of the Isolantite calibration sample, with those of figure 14 which shows the cooling curves for test sample of the same material, we find that a very similar condition exists. In figure 10 $^1/_2$ of the initial temperature is reached in 75 to 110 seconds, while in figure 14 we find that it requires 130–150 seconds to arrive at $^1/_2$ the initial temperature. Why should there be this difference?

If I may be permitted, I should like to suggest one possible explanation for these discrepancies. It is quite possible that the temperature of the rather heavy masses at the ends of the samples under test was quite different during the test upon the calibration sample, and the test upon the test sample. Analysis will show that a very considerable portion of the heat applied to these samples will escape by thermal conduction, and of course the rate of heat escape by thermal conduction will depend upon temperature difference between the rather heavy metallic terminals on the samples and the temperature at the midpoint of the sample. I do not find that Mr. Race made any attempt to determine the temperature of these terminals. I am informed by those more familiar with high-frequency radio matters than I, that there is a possibility during the application of the high voltage, high frequency test, that some heat will be developed in the rather heavy terminals on the test sample. If this is the case, it would explain the difference in cooling rates that I have pointed out above.

If, as I suspect, a very considerable part of the heat in both the calibrating and the test samples is carried away by thermal conduction, the question of thermal conductivity of the materials under test will have a very decided bearing upon the results attained. Thermal conductivity of materials such as Mr. Race is experimenting with, varies over a very wide range. For instance, reference to the Smithsonion Physical Tables, confirmed by the International Critical Tables, give values as follows:

For crystalline quartz perpendicular to axis of 0 degrees centigrade

$k_t = 0.0173$

For crystalline quartz parallel to axis, same temperature, the value of $k$ is 0.0325. For hard rubber at 0 degrees centigrade the value of $k$ is 0.00037, being thus about 1 per cent of that for crystalline quartz. I can find no values of this constant for fused quartz, but I understand it to be of the order of 10 per cent or 15 per cent of that of crystalline quartz.

For Isolantite the value of $k$ is 0.00175. It will thus be noted that the thermal conductivity of the materials which were tested by Mr. Race vary over a very wide range. For instance, crystalline quartz parallel to the axis has a thermal conductivity, which is approximately $3^1/_2$ per cent of copper, while hard rubber has only about 0.04 per cent of that of copper, a variation of nearly 100 to 1. If, as I suspect, there is an appreciable dissipation of heat by thermal conduction during the 2 minute application of high potential, high frequency, to the test samples, will not this variation in thermal conductivity lead to results which are far from accurate?

The methods which Mr. Race is proposing in this paper certainly are interesting, and are worthy of additional study, but I would question whether the results so far obtained are of a very high degree of accuracy. I believe that if Mr. Race had taken his cooling curves between the center of his sample and the metallic terminals thereof his results might have led to determinations quite different from those cited in his paper.

There is one other point that might be mentioned before closing this discussion. If the information which I have received is correct, namely, that heat is developed in the metallic terminals during the high-potential high-frequency voltage application, this very fact would cause the results as reported in the paper to be quite erroneous. I should like to inquire whether or not any tests have been made to determine if there is such a loss in the metallic terminals during the period of high-potential high-frequency application.

**C. L. Dawes** (Harvard University, Cambridge, Mass.): To my mind the authors have developed a new and valuable technique in the methods of measuring dielectric losses. It permits measurement of such losses at high voltages simultaneously with high frequencies, which would otherwise be quite difficult. Also, because of the rapidity with which measurements can be made, the method is valuable not only for control work but for the rapid comparison of different dielectric materials. In the method as it has so far been developed, there are some possible sources of error. In figures 8 and 10, which give the cooling curve for the calibrating samples with fused quartz and Isolantite, the rate of cooling is much greater than with the test samples, as given by figures 13 and 14. This is explained, I believe, by the fact that with the calibrating samples the power is applied only to the surface. On cooling, some of the heat flows inward toward the center, thus producing a more rapid rate of cooling than with the test sample. With the latter, heat is produced throughout the body of the sample and the heat flow must necessarily be outward toward the surface. This gives a lesser rate of surface cooling than for the calibrating sample. Also it is questionable whether or not the placing of the thermocouple on the surface of the sample not covered by the surface layer of resistor material gives a true criterion of the cooling of the calibrating sample itself. Heat must flow over more or less irregular paths from the heated surface to the point of contact of the thermocouple. To my mind, these 2 difficulties might be overcome by calibrating with steady-state measurements, using the method of Baldwin.

Moreover, in calorimetric measurements the losses over the surface as well as the internal losses of the sample are measured. That is, surface losses cannot be eliminated by the usual guard electrodes, as in electrical measurements. Also the potential difference is applied between the 2 ends of a sample the length of which is considerable in comparison with the diameter. Hence the field between the electrodes will not be uniform and the dielectric lines will diverge outward as they leave the electrodes. This makes the stress per unit volume less at the midzone of the sample than at the ends. Hence the loss per unit volume throughout the sample is not constant. This, however, probably would have little or no effect so far as the comparison of samples of similar geometry is concerned.

The authors have attempted a very difficult problem and in their first attempt may not be expected to have brought the method

to perfection. They should be complimented on having obtained such rational results under very critical and difficult conditions.

**L. A. Burckmyer, Jr.** (Cornell University, Ithaca, N. Y.): This paper is very outstanding in its clear and full presentation of the test data. However the authors seem to have given only a small amount of attention to the interpretation of these data.

There is evidence that temperature conditions were not governed by the simple heat-storage relations that the authors relied on in determining the loss of a sample by the use of a calibrating resistor of different material. Thus equation 4 states, in effect, that the quartz calibrating resistor requires 0.25 watts (per cubic centimeter) per degree per calorie per cubic centimeter, on a 120-second test, or 30 watt-seconds per calorie, instead of 4.186, or the temperature difference $\Delta T_0$ is about $1/7$ the temperature rise that would occur with no heat loss.

There are 2 possible explanations:

(*a*). The values $\Delta T_0$ do not represent actual temperature rise, or
(*b*). The heat lost plays a very important part in the temperature attained.

Both of these are true, as can be shown by analysis of the cooling curves of, say, the quartz calibrating resistor. The uppermost curve (figure 8) shows a thermal time constant of about 150 seconds, indicating a heat loss which should have resulted in a temperature rise of about 2 degrees, or about 5 times $\Delta T_0$, during the heating period. (With no heat loss, the rise would be about 3 degrees.)

In view of the construction of the apparatus, it would not be unreasonable to assume that $\Delta T_0$ represents only about $1/5$ the actual rise, but to justify extrapolation of the cooling curves by drawing them as straight lines it is essential that $\Delta T_0$ be a *constant* fraction of the true rise. However, the slopes of the cooling curves on the quartz calibrating resistor differ by as much as 1.6 to one, and the average of these is about twice as great as the slope of the cooling curves on the quartz test sample, raising a question as to the significance of the results even when the calibrator and sample are made of the same material. As it is unreasonable to ascribe these variations to inconstant coefficients of heat transfer over the narrow range of working temperatures, it seems likely that $\Delta T_0$ does not even represent a fixed fraction of the true temperature rise; or, in other words, that the assumption of a linear cooling curve is arbitrary and unjustified.

The heat loss of the quartz calibrating resistor is about 6 times as large as can be accounted for by even black-body radiation. This discrepancy persists for any assumed ratio of actual temperature rise to $\Delta T_0$. Hence the temperatures must have been controlled largely by conduction, presumably to the massive metallic end pieces. If this is so, the inferred losses on all materials other than fused quartz and Isolantite can have little significance, for the conduction effects were not taken into account and would be entirely different in the calibrating resistor and in the test sample.

In the absence of any published defense of the construction of the calibrating resistor, with its surface heating and with temperature measurement made at the middle of a bare $1/4$-inch strip, any close agreement between the thermal behavior of the calibrating resistor and the test sample must be regarded as a fortunate accident. Certainly conduction plays a part in the heating of the bare strip, and it seems incredible that a radical change in the width of this strip would not have materially affected the calibration data.

With elimination of conduction effects and with a calibrating resistor that simulates the test specimen in all essential respects, it is likely that this method would be capable of yielding accurate results in measurements on dielectrics.

**H. H. Race** and **S. C. Leonard:** Before answering specific questions raised regarding this paper, we should like to make this general comment: The ranges of voltage and frequency over which bridge and substitution measurements can be used to measure dielectric constant and dielectric loss of solid insulating materials is shown in figure 1. Such methods cannot be used at high voltage high frequency, whereas calorimetric methods should be possible at frequencies and voltages equal to or higher than those we have used if a measurable power supply is available. The major disadvantage of previous calorimetric methods has been the time required to reach steady state. This paper reports progress in a 3 months attempt to use a transient calorimeter in this hitherto unexplored field of loss measurements on solid dielectrics. There is need for further refinement of the method which was presented with the hope of stimulating other workers to try transient calorimetry.

Specific questions can be separated into 3 classes:

(A). Thermal Conduction From the Ends of the Samples

When we started this work we planned to use samples 6 inches long with the hope that axial conduction would have a negligible effect upon the temperature of the midpoint. Our first measurements showed that with the maximum voltage available the gradient in long samples of low-loss material was insufficient to produce a measurable temperature difference. Therefore the samples were shortened to $1\frac{1}{2}$ and 2 inches with recognized attendant increases in the effects of axial thermal conduction. Preliminary calculations from the experimental data showed that about 80 to 85 per cent of the heat generated during a 2-minute heating period was being dissipated through the metal electrodes. Therefore, the theoretical thermal characteristics of our specific calorimeter were calculated by Doctor H. Poritsky of our engineering general department.

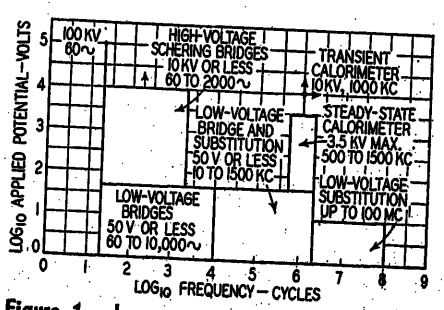

**Figure 1. Loss measurements, solid dielectrics**

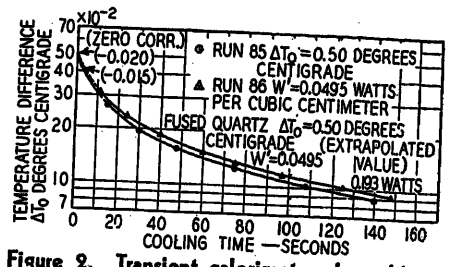

**Figure 2. Transient calorimeter d-c calibration with solid carborundum resistor, 2-minute runs**

His results indicated that (*a*) *assuming zero end conduction, the time constant of radial convection and radiation should be* about 725 seconds, and (*b*) *assuming the metal ends to be infinite heat sumps, the time constant of axial conduction should be about 150 seconds.* This latter value is of the same order as the measured time constants, indicating that the major portion of the heat is being dissipated axially. Because of space limitation, these mathematical studies of heat flow could not be included in the paper, but are available in report form. The fact that a major portion of the heat is dissipated axially should not prevent the use of the differential thermocouple to measure total heat if the thermal circuits have constant coefficients and if the test piece and calibrator are made of the same materials. When the test piece and calibrator are not of the same material the estimation of total heat is certainly less accurate.

(B). Time Function of Temperature Relaxation

We have not used the time constants of the temperature measurements to indicate heat generated, but have extrapolated the data to the time of removal of potential to obtain $\Delta T_0$. We have observed that the time constant of temperature relaxation changes with experimental conditions and that if the ambient temperature is changing the relaxation curves may not have the same slope or may not be exponential in form, however, we found that the extrapolated values of $\Delta T_0$ are effected much less than the time constants by such changes in ambient conditions. Considerable more work must be done to determine the ultimate accuracy of this method. The paper shows the check obtained for the absolute value of loss factor of fused quartz.

(C). Type of Calibrator

Since thermal conductivity of a sample is important, it was considered necessary to make the calibrator of the same material as the test piece or of a material having comparable thermal conductivity. No materials are available having sufficiently high volume electrical conductivity so that they could be used as calibrators which also have the same thermal properties as the materials being tested. A one-point calibration was obtained using a solid carborundum calibrator as shown in figure 2. The cooling curves were not exponential functions and the steepness of the initial slopes caused by its greater thermal conductivity made it difficult to determine the extrapolated value of $\Delta T_0$. Variations as great as 30 per cent could be made in this extrapolation. The value of $\Delta T_0$ as extrapolated in figure 2 when corrected for specific heat and density

agreed with the value of $\Delta T_0$ obtained from the fused quartz calibration curve for the same value of watts per cubic centimeter input.

Since the surface type calibrators gave more consistent data, we asked Doctor Poritsky to make a mathematical analysis of the temperature rise at the center of the uncoated portion assuming uniform heat input to the remaining surface and zero heat loss. The mathematics are too involved to be included here, but indicated a heat rise at this point of 2.8 degrees centigrade for a total heat input of 0.2 watts for 2 minutes. Likewise, if we assume uniform volume heating at 0.2 watts for 2 minutes and zero heat loss the average temperature rise should be 3.0 degrees centigrade. Therefore, the error resulting from surface heating is given by the ratio of 2.8 to 3.0 degrees centigrade. On the other hand we have already shown that heat dissipation to the ends is a much more important factor. This is again indicated by the fact that the measured value of $\Delta T_0$ was only 0.42 degrees centigrade for these conditions.

Whether or not this ratio of 0.42 to 2.8 remains constant is one of the important factors to be investigated more thoroughly. The independent check obtained in the case of fused quartz and the fact that measurements on other low-loss samples give consistent results between different samples of similar materials and yield loss factors of the order of magnitude anticipated indicates that the variation in this ratio may not be as serious as has been assumed.

Case II under "Calculations" was presented as a possible method of determining a value for loss factor for a material that was different from that of the calibrating body. Calibrators were made of several different bodies other than the quartz and Isolantite units described in the paper and correlation of the experimental data thus obtained led to the presentation of case II. We realize that this method is based on a limited amount of experimental data and that case I is the preferable method.

On the whole we are pleased with the initial results obtained with the transient calorimeter as reported in this paper. The complete development of a measuring technique built around this method obviously will require a large variety of samples. In the meantime we believe that with adequate manipulation and analysis that satisfactory results are obtainable.

## Automatic Boosters on Distribution Circuits

**Discussion and author's closure of a paper by Leonard M. Olmsted published in the October 1936 issue, pages 1083–96, and presented for oral discussion at the power distribution session of the winter convention, New York, N. Y., January 26, 1937.**

J. A. Brooks (New York and Queens Electric Light and Power Company, Flushing, N. Y.): The author has discussed in detail the application of automatic step boosters on 4-kv distribution feeders. I am inclined to agree with his views in the case of most rural circuits. That is, I feel that an automatic booster controlled by voltage relays is the solution to low-voltage problems where neither the feeder nor the bus to which the feeder is connected are regulated. In such a case, the voltage on the feeder is determined not only by the load on the feeder but by external conditions quite remote from the feeder itself. As a consequence, the feeder voltage is likely to have a large spread and voltage control for the booster must necessarily be the choice.

However, in the cases which the author describes, where the feeder voltage is held substantially constant at some feed point by induction regulators in the station, it appears to me that the possibility of current control for the boosters has been dismissed too lightly. The author states that current control operates on the principle that the voltage drop in the line is directly proportional to the current flowing. Actually, of course, the voltage drop depends upon 3 factors, they are: (1) The impedance of the circuit; (2) the current flowing in the circuit, and (3) the power factor of this load current. Of these 3 factors, the circuit impedance is a known constant and I submit that, for a circuit which feeds a suburban load, the power factor is also a constant for any given time of the day. With these 2 factors constant the only variable remaining is the load current. In my opinion, therefore, the assumption on which current control is based is accurate.

In the case which the author cites for a $2^1/_2$ per cent single step booster controlled by voltage relays it is shown that, due to an expected one per cent error in relay accuracy the effective boost obtained is only 1.5 per cent. This amounts to a reduction of 40 per cent in terms of the booster rating. If current control were used in this case and the relay error was the same—one per cent—the effective boost would be lowered by only one per cent of the voltage drop. Since the booster rating will be of the order of magnitude of the voltage drop, the relay error would result in a reduction in booster effectiveness of only one per cent in terms of the booster rating or one fortieth of that when voltage control was used.

P. E. Benner (General Electric Company, Schenectady, N. Y.): Mr. Olmsted has made a very interesting analysis of the application of boosters to the distribution circuits of the Duquesne Light Company. It should be noted that his particular problem was not one of economically regulating small loads and low-capacity feeders but consisted of supplementing the regulation of the feeder induction regulators at the substation. In this connection it would be well to differentiate between the low-capacity low-cost 10-per cent-range regulator and the low-range supplementary booster used in connection with the usual station-type feeder regulator. As shown by figure 1 the pole-type induction regulator and the small 4-step regulator were developed to make it possible to economically regulate small loads and low-capacity circuits. By means of these regulators, capacities as low as 10-kva can be obtained at approximately the same cost per kilovolt-ampere as the larger station-type regulators.

The booster on the other hand is strictly a supplementary device. A one-step booster can be readily arranged to give one $2^1/_2$-per cent fixed boost and one $2^1/_2$-per cent automatic boost. By following through the author's method of analysis, it will be seen that this arrangement gives exactly the same results as a booster having 2 automatic steps because theoretically the first step is always in. Therefore, there is no particular advantage in having the first step automatic. Moreover, the one step device lends itself to a much simpler control and should be especially attractive for this reason. Figure 2 shows several curves similar to those plotted in the author's figure 6. The curve on the one $2^1/_2$-per cent fixed and one $2^1/_2$-per cent automatic step booster has been extended to cover the same range as the $2—2^1/_2$-step booster inasmuch as the analysis shows it will produce the same results. It will be noted that the curves have been terminated so as to indicate the useful range of the device in question. Extending the curves horizontally to the right-hand margin might easily give the impression that the device was economically applicable for the entire variation of primary voltage, whereas it is believed that it would be very questionable to say the least to use a device which did not make full use of the permissible primary-voltage variation.

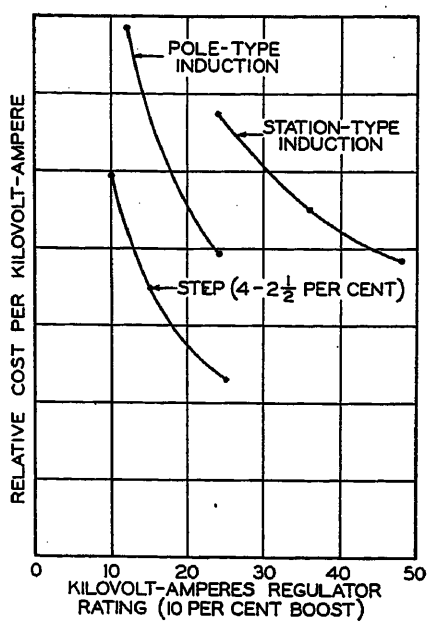

Figure 1

It is believed that further consideration should be given to the analysis by which the author concluded that the 2—1.33-per cent step booster would give the most economical operation for a primary voltage variation of 5 per cent. Figure 3 shows the factors entering into this analysis. The primary voltage varies from 100 per cent to 105 per cent. The booster is selected on the basis that its range plus the band width of its control is equal to 5 per cent. As shown, the band width figures to be plus or minus 1.17 per cent and the range 2.66 per cent. It will be noted that at full load when the incoming primary voltage is 100 per cent, the booster would attempt to hold the outgoing primary voltage within the band width for which the control was adjusted. Ordinarily the voltage held would average somewhere near the center of the band-width setting. However, in this case because of the limited range the maximum voltage which could be held approximates the lower limit of the

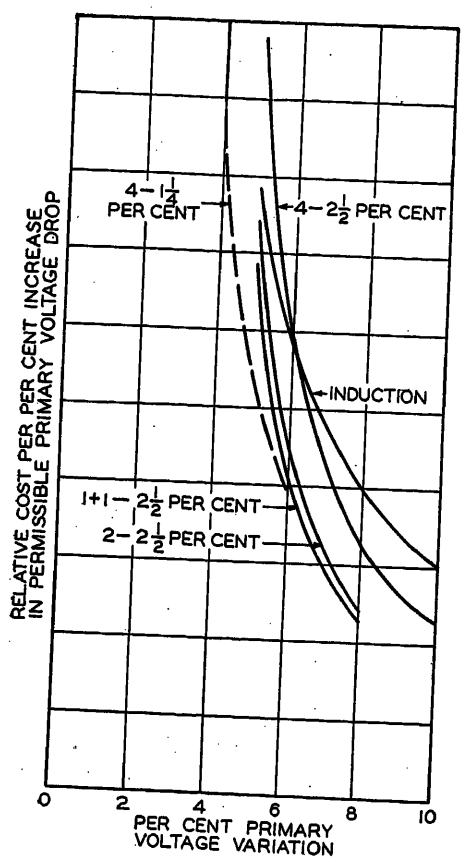

**Figure 2**

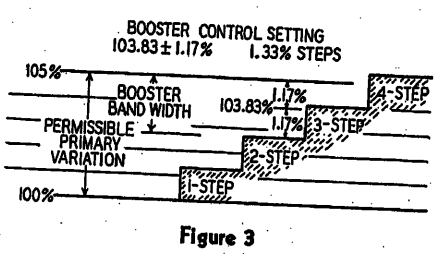

**Figure 3**

band which is a full one per cent lower than would be held if the booster had an additional one or 2 steps. It is believed that this extra one per cent in outgoing voltage is easily worth the extra cost of the larger range device. Referred to the cost of the device itself, if the first 2 steps is represented by 100 per cent the next 2 could be had for approximately an additional 30 per cent. In other words 2 additional steps, one of which as shown by the analysis would be in service at full load, would cost only about 60 per cent as much as each of the first 2 steps.

In view of this analysis it is believed that from the theoretical as well as the practical standpoint rule number 2 governing the selection of boosters should be changed to read, "The voltage range of the booster should be approximately the same as the permissible primary voltage variation in order to allow the booster to hold the maximum voltage possible."

The author has admittedly been conservative in regard to the amount of primary voltage variation permissible. It can be readily seen that the 5 per cent variation used in the analysis could easily be extended to 7½ per cent by assuming the difference in drop between the heaviest and lightest loaded transformers and secondaries to be 2½ per cent instead of 5 per cent. It should be noted that line-drop compensation would be necessary to take advantage of this increase in range from 5 per cent to 7½ per cent. That is, the booster or regulating device would hold voltage not at the point where it was located, but it would compensate for a portion of the distribution transformer and secondary drop.

From a practical standpoint it is obviously desirable wherever possible to use a regulator or booster having a range and size of step applicable to average rather than specific feeder conditions in order to permit a degree of standardization which will justify the low price levels desired on this type of equipment.

**L. H. Hill** (Allis-Chalmers Manufacturing Company, Milwaukee, Wis.): Mr. Olmsted is to be congratulated on having presented a paper which includes considerably more fundametal data than would be indicated by the title of his paper. Ever since the introduction of step voltage regulators, there has been considerable discussion concerning the use of time delay in the control; and Mr. Olmsted shows conclusively that the use of time delay will give good results from a regulation point of view. He also considers the effect of primary relay setting on the number of operations and also the size of step that can be used. His analysis of the effect of size of step on the range of regulation is general and would apply to any type of regulator.

It might be pointed out in connection with figure 5 that since Mr. Olmsted's conclusions are drawn on the basis of a regulator with 5-per cent range, the 8-step regulator would provide a ⅝-per cent step instead of a 1¼-per cent step for this application, in which case the relative effectiveness curve would have been above the curve for the induction regulator.

Naturally since Mr. Olmsted's conclusions are based on a total of 5 per cent regulation, it is necessary to point out that other conclusions might be reached for regulators of the conventional 10-per cent range, such as are needed on more rural-type lines.

It should also be pointed out in connection with figure 6 concerning the relative costs of various automatic voltage boosters the conclusion might be drawn that the size of step were the only variable. As a matter of fact, these costs must be based on equipments made by different manufacturers, and it cannot be assumed that the cost of the various mechanisms is comparable. Actually, there is considerable difference in the quality of mechanism in booster regulators of various steps. There seems to be an impression abroad on the part of some designers—and also operators, for that matter—that the tap-changing mechanism in a branch feeder regulator can be something light and flimsy, simply because it is used for branch regulation. It might be admitted for sake of argument that a regulator on branch service may not operate as frequently as one used for station type service; however, the branch type regulator will undoubtedly operate for much longer periods of time without inspection. The very nature of the application—mounted on poles in more or less inaccessible places—means that inspection and maintenance will be at a minimum; and it will not be unreasonable to expect that branch feeder regulators in many cases will operate for long periods of time without any inspection or maintenance whatever. Accordingly, it is my opinion that the mechanisms used in branch feeder regulators must be of the same order of quality as the tap changing mechanisms used in station-type regulators.

**L. M. Olmsted:** Before replying to the discussions, I wish to correct 2 errors in the published article. In figure 8, the per cent regulation from *B* to *C* should be 3.00 per cent instead of 2.66 per cent. In table II, the relay-band widths should read ±1.00, ±1.10, ±1.25 and ±1.38. It is well to observe also that table II presents estimated data and that a series of experiments intended to check them is under way but not yet completed.

I agree with Mr. Brooks' statement that voltage drop in a distribution feeder depends upon (1) impedance of the circuit, (2) current flowing in the circuit, and (3) power factor of the current. It must be observed, however, that the purpose of a booster on a regulated feeder is to correct for voltage drop between the feeding point and the booster. If there is no load tapped off the circuit between these points, then the current through the booster provides a fairly accurate measure of this voltage drop and could be used to control the booster. Usually most of the load is fed from the circuit between the feeding point and the booster, however, and a considerable part of the voltage drop is caused by load current which does not pass through the booster. In such cases the current through the booster is not an accurate measure of the voltage drop and could be used to control the booster only if the characteristics of loading on the circuit are such that the current flowing through the booster is always proportional to the voltage drop between the feeding point and the booster. For example, assume a circuit passing through an industrial section and into a residential area; voltage is low in the residential area and a current-controlled booster is installed between the 2 areas to correct it. With the relay adjusted to give satisfactory night-time voltage, the residential area might continue to get low voltage during the daytime because its day load might be too light to operate the booster to correct for the voltage drop caused by the low-power factor day-time industrial load between the feeding point and the booster.

It is quite true that the great spread between light-load current requiring no boost and heavy-load current requiring boost might permit a relay setting which would sacrifice less than one per cent of the circuit voltage, but the necessity to allow for disproportionality between booster current and voltage drop could very easily eradicate this advantage. Such considerations led the author to write that "the accuracy with which the voltage is regulated (by current control) depends upon the consistency with which the distribution of load along the circuit is duplicated from day to day. This limitation is overcome by voltage control. . . . . ."

Mr. Benner has advocated the use of boosters having one permanent step and one automatic step in place of 2 automatic steps. Undoubtedly the first booster on a

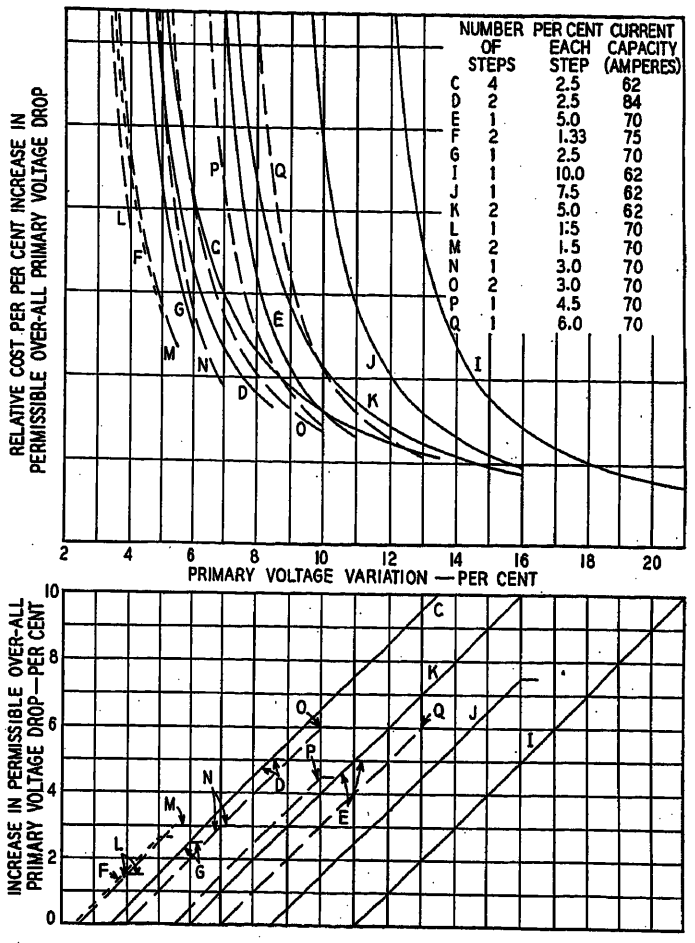

Figure 4

circuit could be of this type, but a second booster in series could not have a fixed step without causing high voltage during light-load periods. A booster having a permanent step cannot be set on neutral and bypassed out of service without interrupting customers beyond the booster. Furthermore, it is difficult to avoid some phase unbalance on long circuits, and a permanent booster might tend to increase the voltage on a phase already high on account of unbalance. The difference in cost is not large, and it is doubtful whether the savings offset the disadvantages.

Mr. Benner's criticism that the limited range of the 2—1.33 per cent step booster results in a full one per cent lower output voltage than could be secured by a 4-step booster is minimized by the fact that the input voltage of 100 per cent, upon which it is founded, actually is the lower limit of a 101 ± 1 per cent voltage band and would exist for comparatively short periods. It is well to note, however, that 4 0.8 per cent steps would hold the output voltage at 104.1 ± 0.9 volts with a lower limit 0.54 volts higher at a relative cost only a little higher than the 2 1.33 per cent steps. Of course 0.8 per cent is not a standard step, but as long as a 4-step regulator with a total range of 5 per cent or less is not standard anyway, I see no reason why the step size should not be selected for the application.

Obviously it is desirable to use a regulator or booster having a range and size of step applicable to average rather than specific feeder conditions. The very fact that these standard ratings have been found so grossly inadequate for applications having limits admittedly close but not unusual leads one to wonder whether a more generally applicable set of standards might be developed. Mr. Benner has noted that the problem "consisted of supplementing the regulation of the feeder induction regulators at the substation" and that the booster was developed for this purpose. Why, then, was a total range of 10 per cent incorporated into the design? The diagrams show the curves of figures 5 and 6 of the paper (corrected for price changes) extended to show the full range of each device. Note that a primary voltage variation of 21 per cent is necessary to secure the full effectiveness of a 1–10 per cent step booster. Surely so great a variation in primary voltage is excessive for any system. If we limit the primary voltage variation to 14 per cent, which certainly could not be considered too close, we find the 1–10 per cent step booster completely outclassed, both in effectiveness and in relative cost, by the 1–7.5 per cent and the 2–50 per cent step boosters although neither is used to its maximum effectiveness.

Boosters of somewhat less range designed for maximum effectiveness at 14 per cent primary voltage variation would have either 1–6.5 per cent step or 2–4.33 per cent steps and the relative cost, taking the price as that of the corresponding standard ratings, would be from 10 to 18 per cent lower because of the increased effectiveness. Following the present established practice of having taps at the quarter points on the one-step design, and of having a series-parallel connection on the 2-step, we would find steps of 1.62, 3.25, 4.88, and 6.50 per cent on the one and steps of 2.16 and 4.33 per cent on the other. These steps are somewhat more adaptable to the close limitations discussed in the paper than are the steps at present available on standard equipment, and indicate that compromise ratings might be found which would prove entirely satisfactory for both types of application. It is suggested that this compromise rating have 1.5, 3.0, 4.5, and 6.0 per cent taps, with a choice of one-step or 2-step tap changers. People requiring close regulation could use 2–1.5 per cent steps to secure a maximum of 3.0 per cent increase within a primary voltage variation of 5.5 per cent. People requiring maximum correction at minimum cost could use 1–6.0 per cent step to secure an increase of 6.0 per cent within a primary voltage variation of 13.0 per cent. Intermediate requirements could be satisfied by 1–3.0 per cent or 1–4.5 per cent step, or 2–3.0 per cent steps. The dashed curves based upon prices of corresponding capacity in standard ratings, show that these proposed steps lower the relative cost of booster operation within 5.0 per cent limits practically to the 2–1.33 per cent special design, and yet can be applied to the wider limits for which the present standard designs are suitable with no increase in relative cost.

Inasmuch as the amount of boost has been reduced, the largest rating of booster in the 2,400-volt class would be 104 amperes at 6.0 per cent or 15 kva, permitting standardization upon the 3 capacities of 5, 10, and 15 kva in place of the present 4. It is my opinion that such a change would be of decided benefit to the industry.

I agree with Mr. Hill's suggestion that 8–$^5/_8$ per cent steps would be more suitable than 8–1$^1/_4$ per cent for the application discussed in the paper. It would not lower the relative cost as much, however, as the one- and 2-step boosters with a total range of 6.0 per cent. Automatic voltage boosters do not receive the same attention in service as the station-type voltage regulators, consequently must be simple and sturdy, approaching as nearly as possible the reliability of distribution transformers. In my opinion time delay is valuable in that it tends to reduce the number of operations, thereby minimizing wear and increasing the time which can be allowed between inspections. Recently a spot welder has been connected on the single-phase extension of the booster application described in the paper, which varies the primary voltage almost 3 volts, and the time delay has proved very desirable.

## Trends in Distribution Overcurrent Protection

**Discussion and authors' closure of a paper by G. F. Lincks and P. E. Benner published in the January 1937 issue, pages 138–52, and presented for oral discussion at the power distribution session of the winter convention, New York, N. Y., January 26, 1937.**

H. P. Seelye (The Detroit Edison Company, Detroit, Mich.): At several points in this excellent presentation of the subject of co-ordination of overcurrent protection, the authors have mentioned the importance of economic considerations and of the rela-

tive amount of customer outage in determining the proper combination of devices. Some light on these factors has been gained from a recent study of outages on the Detroit Edison system.

The Detroit system is divided into 2 sections in which somewhat different conditions prevail. In the suburban part which includes a large number of smaller cities and towns as well as rural territory, the transformers are radial, that is each serving its own separate length of secondary, and are protected by primary fuse cutouts only. In selecting fuse sizes the emphasis has been placed on service continuity rather than protection to the equipment. The smallest primary fuse used is one of 8-ampere rating. This corresponds fairly well with the minimum of 5 amperes for a 20-to-1 ratio system which the authors of this paper have mentioned as giving proper co-ordination with the larger household fuses. The fuse itself is a cartridge fuse of special Detroit Edison design which has an appreciably greater inverse characteristic than the usual expulsion type shown in the curves of this paper. Over a 3-year period an average of only about 75 transformers per year out of a total of approximately 30,000 transformers have been burned out due to secondary short circuits or overload. This is about $^1/_4$ of one per cent. Of these, 38 per cent were $1^1/_2$ kva; 45 per cent, 5 kva; 15 per cent, 10 kva; 2 per cent, 15 kva; and a negligible amount of larger ones. The proportion between number burned out and total in service for each size is: $1^1/_2$ kva, 0.42 per cent; 5 kva, 0.29 per cent; 10 kva, 0.10 per cent; 15 kva, 0.08 per cent. It is evident that, for this system at least, the ratio of burnouts decreases rapidly with size and most of the burnouts occur on $1^1/_2$- and 5-kva sizes. For 15 kva and above the capacity seems to be large enough to burn off most faults.

An estimate of the cost of replacing and repairing burned-out transformers, compared with the cost of using secondary fuses for increased protection, showed that to accomplish any saving such a fuse must cost less than an amount ranging from 75 cents for a $1^1/_2$-kva down to 35 cents for a 10-kva including incidental material and labor of installation. A study of the curves given in this paper shows that it would be rather difficult with the conventional fuses to get much protection from such a fuse on the smaller transformers. As to the benefit to be gained in service continuity, on this system most of the $1^1/_2$- and 5-kva transformers serve only one customer so the loss of service due to their burnouts is not great. Also, the records available indicate that only about $^1/_2$ of the faults which would blow a secondary fuse, and hence interrupt service, do burn out the transformer, the other half clearing, whereas with fuse protection these would be likely to cause interruption.

In the city of Detroit, transformers are banked, that is, the secondaries tied solidly together and the transformers protected by both primary and secondary fuses in their leads. The paper points out the advantages of banking (page 147) in reducing voltage variations and the emergency duty thrown on any transformer and its protective equipment. It apparently favors the "loose" bank, however, with fuses midway between transformers rather than the solid bank, giving a number of reasons, most of which are not as serious in practice as they appear from a distance. It is true that solid banking requires somewhat more care in design than loose banking—for example, primary rings are quite a necessary accompaniment of large banks—but 30 years successful operation of this scheme in Detroit has shown conclusively that it is economical and effective in decreasing customer outage. Its advantage over the loose bank, in addition to maintaining service in case one transformer develops a fault, is that the capacity of 2 or more adjacent transformers is available to burn off a secondary short whereas, with the loose bank, the intermediate fuses are likely to blow, leaving conditions the same as for a radial system. Although cascading of a whole bank in such a case is a possibility which is frequently mentioned as a serious disadvantage, it actually occurs in relatively few cases.

A careful record of all fuses blown on the Detroit banked system over a period of 18 months, and involving about 20,000 transformers, showed only 5 cases of cascading in banks containing more than 4 transformers and in each of these only one side of the $^{115}/_{230}$-volt secondary was involved. Of the remaining cases, 50 per cent had only 2 transformers in bank, the remaining 50 per cent being about equally divided between those with 3 transformers and those with 4. In nearly all of these, the transformers were small and also usually only one side of the secondary went out. On the whole system, 267 transformers, or about $^9/_{10}$ of one per cent per year were involved in these outages but the actual service outage amounted to only half that in transformer-secondary units or $^{45}/_{100}$ of one per cent. The conclusion is evident that the bigger banks do burn off most of the faults which occur and that the best banks have more than four transformers, although of course it is not always practical to make them. Further study of this record showed that the solid banks allowed about 65 per cent less actual interruption than would probably have been experienced with a radial system, and 50 per cent less than with loose banks. Considering the small banks of 2, 3, or 4 transformers alone, the indications were that the solid bank was at least as good in this regard and probably a little better than either of the other schemes, there being many cases in which only one or two fuses were found blown without any service interruption, even where only two transformers were tied together. Transformer burnouts due to service shorts or overloads in this area are negligible.

This is not intended to disparage the "loose bank," which no doubt has its field. It is wished to emphasize what the authors have indicated in their paper that banking of transformers is an important means of improving protection to service and to point out that solid banking is practical and effective where it can be properly applied.

**E. J. Burnham** (General Electric Company, Schenectady, N. Y.): The paper by Lincks and Benner brings out facts and information which throw considerable light on the problems of overcurrent protection. By using these facts and studying the results much can be gained from the standpoint of the user and fromthe standpoint of the manufacturer.

Being somewhat familiar with the work which the New York Power and Light Corporation has done and is doing along the lines suggested in this paper, the following comments may be in order. Over the past 2 years this company has put in much hard work and effort studying their distribution system by districts to find ways and means of improving service to customers and doing it economically.

In studying a district the plan has been to first inspect the lines and make recommendations as to putting them into first class physical shape. This would include tree trimming where desirable, and seeing that crossarms, braces, and equipment on the poles were installed properly.

Secondly, decision would be made as to the type, rating, and location of overcurrent devices for each circuit in a district. This would usually mean several changes and some additional devices. Time-current characteristics were plotted for the fuses and devices, in manner shown in the authors' paper. Selections were made only after it was reasonably certain as shown by the curves plotted, that no fuse blowing would cause damage to another fuse or incorrectly cause a relay to operate and thereby trip a circuit unnecessarily.

This program has now been carried out over considerable time with what seems to be about 100 per cent results. In some of the long rural lines as many as 4 fuses have been placed in series. These might be rated for example—15, 25, 40, and 50 amperes. Some of the longer lines have been operating this way for about one year with good results as reported from the districts. However, steps are now being taken to improve the way of obtaining and reporting operating results to make sure the fuses and overcurrent devices are operating as expected. It is also the plan to obtain more information regarding the ratio of permanent to temporary faults for different circuits so the benefits to be derived from the use of reclosing devices may be determined. This seems to be a step in the right direction, because if it is worth while to spend much time and effort selecting and applying fuses and overcurrent devices, it certainly is worth while to get complete outage data and then analyze it to determine if the devices are operating as expected and also determine if any improvements can be made in the devices themselves or in the ways of using them.

**R. H. Earle** (Line Material Company, South Milwaukee, Wis.): There is a certain type of low-cost rural system now being built in different parts of the country which probably includes more of the interesting problems described by Messrs. Lincks and Benner than any other type of power distribution.

I refer to those systems in which power is delivered to individual farms through $1^1/_2$- or 3-kva transformers supplied by 4,800-volt or 6,900-volt single-phase grounded branch lines or subbranch lines. At the customer's service entrance 60-ampere fuse boxes are provided. The transformers have internal fuses and have spill-over gaps instead of lightning arresters. All branch lines have repeater fuses or reclosing breakers where the line branches off from the main feeder. When one of the gaps flashes over due to lightning the branch-line

fuse blows to clear the circuit. After a momentary interruption the next fuse of the repeater comes into the circuit and power is restored.

The 60-ampere fuse which it is possible for the customer to insert in the service box is considerably oversize for the initial load, which the customer is expected to provide and this 60-ampere fuse is, of course, too large to afford much overload protection to the transformer. The likelihood of this load increasing, however, warrants the large service fuse although first cost prohibits the installation of a larger transformer.

If the transformer fuse is installed inside the tank, it is important that the fuse co-ordinate with the 60-ampere secondary fuse and that it blow only in case of dire necessity because of the inconvenience of replacing the link. As a result the size of this link is selected so as to blow in case of a short circuit between service wires leading to the customer's house but to let the 60-ampere secondary fuse take care of less serious trouble.

The spill-over gaps that are used instead of lightning arresters require the system to be broken up into as small sections as possible so that when one of these gaps flashes over and blows a branch line fuse, only a few customers will be affected. This sectionalizing requires that the fuse links on the various branches and subbranches be spaced closer together than is ordinarily permissible. The result is that certain values of fault current will blow not only the nearest fuse but will also take out the next larger fuse in the series. A larger number of customers are affected than is entirely desirable, but since all fuses are of the repeater type the interruption of service is momentary.

A system of this kind obviously makes certain sacrifices in quality of service in order to reduce the cost of the lines to a point where it is possible to build them, and is a good example of the increasing demand being made on fuses for greater accuracy in co-ordination.

manent line faults varying from 64 to 85 per cent, 3 companies from 5.7 to 7.5 per cent, and in the case of the ninth company there seems to be more permanent faults than total faults on the circuits.

It would be very interesting to know more about the differences in conditions existing between 5 companies with high percentages of permanent faults and the 3 companies with low percentages. A great number of conditions might be responsible, such as nature of area served, type of construction, tree conditions, relay protection, etc. The differences are so great, however, that there should be some apparent reason for them.

The idea of instantaneous tripout on initial fault and time delay on reclosure is especially attractive from the standpoint of preventing permanent damage. It would be interesting to know from those companies using it, whether it has had any influence in this respect.

**L. M. Olmsted** (Duquesne Light Company, Pittsburgh, Pa.): Mr. Lincks and Mr. Benner have presented a very good account of the technique of co-ordinating overcurrent protection on a distribution system.

Similar studies by the Duquesne Light Company have indicated several difficulties, however, which might well be considered at this time.

The diagram below shows curves for a 10-kva 2,400-volt transformer serving an individual consumer. Full-load current on the secondary is 42 amperes, and inasmuch as it is common practice to permit loading up to 150 per cent of rating, this current may be as great as 63 amperes. The next larger commercial size of fuse is 100 amperes which size is taken as the basis of co-ordination. The secondary connections are 3-wire grounded-neutral and practically all of the consumers' load is connected line-to-neutral, consequently short circuits are practically all from one line to netural. This gives a transformation ratio of 2,300 to 115, so that 20 amperes primary current is equivalent to 400 amperes of secondary short-circuit current. Curves for 3 different types of 100 ampere secondary fuses are shown on this basis.

There seems to be a growing trend toward thermally tripped circuit breakers, however, and it is advisable to compare their characteristics with the curves of the fuses which they replace. The commercial size next larger than the 63 amperes load current for this 10-kva transformer is 70 amperes; corresponding curves are shown on the diagram. It is very evident that these devices are much slower blowing than fuses, which has permitted the sales feature of being less subject to tripping by motor-starting currents. The co-ordination of primary fuses, however, must be with the circuit breaker rather than fuses.

In order to provide some degree of protection to the transformer and secondary system, it is desirable to use a primary fuse of about 15 amperes continuous rating. The curves for four such fuses, each one rated for 100 per cent current and 3 of them universal, are shown as *A*-15, *B*-15, *C*-15, and *D*-15. *A*-15 co-ordinates with ample margin but has a rather high continuous carrying capacity. *B*-15 is very close at heavy currents but probably co-ordinates satisfactorily and has a more reasonable continuous-carrying capacity. *C*-15 and *D*-15 fail to co-ordinate for short circuits exceeding approximately 6 times full-load current. This comparison demonstrates the marked difference in characteristics for supposedly interchangeable fuses of different manufacture.

The comparatively recent agreement among fuse manufacturers to rate fuses for continuous operation at 100 per cent current might seem to offer some hope that the characteristics of fuses gradually will be brought into closer agreement. In that light it is unfortunate that manufacturers *B* and *C* both superseded a fuse with characteristics which would have co-ordinated

**G. B. Dodds** (Duquesne Light Company, Pittsburgh, Pa.): The authors have correlated a great amount of information relative to the protection of distribution circuits. The information they have obtained regarding outage data of various companies is particularly interesting.

As the authors have pointed out, there is a wide variation between the companies in the frequency and nature of outages. However, in one respect there is a disappointing similarity. This is in regard to the permanent line outages (per 100 miles of line) as shown in line 1, table II. Although the numbers vary greatly for the different companies, when they are compared with the total outages due to line troubles (per 100 miles of line) on line 1 of table I and expressed on a per cent basis of the total line faults, the results are alarmingly consistent for some of the companies. For example, comparing line 1 of table I with line 1 of table II, it is seen that of the total line faults, the following percentages are permanent for the various companies: 64 per cent, 61 per cent, 6 per cent, 65 per cent, 70 per cent, 7.5 per cent, 85 per cent, and 5.7 per cent.

It appears from these figures that 5 of the 9 companies have percentages of per-

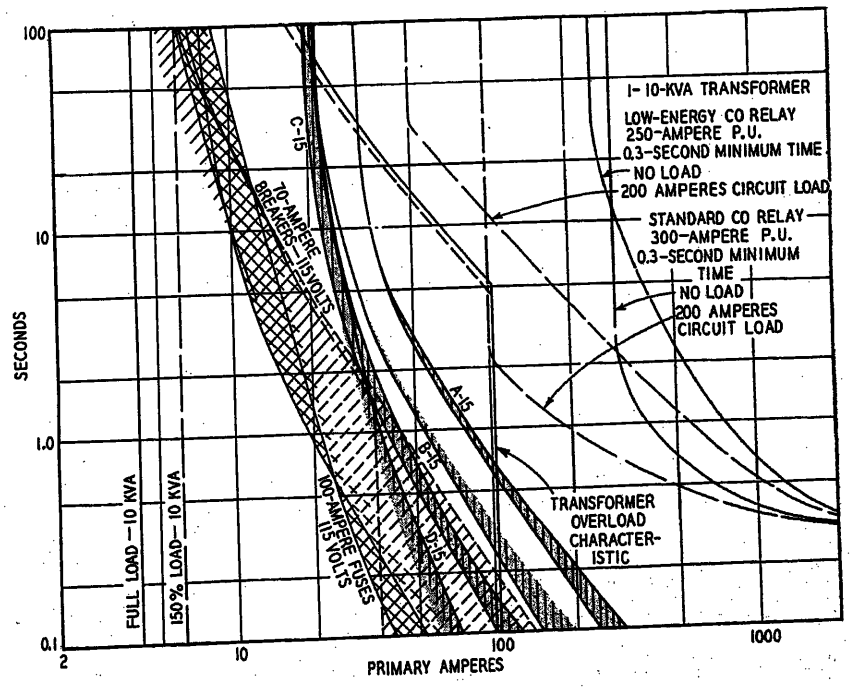

Figure 1

more satisfactorily when they introduced *B*-15 and *C*-15. There seems to be a decided trend toward "fast blowing" primary fuses, probably intended to afford better selective action between transformer fuses and line sectionalizing fuses. This trend is entirely opposite to the trend of consumers' overload protection and seriously complicates the co-ordination of primary and secondary protective devices.

**G. F. Lincks and P. E. Benner:** The authors greatly appreciate the contributions made by those discussing this paper. This should enhance its value for those interested in the improvement of service continuity on distribution systems.

It is assumed that the 100-ampere fuse and 70-ampere circuit breakers referred to by Mr. L. M. Olmsted, are those located at the meter board on the consumer's premises.

The design of the fuse links referred to as "*C*15" in Mr. Olmsted's discussion, was made to fit a scientifically developed set of time-current curves as shown in figure 4 of the published paper. In developing these, each fuse link was made to blow within 5 minutes at as low a percentage above the rating as possible and still carry the rating continuously and without exceeding a temperature rise of 30 degrees centigrade above an ambient temperature of 40 degrees centigrade. Motor starting acceleration time-current curves were plotted for motors representing 75 per cent of full-load current of a transformer fused with a fuse link rated at 2 times the full-load current, which is the lowest of the fusing practices developed and quite generally used by the utilities for the primary of distribution transformers. These practices apply to fuse links rated to blow at 150 per cent of their ratings within 5 minutes and a similar application was made in the development of the curves in figure 4

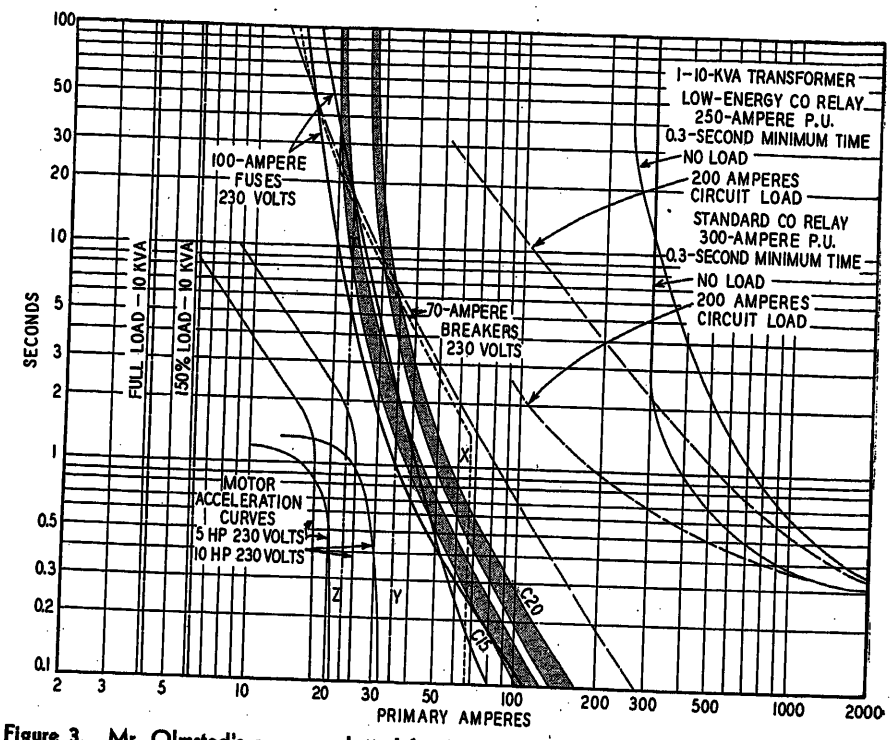

**Figure 3. Mr. Olmsted's curves replotted for 230-volt fault conditions and with 5- and 10-horsepower 230-volt motor acceleration curves**

of the published paper, although some fuse links were renamed later in order to meet the new 100 per cent continuous current carrying rating standards. Induction type relay curves approach these motor starting current curves in the range between one and 3 seconds, thus quite definitely locating the one-to-3-second range of the time-current curves for the fuse links best adapted to co-ordinate with both. The shorter-time, higher-current range of the fuse-link curves was made to co-ordinate with plunger-type relays of which there are many in service and with the interrupting rating of the fuse cutout for which the fuse links are designed. The curves for all ratings were made to parallel each other as closely as possible so the smaller fuse links will protect the larger fuse links to the highest currents possible when connected in series for line sectionalizing. The design of the actual fuse links was made so as to produce these scientifically developed curves.

In figure 2, the full-load full-voltage motor-starting-acceleration time-current curves for 3- and 5-horsepower 115-volt motors are plotted with a duplicate of Mr. Olmsted's curves for the 100-ampere fuses, the 70-ampere circuit breakers and the "*C*15" 15-ampere fuses. The 3-horsepower motor has a full-load current of 28 amperes or 65 per cent of the full-load current of the 10-kva transformer, thus closely approximating that used in the development of the "*C*15" curves. The full-load current of the 5-horsepower motor and 10-kva transformer are approximately equal. It can be seen that both of these motor-starting curves indicate successful co-ordination with the 100-ampere fuse, while the less inverse curves of the circuit breakers allow an excessively wide range above the motor-starting curves. As a result, these slower—less inverse—characteristics of the breaker prevent reasonably close co-ordination with branch-line plug or cartridge fuses (connected on either the line or load side) on the consumer's premises and, as Mr. Olmsted points out, interfere with the application of the primary fuse links scientifically developed to provide close co-ordination with both induction relays and motor-starting currents. Actual studies by the engineers of several utility companies have shown that slower (less inverse) primary fuse link characteristics than the "*C*15" curves will necessitate higher feeder circuit breaker relay settings, which

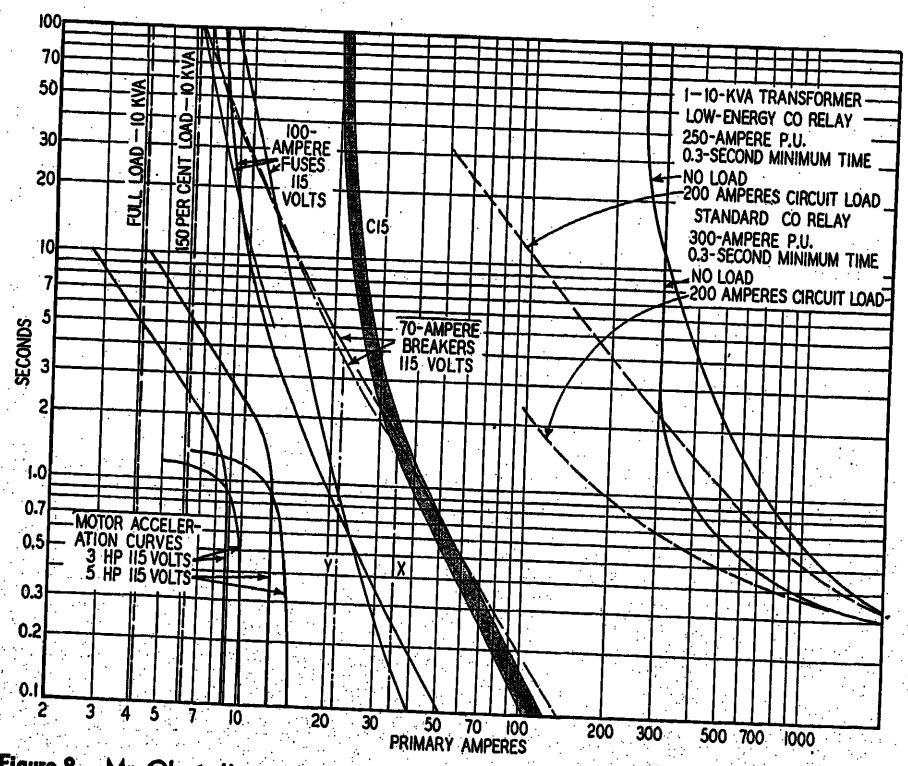

**Figure 2. Mr. Olmsted's curves replotted (115-volt faults) with 3- and 5-horsepower 115-volt motor acceleration curves**

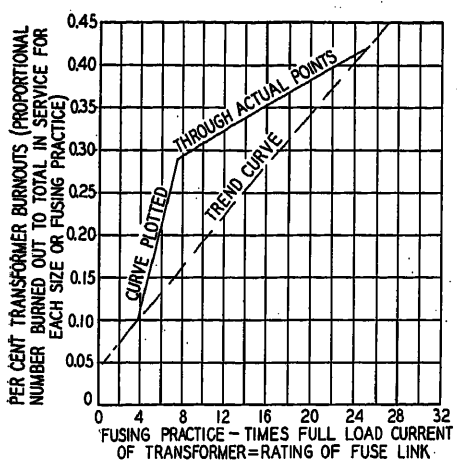

**Figure 4. Primary fusing practice—transformer burnout curve**

Based on using an 8-ampere fuse link with 1 1/2-, 5-, 10-, and 15-kva 4,800-volt transformers which Mr. Seelye states is the practice for the transformers to which the data in his discussion applies.

| Transformer Rating | Fusing Practice × Full Load | Per Cent Burnouts Per Size Installed |
|---|---|---|
| 1 1/2 | 25.0 | 0.42 |
| 5 | 7.2 | 0.29 |
| 10 | 3.8 | 0.10 |
| 15 | 2.5 | 0.08 |

in turn will interfere with the protection on the transmission system. This indicates the need for making the time-current characteristics of the secondary circuit breakers more inverse.

Mr. Olmsted has chosen the less conservative example on the basis that the majority of faults will occur between line and neutral (115 volts) where the transformation ratio for short circuit and surge currents is 20 to 1. Figure 3 illustrates the effect of line-to-line 230-volt faults for the same installation except with 5-horsepower and 10-horsepower, 230-volt motors having full-load currents of 23 and 43 amperes, respectively. It can be seen that a 20-ampere primary fuse link "*C*20" figure 3 is necessary instead of the 15-ampere fuse link "*C*15" in order to be protected by the 100-ampere cartridge fuse. However, this is not unreasonable when one considers that with the wide variation in the many different makes of cartridge fuses purchased on the open market out of the control of the utility engineer, the 100-ampere rating, in meeting the Fire Underwriters' specifications, blows at 150 amperes secondary current or 15 amperes primary current (150 per cent of its rating) within 4 minutes, while most 15-ampere primary fuse links blow at 22.5 amperes primary current (150 per cent of its rating) within 5 minutes. The curves in figure 3 show the conditions of figure 2 made worse by the lower transformation ratio, thus accentuating the need for speeding up (making more inverse) the characteristics of secondary circuit breakers for use on the consumers' premises, in order that as a comparatively new device entering the field, it may better line up with existing conditions and equipment.

The instantaneous trip shown by Mr. Olmsted for one of the 70-ampere circuit breakers, see curve *X* figures 2 and 3, as taken from Mr. Olmsted's curves, might be helpful on 115-volt faults if set to cut off at lower currents, see curve *Y* figure 2. However, as shown by curve *Y* figure 3, this does not appear to offer a solution on 230-volt faults, where the full-load current of the 230-volt motors closely approximates the full-load current of the transformer. With smaller 230-volt motors having full-load currents approximately 75 per cent of that for the transformer or even large 115-volt motors, the setting of the instantaneous trip might be made low enough, curve *Z* figure 3, to permit co-ordination with the motor acceleration curves and the "*C*20" primary fuse links of figure 3 but the co-ordination of branch line, plug, or cartridge fuses might prove difficult with such an installation.

With this background and to more directly answer Mr. Olmsted's question, the trend has been to faster time-current characteristics for primary fuse links during the past years,[1,2] so as to permit the closer co-ordination with existing induction type relays which many utility engineers have declared a vital necessity.

Mr. H. D. Seelye has made a real contribution in enlarging on the economies of secondary protection for individual transformers and outlining the advantages of the secondary banking, which he calls "solid," meaning with fuses in the secondary leads and not everything solidly tied together as is being used by another utility pioneering in this phase of secondary protection.[3] Mr. Seelye's data confirms that given in table I and II of the paper in showing that the normal primary fusing practices just mentioned are affording a high degree of protection to the transformer except for the lower kva ratings where the ratio of fuse rating to transformer full load current is much higher. The curve figure 4 shows how the percentage of transformer burnouts per size installed, as taken from the tabulation in Mr. Seelye's discussion, varies with the fusing practice. It is of interest to note that 3 of the points fall on a straight curve, indicating a trend which, of course, may or may not apply to higher-rated transformers. Mr. Seelye's records of the types of loading and any other causes for the higher percentages of burnouts with 5-kva transformers would be of value. Possibly, the increased use of 5-kva transformers for range and hot-water heating loads might be an explanation for the higher percentage of burnouts which, if true, would also raise the percentage of burnouts for 3-kva transformers above such a trend curve plotted for other utilities' systems where they are using these for similar loads. As Mr. Seelye indicates, the use of secondary protection depends on the degree of improvement in protection which can be secured and a comparison of the savings made possible thereby *vs.* the cost of securing these savings for the particular conditions pertaining on each specific system.

It was not the intent of the authors to favor the "sectionalized" or "loose" banking or any of the other types of protection covered in the published paper, but rather to investigate the effect of each of the trends in distribution protection so utility engineers may be better enabled to decide which best suits his requirements. If emphasis was placed on the "sectionalized" banking, it was because this method appears to predominate in the installations known to the authors and because it does permit securing the benefits without increasing the primary fusing practice. Actual service experience has proved that this latter is important for those wishing to sectionalize the lines now or in the future. Mr. Seelye points out that the so-called "solid" banking is best adapted to ring feeders where the secondaries of a large number of transformers are connected together which he states is not always practical to adapt to existing systems. He rates the "solid" and "sectionalized" or "loose" banking as equal where 2, 3, or 4 transformers are connected together, although having previously discounted the effect of each on line sectionalizing as discussed in the paper since he believes this is not a serious operating problem.

Mr. E. J. Burnham's discussion of the experiences of the New York Power and Light Corporation with fused line sectionalizing, which includes not only straight radial circuits but those that are more complicated and interconnected, exemplifies the growing trend toward this effective method of reducing consumer minutes outage. The improvements embodied in modern fuse cutouts and fuse links[1,2] along with the protective characteristic charts,[4] the total clearing time-current curves and the simplified methods of calculating the currents in primary line short circuits[5] now available have made primary-line sectionalizing with fuses practical even to a much greater degree than heretofore. Mr. Burnham supports the paper in stating that more actual operating data expressed in numerical terms are necessary to help toward the more effective application of this and other methods of distribution protection. However, as exemplified in Mr. Burnham's discussion, the practical and more general knowledge of utility engineers on the reductions in line outages by line sectionalizing when applied according to modern methods has placed this method of line protection beyond the experimental stage. In addition to the benefits mentioned by Mr. Burnham and in the paper, fused sectionalizing when applied in accordance with figure 12 of the published paper can be made effective in extending protection to the lines out beyond the point where the line impedance limits fault currents to values below the minimum pickup current setting of the feeder circuit breaker relay. Permanent faults might otherwise anneal the copper or actually burn down the lines.

Mr. G. B. Dodds has brought out an important point in regard to permanent *vs.* temporary faults. He appears to favor a system on which temporary faults predominate, whereas some other utility engineers have expressed their belief that the causes of temporary faults are subject to correction and thus believe permanent faults should predominate. Possibly this variance in viewpoint may influence the system design, which, along with the other conditions Mr. Dodds suggests, might be responsible for the difference between the 5 companies having a percentage of permanent faults varying from 64 per cent to 85 per cent and the 3 companies varying from 5.7 per cent to 7.5 per cent.

The authors appreciate Mr. Dodds calling attention to the misplaced decimal point in table II. In checking this table, other similar errors suggest reprinting the data in correct form.

Mr. Dodds expressed interest in the idea of instantaneous tripout on initial opening

**Table II. Comparison of Permanent Primary Line Outages with Distribution Transformer and Secondary Outages (Reprinted to Include Corrections)**

| Company | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 |
|---|---|---|---|---|---|---|---|---|---|
| 1....Permanent line outages (per 100 miles of lines) | 18.65 | 8.3 | 2.54 | 35.0 | 14.0 | 1.0 | 34.0 | 1.7 | 0.4 |
| 2....Distribution transformer and secondary outages (per 100 distribution transformers) | 7.2 | 4.1 | 8.7 | 5.6 | 8.1 | 0.9 | 7.8 | 3.0 | 11.6 |
| 3....Transformers per mile | 11.9 | 9.5 | 13.5 | | 10.7 | | 7.9 | | 8.9 |
| 4....Transformer outages for one mile of line due to permanent line faults | 2.22 | 0.79 | 3.43 | | 1.5 | | 2.68 | | 0.36 |
| 5....Transformer outages for a one-mile line due to transformer and secondary faults | 0.86 | 0.39 | 1.73 | | 0.87 | | 0.63 | | 1.03 |
| 6....Transformer outages for a 1/2-mile line due to permanent line faults | 0.505 | 0.20 | 0.83 | | 0.38 | | 0.07 | | 0.09 |
| 7....Transformer outages for a 1/2-mile line due to transformer and secondary faults | 0.43 | 0.20 | 0.86 | | 0.44 | | 0.31 | | 0.62 |

of the feeder circuit breaker and time delay on reclosure so as to permit branch line fuses to isolate permanent faults. The Toledo Edison Company have reported very favorably on their experiences which we believe extend over a period of several years. One or 2 other companies in that district have also adopted this scheme. Without doubt many engineers would welcome the publishing of any operating data they have accumulated.

Mr. R. H. Earle brings out an interesting trend in rural distribution with respect to a practice of wiring residences with 60-ampere meter switches and receptacles for future needs while installing low kva transformers rated for the present load. He states that the internal transformer fuses are selected to blow on short circuits between the service wires leading to the house. However, from the available published data, internal transformer fuses in the primary leads are usually rated too high to blow even on secondary line faults close to the transformer. Thus a secondary protective device is required if faults are to be cleared between the service entrance fuse and the transformer. As shown by curves $I'$ and $I''$, figure 9 of the paper, the rating of the internal transformer fuses is generally so high that there is very little, if any, range for sectionalizing the primary line even at one point. Thus the breaking up of the line into many sections even with the overlapping of fuse blowing as suggested by Mr. Earle, if possible at all, could only be accomplished by an extremely high setting of the feeder circuit breaker relay. On the other hand, the spillover gaps used for lightning protection require the positioning of the time-current characteristic curve for the relay, recloser or sectionalizing fuse, so it always functions on the lowest dynamic follow current at the gap furthest out on the line with sufficient speed to protect the gap. In many instances, this time-current characteristic curve is to the left of (faster than) the curve for the internal primary fuses in the transformer so the relay, recloser, or fuse on the primary lines operates ahead of the internal fuses. Under such conditions, all permanent transformer and line faults interrupt service on the entire feeder or the sectionalized portion. As explained in the paper some utilities, using the recloser for such service, shunt it manually with a fused cutout and fuse link rated high enough to permit the internal fuses to blow first when checking to determine whether the fault that caused the recloser to lock-out is on the line or in a transformer. Counters on such reclosers have indicated as high as 25 or more operations without lock-out in one lightning storm, evidently due to gap flashovers. Such operation would make impractical two or three reclosures on repeating fuses. The experiences of any utilities employing such fuses on this type of rural circuit would be valuable.

## Pole Flexibility as a Factor in Line Design

**Discussion and authors' closure of a paper by Howard P. Seelye and Myron Zucker published in the January 1937 issue, pages 91–100, and presented for oral discussion at the power distribution session of the winter convention, New York, N. Y., January 26, 1937.**

F. W. Deck (Philadelphia Electric Company, Philadelphia, Pa.): This paper is a distinct contribution to the advancement of our theoretical knowledge in a field where practice has heretofore been based almost entirely upon experience and established precedent. It will be very helpful to those engineers whose problems permit the use of this theoretical knowledge of pole flexibility, to have available a theoretical basis upon which they can establish well-defined rules for the use of the men in the field. In some localities it may not be possible, due to the particular conditions involved, to utilize these theories, or it may not be necessary since their utilization is not demanded by the conditions encountered.

Within the Philadelphia Electric Company area, our engineering and operating forces have not so far encountered the need for a concentrated study of methods such as Messrs. Seelye and Zucker have developed, due to the fact that there has been a lack of the particular problem which the authors describe as existent in the Detroit district. In the development of standards for pole line construction, we have utilized the higher stress values which have been developed in the regulations and codes within recent years, and these values are leading to the use of smaller poles. It has not been necessary to make frequent use of the smaller size poles of other utilities as guy stubs.

Sometimes we "rake" the end poles of a line to a specified amount so that when the wire loads reach the normal tension at 60 degrees Fahrenheit the pole tops are in a vertical position. Of course, when heavy ice loads are applied, there is an additional deflection of the pole; but the pole, even designed thus as a semirigid structure, is not called upon to withstand a greater load than 60 per cent of the ultimate strength of the wire.

If the fixity of the pole in the ground can be precisely determined, and if no loads occur during either the period of construction or actual service which would cause a stretching of the wire to a point outside of the range covered by the initial modulus of elasticity, then the method of design prescribed in the paper can be used with accuracy. These factors, however, deserve attention and must be thoroughly taken into consideration in the application of the method described by the authors. If the pole in question is blocked against foundation movement, the likelihood of any considerable variation in its position at the base, from the fixed vertical, is very slight. However, it may not always be possible to block or concrete the base of these poles, and in such cases it is well to remember that the change of position of the top of the pole due to movement of the pole in the ground may lead to as great or even greater change in the span length, with the accompanying tensional changes in the wires than the actual flexing of the pole itself. Even if the pole is blocked below the ground line, freezing and thawing of the soil at the ground line is responsible for a difference in the resistance to movement of the base of the pole.

Also, if for some reason or other the wire is stretched during the construction to a point greater than the average tension sustained under normal conditions, the computation may be considerably in error unless some allowance for this change has been made in the selection of the wire modulus used. Heavy loading would also cause a plastic extension of the wire material and have something of the same effect. These wire effects are, however, much less pronounced in copper than in aluminum or in composite cables where aluminum is present.

A pole system is not necessarily constructed with such refinements that the effects of unequal construction loads can be entirely eliminated, and therefore it is possible that flexibility in the poles might be an

important contributing factor in this type of design, extending farther back into the line than the 2 poles of the span considered.

Wood as a material cannot be subjected to the ordinary principles of design with the same freedom as materials such as steel and concrete. The fibrous composition of wood raises shear to a much greater importance than in materials having a more crystalline and homogeneous construction. Longitudinal shear or shear parallel with the fiber, together with effect of defects in the wood on the distribution of shear are of the utmost importance in some types of wood design; and while they do not achieve nearly the importance in the cantilever pole used to support wires as they do in the horizontal beam, still they are factors not to be lightly dismissed. Their effect upon the section modulus to be used and consequently upon the proper cross section of the pole is worth while considering. Poles may when newly erected, and more frequently after they have been in service for some time, have a central section which is not of full value. The unit stresses allowed take care of these considerations to some extent, but not entirely so. The articles written by Mr. J. A. Newlin, of the Forest Products Laboratory, United States Department of Agriculture, are interesting in regard to these last points since they are the result of Mr. Newlin's long and varied experience in testing, designing, and using wood in all kinds of work.

With regard to the methods which are developed in the paper in determining the bending in the pole and the final position of equilibrium, it is well to remember that in cases where lateral as well as transverse loads come upon the same pole, sometimes at different levels, the "deflection constant $p$" is affected and should be either a partial constant for each direction of bending or else a combination constant for the resultant direction of bending. If these loads are applied at different levels, the determination of the combined bending effect is somewhat more involved, but some answer to this question must be determined, or else only a part of the stress in the pole will have been considered and hence the computations may be in error.

This paper should arouse great interest among those who have to do with the design and construction of wood-pole lines, and should encourage studies and experiments to determine the movement of a pole in the ground when the pole is not blocked, and where average types of soil are encountered. Further studies should also be developed to show the combined effects of vertical and horizontal longitudinal and transverse loads occurring simultaneously. Also, in this connection it would be interesting to know the magnitude of the actual guying effect which the supported wires provide against lateral transverse deflection in the individual poles in a long line of poles.

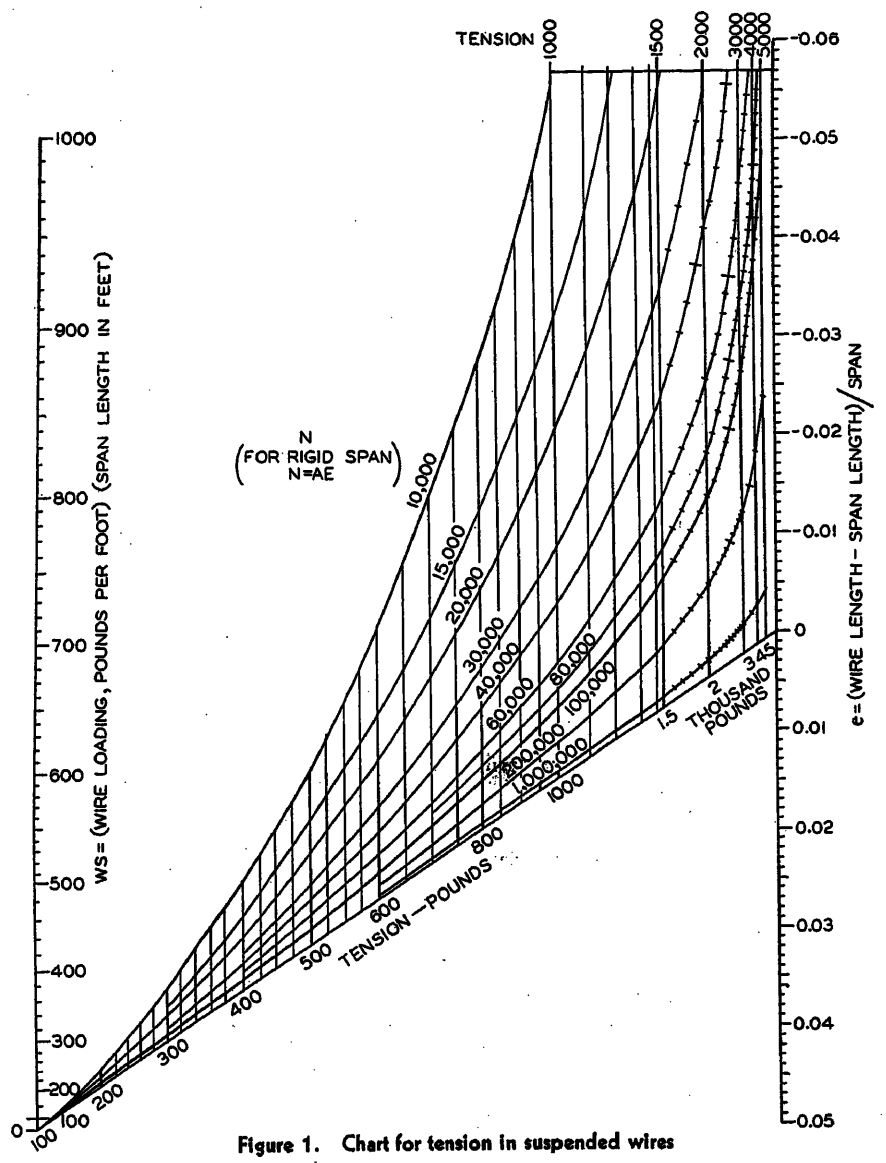

Figure 1. Chart for tension in suspended wires

**A. B. Campbell** (Edison Electric Institute, New York, N. Y.): The presentation of this paper offers a needed opportunity to discuss wood-pole flexibility in connection with the design of overhead lines. Since the second edition of the National Electrical Safety Code was published about 20 years ago, it has contained a general requirement that did not permit taking into account the deformation or deflexion of any part of a supporting structure in the calculation of stresses. This requirement has been included in subsequent editions. Inasmuch as this code forms the basis for the minimum construction requirements in force by several state regulatory commissions, the requirement just mentioned is given legal status where this part of the code has been adopted.

Actually, flexibility is oftentimes desirable in the supporting structure of an overhead line, particularly when these supports are wood poles. It constitutes one of the greatest assets of a structure in resisting ice and wind loads, and probably is the explanation why many lines have not failed when theoretically they might have been expected to do so.

The code requirement referred to above has made it necessary to assume a wood pole as a rigid structure. Compliance with this assumption has usually been obtained by the use of guys or braces, some of which have in themselves introduced electrical conditions that have resulted in conductor failures which the installation of the guys were intended to prevent. Furthermore an attempt to make a wood pole into a rigid structure by the use of guys which are not required to support a constantly unbalanced load, is likely to introduce a mechanical condition which prevents the distribution and equalization of stresses throughout the pole and thus causes failure at or near the point where stresses are concentrated. There is little doubt but that a rigidly guyed pole is less capable of withstanding impact loads than one which is free to deflect within reasonable limits under load and then return to its normal position when the load is removed.

This is one phase of the problem. Another is that no generally accepted method has been developed which would make possible a precise solution. Attempts have been made and considerable thought given to the problem but several factors are involved which make an exact solution impossible. For example, the effect of moisture content in the pole and the varying conditions in earth settings are not only difficult to evaluate but vary from day to day. It is well known that a relatively small longitudinal movement of a pole top can result in excessive conductor tensions or greatly reduced clearances. Since this effect would vary quantitatively with weather conditions, no exact method of calculating this effect seems possible. Therefore the code rule previously

referred to was perhaps the best method known at the time the code was formulated to hold variations in sags, tensions, and clearances within desired limits.

The past several years have furnished a wide experience in the performance of wood poles under normal loading and storm conditions. In my opinion some of the conditions for which guys are used seldom occur and when they do the guyed pole, when properly selected, seems to possess the ability to equalize stresses and remain unbroken. For this reason I favor the omission of unnecessary guys and the use of an approximate method such as the authors of this paper have developed whereby a reasonable advantage may be taken of the inherent flexibility of a wood pole structure. It is to be hoped that further attention will be given to the subject covered by this paper and an effort made to co-ordinate loadings with the flexible characteristics of wood pole structures.

**H. P. Seelye and Myron Zucker:** Mr. Deck has summarized the elements that must be considered in designing flexible spans. However, it must be emphasized that while such items as load distribution up the pole, strength of pole foundations, elastic limit of the wire, and pole constants enter into the problem, they are by no means indeterminate.

In discussing these variables, the governing fact is this: a relatively great variation in deflection constant will cause but little change in the relation between stringing and loaded tensions. Therefore, pole and foundation movement per unit load need be determined only with reasonable accuracy. The 2 elements of uncertainty in pole flexure are variation of fiber stiffness, and vertical distribution of load. The former is admittedly a variable, although not to quite the extent that might be indicated by tests on small specimens. Deflection constants derived from tests on 15 full-size poles have agreed within ±25 per cent of calculated values. As to the latter, a reasonable approximation may be made, for wires in the same zone, by using the deflection constant for a load height equal to the square root of the sum of individual heights squared. For more widely separated loads or loads in different directions an analysis of deflections may be made. It is relatively complicated and requires solution by successive approximations as described in the paper for joint-use leads.

As to foundation movement, the results of several short-time and numerous long-time full-size tests have enabled us to specify foundation designs for various types of soil and ranges of load, so that poles may be held with a negligible or reasonably predictable foundation yield. Considering the relative unimportance of deflection constant, mentioned at the beginning of this paragraph, the accuracy is well within the limits assumed for standard loading conditions.

It is of course possible to stretch wires past their elastic limit. However, the tendency for this to happen is less in flexible spans than in rigid spans where the effect is generally neglected. In addition, a study of $N$ will show that the wire stretching is generally a minor factor compared with pole bending.

Straight-grained woods are greatly to be preferred for holding dead-end loads, since their moduli are more consistent and they yield less initially and over a period of time than do knotty poles, due to the large bending effect in the latter when moderate loads straighten out the curved fibers surrounding the knots.

Informal discussion has shown that a chart in terms of tension instead of sag is needed for convenience in calculation. Substituting equation 6 in equation 5 gives the relation

$$e = \frac{w^2S^2}{24T^2} - \frac{T}{AE} \qquad (5a)$$

This may be charted as in figure 1, which is manipulated in the same manner as figure 9. Thus, with $w_1S$, $N$, and $T_1$ known $e$ is found; appropriate changes are made in $e$ for temperature variation and external forces; and then with $e'$, $N$, and $w_2S$ known, $T_2$ is read. The chart may be used whenever tensions are involved, and is especially valuable when tension is specified under one set of conditions and is to be found for another set. The range of figure 1 may be extended by using any desired scale multiplier on the $wS$, $T$, and $N$ values (not affecting $e$).

Mr. Campbell mentions some variables—moisture content and pole setting—which are difficult to evaluate. This difficulty must be admitted, but it applies equally well (as do the points enumerated by Mr. Deck) to the design of poles for transverse loads. The uncertainty of actual loads and the judgment needed in specifying safety factors overshadow the other unknowns in both cases. At any rate, satisfactory results have been obtained with numerous special cases of flexible dead ends designed according to the principles outlined in the paper.

Mr. Campbell's comments bring out the advantage of flexibility under certain conditions and point to the fallacy of the common idea of "being on the safe side." This reinforces the thesis of the paper: that calculation of dead ends on the assumption of rigidity may actually make some elements in the line undersize. Regardless of the merits of unguyed poles, it is certain that where they *are* used, the design should be based on the fact of flexibility rather than the fiction of immobility.

## A Review of Overhead Secondary Distribution

**Discussion and author's closure of a paper by W. P. Holben published in the January 1937 issue, pages 114–22, and presented for oral discussion at the power distribution session of the winter convention, New York, N. Y., January 26, 1937.**

**Harold Cole** (The Detroit Edison Company, Detroit, Mich.): Mr. Holben's paper is, I think, a valuable addition to the technical information on the matter of secondary-distribution economics. The secondary wires and their associated transformers form such a large proportion of the investment of an electrical distribution system that the importance of sound engineering in this field cannot be overemphasized. The comparison of the results of studies made on 5 large systems shows very little difference in conclusions, despite some rather wide variations of assumptions as to cost factors. The interesting thing is that the investigators agree that wire sizes from number 4 to number 2 are the most economical for the densities of load found largely in urban districts, and that through a rather large range of load densities there is not a great variation in the relative cost of the secondary distribution system, no matter whether number 4, number 3, or number 2 wire is selected, providing, of course, that the transformer size and spacing is selected to give the minimum cost of the combination of the 2. If the smaller wires are installed initially, the later cost of more frequent relocation of transformers or of secondary replacement, or both, offsets the initial saving in investment to a greater or lesser extent, depending on the rate of growth of load.

All of this would indicate that a rather wide latitude is possible in the proportioning of secondary copper and transformers without affecting greatly the over-all economy. The important thing to my mind, therefore, is that a program of development is laid out that is best suited to the conditions in the particular area under consideration and that it is carried out under intelligent supervision. Haphazard development results in costly rearrangements later on or else perpetuates uneconomical layouts made in an effort to take care of the immediate necessity at the least cost without consideration of over-all economy.

An effective way of providing for an orderly development of the distribution system is to draw up master plans which show the location of all poles, transformers, secondary and primary mains in all areas which have been subdivided into city lots. If the facilities are built as required in accordance with these plans, the cost of the initial extensions may be slightly higher than would be possible with expedients which take account only of the cost of providing service to the few scattered customers first applying, but in an area which is expected to build up solidly in a few years, the added cost of later rearrangement of facilities amply justifies the slightly higher first cost.

In my own company we have prepared such master plans, not only for undeveloped areas but for the older sections of the city where replacement of poles will be required in the future. In this way, the relocation of transformers and replacement of wires may often be carried out at time of pole replacement at a minimum of expense. The planning of these layouts is supervised by an engineer of long experience in distribution design and every effort is made to adapt the layout to the type of load which may be expected to develop in that area.

In residential areas we have adopted number 2 copper wire as standard for secondary mains and initial transformer spacings are usually 700 to 800 feet. The initial transformers may be as small as 5 kva but where development is expected to be rapid or where range load will probably develop, we will use the 10-kva size. A spacing of about 800 feet is necessary with these small transformers if noticeable voltage dips caused by starting of small household appliance motors are to be avoided. Ability to give adequate voltage for electric ranges in the early development stages also requires spacings of this order. The same secondary

wire and transformer spacing will be adequate for load densities up to about 50 kw per 1,000 feet. It is only necessary to change transformer sizes as the load requires. We feel that any possible saving in the use of wire smaller than number 2 in the early development stages would not justify the poorer quality of service which would result, especially in view of the present trend to more complete home electrification with the increased use of appliances equipped with electric motors as well as the larger heating appliances which will ultimately result in much greater load densities. On the other hand, the use of conductors larger than number 2 does not seem to be required in residential areas, even with the increased load densities to be expected, as a relocation of transformers on number 2 secondaries will permit going to much higher densities when they develop before the system becomes uneconomical.

Incidentally, the banking of transformers on a more or less continuous secondary main, such as practiced in Detroit and now being rapidly extended to other parts of our system where conditions are at all favorable, is very helpful in many ways to the economical development of the system. Steady state voltages are more easily maintained on the secondaries and voltage dips due to motor starting are much less troublesome, to say nothing of decreased outages due to transformer failures and less transformer capacity required.

I want to emphasize that the orderly development of a distribution system requires a trained personnel to supervise that development. The men who are responsible for this development should be men of engineering training, and should not be burdened with so much detailed routine work that they do not have time to adequately study the engineering problems involved in additions to or changes in the system. The use of master plans, however, will be of much aid to these men in helping them to make rapid decisions and still not overlook some important considerations which would not escape one who had sufficient time to study all of the conditions involved. The field engineer need then only concern himself with situations where new considerations develop which make it desirable or necessary to modify the original plans.

I want also to urge the importance of making studies such as those reviewed by Mr. Holben for each particular system. I do not wish to minimize the value of the presentation of such a review but there is some danger, I think, that some of the general conclusions may be misinterpreted by those who have not carefully studied all aspects of the problem. A study which takes account of all of the local field conditions and operating practices will make certain that development plans will be adopted which are best suited to the particular system.

W. P. Holben: Mr. Harold Cole, in his discussion of the paper "A Review of Overhead Secondary Distribution," has presented a number of points that are worthy of serious consideration. In fact, I am heartily in accord with these items as well as the results to be obtained by using his recommendations and will therefore repeat them in outline form.

1. Importance of sound engineering to include studies for each particular system
   - *a.* To account for all local conditions
   - *b.* To avoid misinterpretation of the general conclusions
2. Need for a program of development
   - *a.* Intelligent and experienced supervision
   - *b.* Master plans with future steps indicated
   - *c.* Procedure in new developments

The summary and conclusions, included in the paper, have stated some necessary exceptions to the principles recommended by the respective authors. There are other natural differences of opinion and local operating practices that will probably affect the application of these principles of design on various systems. Further study therefore along the following lines should provide valuable information and knowledge on the subject of overhead secondary distribution.

1. A classified list of necessary exceptions with the best engineering solution for the principal classifications
2. Flicker conditions and economical solutions.
3. Transformer loading practice and a summary of experience records especially for the higher per cent loadings
4. Banking transformers, single-phase, and 3-phase, for large appliance load to meet capacity and flicker conditions

Mr. Cole has referred to the practice of banking transformers in Detroit. He reports improved voltage conditions, decreased outages and less transformer capacity required for areas served in this manner. It is apparent therefore that such advantages warrant a thorough study of this type of a secondary system. Mr. Sweetman and Mr. Arnold have contributed the suggestion that the new development in transformer design and use of a secondary breaker for transformer protection warrants further development of secondaries with banked transformers at least on a trial basis. With a probable increase of flicker complaints as the appliance load increases, it follows that banking should be considered as a possible solution since this method cuts sudden voltage variations to approximately half of that experienced on radial secondaries under similar conditions.

## Negative-Sequence Reactance of Synchronous Machines

**Discussion and author's closure of a paper by W. A. Thomas published in the December 1936 issue, pages 1378–85, and presented for oral discussion at the synchronous machinery session of the winter convention, New York, N. Y., January 27, 1937.**

S. B. Crary (General Electric Company, Schenectady, N. Y.): This paper presents a very complete theoretical and experimental analysis of the AIEE method of measuring the negative-phase-sequence reactance and should result in a more accurate description of the method of testing by the AIEE.

Figure 1 of this discussion presents in a little different way than in the paper, the

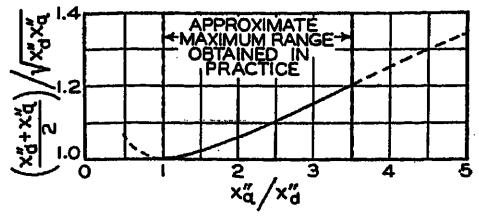

**Figure 1. Ratio of the 2 expressions for $x_2$ as a function of the ratio of the subtransient reactances. Full line indicates approximately the maximum range obtained in practice**

variation between the 2 limiting values of negative-phase-sequence reactance as a function of the ratio between $x_q''$ and $x_d''$. In this figure the approximate maximum range to be expected in practice is indicated by a solid line. As seen from this curve the maximum variation to be expected is about 20 per cent for a ratio of $x_q''$ to $x_d''$ of 3.5. This variation, of course, would decrease quite rapidly with increase in the amount of external reactance. Accordingly, the value $(x_d'' + x_q'')/2$ can be used for most practical purposes in system calculations involving this reactance.

J. C. Balsbaugh (Massachusetts Institute of Technology, Cambridge): Reference is made to the application of the negative-sequence reactance of synchronous machines to the study of power system fault currents. I should like to add several significant factors in the application of this reactance.

For a line-to-line fault in a power system as viewed from a generator, the negative-sequence reactance is given in general by the equation

$$x_2 = \sqrt{x_d'' x_q''}$$

in which $x_2$ is the equivalent negative-sequence impedance from and including the generator to the fault, $x_d''$ and $x_q''$ are the sum of the generator subtransient reactances $x_{dg}''$ and $x_{pq}''$, respectively, and the equivalent external reactance $x_e$. The negative sequence reactance $x_{2g}$ of the generator, is equal to $x_2 - x_e$ and is equal to the geometric mean of the generator subtransient reactance with $x_e = 0$, and approaches the arithmetic mean of the generator subtransient reactances with $x_e$ large relative to $x_{dg}''$ and $x_{qg}''$. The equivalent external reactance $x_e$ is not in general the reactance from the machine to the point of fault, but in a power system with a group of machines feeding into a fault through a network, it is the equivalent reactance as viewed from the generator terminals.

It is further important that the foregoing negative-sequence reactance does not apply in general to all line-to-line faults in a power system, but only those faults that are line-to-line faults as viewed from the generator terminals. Thus consider an individual generator tied to a line through a Δ-Y grounded transformer and a ground fault on the line. In this case a line-to-ground fault on the line becomes an equivalent line-to-line fault on the generator and $x_{2g}$ is determined as given in the foregoing, and $x_e$ must be determined as an equivalent impedance as viewed from the generator terminals.

It can also be shown that the negative-sequence reactance in general for a line-to-

**Table I. Definitions of Negative-Sequence Reactance**

| Method | Analytical Expressions | | Numerical Value $x_d' = 0.35$ $x_q = 0.70$ $x_d = 1.0$ | |
|---|---|---|---|---|
| | Fundamental | Root-Mean-Square | Fundamental | Root-Mean-Square |
| (1) Application of sinusoidal negative-sequence voltage | $\frac{2x_d' x_q}{x_q + x_d'}$ | $\frac{\sqrt{2}x_d' x_q}{\sqrt{x_q^2 + x_d'^2}}$ | 0.47 | 0.44 |
| (2) Application of sinusoidal negative-sequence current | $\frac{x_q + x_d'}{2}$ | $\frac{1}{2}\sqrt{(x_q + x_d')^2 + 9(x_q - x_d')^2}$ | 0.53 | 0.74 |
| (3) Initial symmetrical component of sudden single-phase short-circuit current | $\sqrt{x_d' x_q}$ | $x_d'(\sqrt{1-b^2}-1) + \sqrt{x_d' x_q}\times\sqrt{1-b^2}$ | | |
| (4) Sustained single-phase short-circuit current | $\sqrt{x_d' x_q}$ | $x_d(\sqrt{1-b^2}-1) + \sqrt{x_d' x_q}\times\sqrt{1-b^2}$ | 0.50 | 0.48 |
| (5) Same as (4) with 0.35 p.u. external reactance | | | 0.50 | 0.47 |
| (6) AIEE | | $\frac{x_q + x_d'}{2}$ | | 0.50 |
| | | | | 0.53 |

ground fault (as viewed from the generator terminals) in a power system is

$$x_2 = \sqrt{\left(x_d'' + \frac{x_0}{2}\right)\left(x_q'' + \frac{x_0}{2}\right)} - \frac{x_0}{2}$$

in which $x_2$ is the equivalent negative-sequence reactance from and including the generator to the fault, $x_d''$ and $x_q''$ are the sum of the generator subtransient reactances $x_{d0}''$ and $x_{q0}''$, respectively, and the equivalent external reactance $x_e$ and $x_0$ is the equivalent zero-sequence impedance from and including the generator to the fault and is equal to sum of the generator zero-sequence impedance $x_{0g}$ plus the equivalent zero-sequence external impedance $x_{E0}$ to the fault. The negative-sequence reactance of the generator $x_{2g}$ for the condition is equal to $x_2 - x_e$.

Thus it is seen that accurate determinations of negative-sequence impedances of generators for use in connection with fault studies in power systems involves the circuit connections and other system impedances. These and other considerations should be taken into account in the measurement of negative-sequence impedances of synchronous machines and in their application.

**C. F. Wagner** (Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.): Mr. Thomas is to be congratulated in raising the general question of the nature of the negative-sequence reactance of synchronous machines. A particularly valuable contribution is his analytical proof that the AIEE method of measuring the negative-sequence reactance gives a quantity equal to the arithmetic mean of the reactances in the 2 axes.

In reading this paper I have been prompted to make a table to show some of the methods that might be suggested to measure the negative-sequence reactance. In preparing this table a salient-pole machine without amortisseurs has been considered because the effects in question should be pronounced in such a machine. Resistances will be neglected. The first method consists in applying a sinusoidal set of negative-sequence voltages to the machine. Using the fundamental component of current in defining the reactance results in the expression[5]

$$\frac{2x_d' x_q}{x_q + x_d}$$

but if $x_2$ be defined in terms of the root-mean-square values the reactance is equal to

$$\frac{\sqrt{2}\,x_d' x_q}{\sqrt{x_q^2 + x_d'^2}}$$

However, if a sinusoidal set of negative-sequence currents be made to flow through the machine a fundamental and third harmonic voltage are set up across the armature. In terms of the fundamental component $x_2$[5] is equal to $x_q + x_d'/2$ and in terms of the root-mean-square values is equal to

$$\frac{1}{2}\sqrt{(x_q + x_d')^2 + 9(x_q - x_d')^2}$$

If $x_2$ be defined as such a quantity which with $x_d'$ will give, upon applying symmetrical components, the proper fundamental component of current for the initial a-c component of a suddenly applied single-phase short-circuit current, then $x_2$ is

$$\sqrt{x_d' x_q}$$

and to give the proper root-mean-square value of current $x_2$ is

$$x_d'(\sqrt{1-b^2} - 1) + \sqrt{x_d' x_q}\,\sqrt{1-b^2}$$

This is the method described in paragraph 184 of the Preliminary Report on a Proposed Test Code for Synchronous Machines (January 1937).

If $x_2$ be defined as that quantity which will give the proper fundamental component of sustained single-phase short-circuit current when the method of symmetrical components is used, then $x_2$ is again

$$\sqrt{x_d' x_q}$$

and to give the proper root-mean-square value of current, $x_2$ should be

$$x_d(\sqrt{1-b^2} - 1) + \sqrt{x_d' x_q}\,\sqrt{1-b^2}$$

The AIEE method which is also based upon the sustained single-phase short-circuit test but with different metering connections gives, as Mr. Thomas has shown, the value of $x_2$ as $(x_q + x_d')/2$.

It is difficult to draw conclusions of the relative merits of the different expressions until numerical values are inserted. To this end a typical machine was chosen having the constants

$x_d' = 0.35$
$x_q = 0.70$
$x_d = 1.0$

and the numerical values corresponding to the different analytical expressions were tabulated on the right-hand side of the table.

Let us now analyze these results in view of the utility of the quantity and the applicability of the method as a testing means. The greatest use of $x_2$ is in connection with short-circuit and stability studies. It would appear then that the results obtained by the root-mean-square values for the single-phase short-circuit tests, would be the most important, preference being given to the sustained value because it results in a somewhat smaller value of reactance and also, because it does not require an oscillograph, is an easier method to apply. The AIEE method gives a value of $x_2$ somewhat greater than the value obtained by the single-phase short-circuit test. With regard to the ease in making the test it will be noted that the only difference between the single-phase short-circuit method and the AIEE method is that the latter requires an extra wattmeter whereas the former requires a previous knowledge of the synchronous reactance. The difficulty of obtaining either a sinusoidal negative-sequence voltage or current would eliminate the first 2 methods as test methods.

I am therefore submitting this discussion for your consideration. It would appear that the sustained single-phase short-circuit test for root-mean-square values is a better test for salient-pole machines than the present AIEE method. In terms of the test values this quantity is expressed by the equation

$$x_2 = \frac{\sqrt{3}\,E}{I} - x_d$$

where

$I$ = root-mean-square value of armature current in the short-circuited phase
$E$ = open-circuit voltage before the short circuit is applied or the no-load voltage corresponding to the field current at which $I$ is read

For turbogenerators saturation introduces variables of such greater magnitude that the appropriate method of measuring the unsaturated value becomes inconsequential. Perhaps the best solution for turbogenerators is to simply use the subtransient reactance.

**W. A. Thomas:** I wish to emphasize the need of agreement on the use or abandonment of the per-unit system of notation. I have deliberately avoided throughout my paper such short-hand systems as per-unit or per-cent notation.

To a large group of engineers and especially to students who are reading the literature for applications of fundamental principles, such special systems are not easily understood. Some equations when written in a per-unit system lose their dimensional check and thus invite confusion.

May I suggest a return, in all synchronous-machine papers, to the use of fundamental units of voltage, current, and reactance?

# Two-Reaction Theory of Synchronous Machines

**Discussion and author's closure of a paper by S. B. Crary published in the January 1937 issue, pages 27–31, and presented for oral discussion at the synchronous machinery session of the winter convention, New York, N. Y., January 27, 1937.**

W. V. Lyon (Massachusetts Institute of Technology, Cambridge): Mr. Crary's method of analysis is particularly suited to transient conditions of operation. For some cases of steady-state operation a simpler method of analysis may be preferred. The criterion for self-excitation of a salient-pole machine when it is running synchronously ($s = 0$) with the field circuit open and delivering current to a balanced capacitive load having series constants of $R$ and $X$ was given in my discussion of "Synchronous Machines—I," by Doherty and Nickle, AIEE, page 947, 1926). In this discussion I said:

"There is a problem of some interest that the authors did not mention. It is that of a synchronous generator which, when feeding an open-circuited transmission line, loses its field excitation. If $R$ and $X$ represent the equivalent resistance and reactance of such a line on open circuit then it is readily shown for this case that

$$(R + r)^2 = -(X + x_q)(X + x_d) \qquad (1)$$

This shows that $X$ is capacitive and lies between $x_q$ and $x_d$. Since the values of $x_q$ and $x_d$ depend upon the saturation, a graphical solution of the foregoing relation can be made which will determine the saturation, and from that the terminal voltage can be found."

This equation 1 is derived from the equations which apply to the steady-state operation of a salient-pole synchronous machine.

$$\left.\begin{aligned} E &= (R + r) I_q - (X + x_d) I_d \\ 0 &= (R + r) I_d + (X + x_q) I_q \end{aligned}\right\} \qquad (2)$$

where $E$ is the excitation electromotive force due to the d-c field and $R$ and $X$ are the series resistance and reactance of the capacitive load ($X$ is inherently negative).

If $E = 0$ it follows that

$$(R + r)^2 = -(X + x_q)(X + x_d)$$

from which the critical value of $X$ for self-excitation is

$$X = \frac{-(x_d + x_q) \pm \sqrt{(x_d - x_q)^2 - 4(R + r)^2}}{2}$$

This agrees with Mr. Crary's equation 24. The greatest value of $X$ for which self-excitation can occur is determined by substituting for $x_d$ and $x_q$ their *unsaturated* values. If it be assumed that there is *no* resistance in the circuit, either $(X + x_d)$ or $(X + x_q)$ equals zero. Due to the effect of the reluctance toque, the machine will undoubtedly operate stably so that $I_q = 0$ and hence it is $(X + x_d)$ that equals zero. The synchronous reactance in the direct axis equals $x_m/k + x_a$, where $x_m$ is the unsaturated value of the magnetizing reactance in the direct axis and $k$ is the saturation factor (see "Saturated Synchronous Reactance," C. Kingsley, Jr., AIEE, March 1935). Consequently

$$|X| = \frac{x_m}{k} + x_a$$

or

$$k = \frac{x_m}{|X| - x_a} \qquad (3)$$

Since $x_m$ and $x_a$ are both constant, the value of the saturation factor for any value of $X$ numerically less than $(x_m + x_a)$ but numerically greater than $x_a$ can be found, and hence the electromotive force $E_a$ due to the resultant air-gap flux can be determined. The terminal potential $V$ is

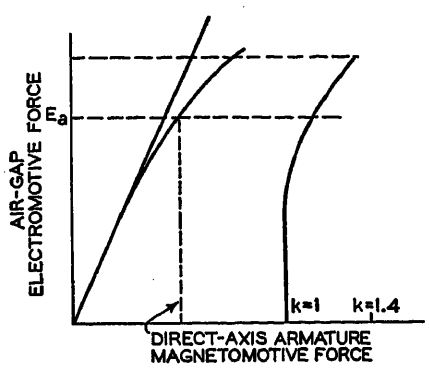

Figure 1

$$V = \frac{|X|}{|X| - x_a} E_a \qquad (4)$$

The resistance $(R + r)$ can be taken into account if desired, but the expressions are not as simple. In this case the stable operating point depends both upon the direct-axis synchronous reactance and upon the quadrature-axis synchronous reactance. It is necessary to assume in what manner *each* of these reactances is affected by saturation. As a first approximation assume that the magnetizing reactances in each axis are affected *equally* by saturation. That is, assume that

$$x_d = \frac{x_{md}}{k} + x_a \qquad (5)$$

$$x_q = \frac{x_{mq}}{k} + x_a \qquad (6)$$

This approximation is better when the resistance, $(R + r)$, in the circuit is well below its limiting value of $\frac{x_d - x_q}{2}$ for which condition the internal power-factor angle is 45 degrees and $I_d$ equals $I_q$. If these values of $x_d$ and $x_q$ are substituted in equation 1,

$$\frac{1}{k} = \frac{-(X + x_a)(x_{md} + x_{mq})}{2x_{md}\,x_{mq}} \pm \sqrt{\frac{(X + x_a)^2 (x_{md} - x_{mq})^2 - 4x_{md}\,x_{mq}(R + r)^2}{2x_{md}\,x_{mq}}} \qquad (7)$$

It follows that the greatest numerical value of

$$\frac{R + r}{X + x_a}$$

is

$$\frac{x_{md} - x_{mq}}{2\sqrt{x_{md}x_{mq}}}$$

This determines the greatest value of the power factor at the air gap in terms of the unsaturated values of the magnetizing reactances in the 2 axes. The sign before the radical in equation 7 must be taken so that $k$ is greater than one. If both values of $k$ are greater than one, the larger value should be chosen, since the flux will stabilize itself nearer the direct axis than the quadrature axis.

Consider the following numerical case: Let

$x_{md} = 0.85$ $\qquad X = -0.80$
$x_{mq} = 0.40$ $\qquad R + r = 0.20$
$x_a = 0.15$

Whence, using the minus sign before the radical, $k = 1.07$. If the plus sign is used before the radical, $k = 0.764$. The greatest value of $(R + r)/(X + x_a)$ is 0.386. From equation 2, since $E = 0$,

$$\frac{I_q}{I_d} = \frac{R + r}{X + x_q}$$

The tangent of the angle between the axis of the field pole and the axis of the fundamental component of the armature flux is

$$\frac{I_q\,x_{mq}}{I_d\,x_{md}}$$

and in this numerical example is

$$\frac{0.20}{-0.80 + \frac{0.40}{1.07} + 0.15} \times \frac{0.40}{0.85} = 0.341$$

The displacement of the armature flux with respect to the field poles is 20 degrees. This small displacement tends to justify the assumption that saturation affects the magnetizing reactances in the two axes equally.

There is another point that I wish Mr. Crary would discuss. It is well known that an induction generator may self-excite on a capacitive load. With a cylindrical rotor there is no tendency of the rotor to occupy one position rather than another with respect to the rotating armature magnetomotive force. On the other hand, there is a strong tendency for the rotor of a salient-pole machine to lock with the rotating armature magnetomotive force and run so that the quadrature component of the armature current is just sufficient to satisfy the condition that the power developed $I_d I_q (x_d - x_q)$ is sufficient to carry the load $I^2(R + r)$. What is the criterion which determines whether the machine will run as an induction or as a synchronous generator? If the resistance, $(R + r)$, in the circuit is greater than its critical value of $(x_d - x_q)/2$ so that the machine cannot operate stably as a synchronous generator, will the machine operate stably as an induction generator at a slip sufficient for the development of the necessary power?

C. Concordia (General Electric Company, Schenectady, N. Y.): We have recently had occasion to apply the methods given by Crary to the determination of the stable and unstable regions of operation of an induction motor when operating with series capacitance. Curves have been determined for induction motors similar to figure 1 of the paper. In this case only the unshaded portion of the unstable region of figure 1 appears since the ordinary induction motor has a symmetric rotor. Takahashi (reference 4 of the paper) has given similar induction motor curves for some cases and our results have been in complete agreement with his.

Also by a simple extension of the theory to the case of a resistor in shunt with the series capacitor we have shown that for this extended case, the final equations 14 and 15 of the paper will still apply if only the first $p$ in each of these equations is replaced by

$$\left(p + \frac{x_c}{R}\right)$$

where $R$ is the shunt resistance. The complexity of the equations is therefore not increased and the only change is in the introduction of the quanity $x_c/R$, which may be interpreted as the reciprocal of the time constant of the capacitor-resistor circuit considered by itself. Using these extended equations the regions of stable and unstable operation of induction motors have been determined as affected by the value of shunt resistance. It has been found that if $x_c/R$ be plotted as a function of $x_c$ just as the series resistance $r$ was plotted in figure 1 of the paper, the unstable regions in the 2 cases are very similar in both form and magnitude.

S. B. Crary: Professor Lyon has made an analysis of the phenomena of self-excitation based upon the steady state equations, that is, $i_d$ and $i_q$ are constants for any given set of circuit conditions. The phenomena cannot be properly described by such an analysis, as self-excitation is produced under the conditions when the armature magnetomotive force is pulsating with respect to the direct and quadrature axes, $i_d$ and $i_q$ are varying with time. From the steady state equations for the direct and quadrature components of armature current (equations 33 and 34) one might suspect that the critical values of armature circuit capacitance ($x_c$) corresponds to the condition when the denominator of this expression equals zero. However, the denominator being equal to zero merely indicates that the steady state components of armature current would be very large at 2 definite values of capacitance (infinite neglecting saturation) if the field excitation or armature voltage is finite.

The condition when the denominator of the steady-state equations equals zero corresponds to the 2 points at which one of the roots of equation 21 (with $T_0 = 0$) is zero. This corresponds to the points at which the roots change sign. The time constant of build-up of the armature current is infinite. Accordingly, the transient and steady-state equations are in agreement at these 2 critical points, but the steady-state equations do not by themselves indicate the region of self-excitation.

In order to explain why self-excitation will occur for values of $x_c$ from $x_d$ to zero, Professor Lyon says "Due to the effect of the reluctance torque the machine will undoubtedly operate stably so that $i_q = 0$ and hence it is $(X + x_q)$ that equals zero." No reluctance torque as ordinarily defined exists unless there is an applied armature voltage. If self-excitation exists $i_q$ will not be a constant value equal to zero, so that the explanation based upon the steady-state equations is misleading and unnecessary.

Professor Lyon asks about stability and "What is the criterion whether a machine will run as an induction or as a synchronous generator?" A machine will run as a synchronous generator when connected to an impedance load when there is a unidirectional field excitation corresponding to that produced by residual or d-c excitation. The machine will operate as an induction machine if the circuit constants and the speed are such as to produce self-excitation. Stability is determined by the balance between the electrical and mechanical torques. No electrical torque will be developed for the case when there is no field excitation or applied armature voltage unless the machine self-excites. If the machine self-excites the electrical torque after the currents have reached their maximum values as limited by saturation will pulsate if the machine is of salient pole construction, but will be constant if the rotor is symmetrical.

The results of Mr. Concordia's work, which he has only very briefly described in his discussion, constitute an important extension of the theory, as many cases occur in practice which do not correspond to the comparatively simple cases studied in this paper. It is hoped that his results will shortly be made generally available by presentation to the AIEE.

There is one point in regard to the derivation of equations 18 and 19 which it would be well to point out at this time. In the derivation of these equations for $i_d$ and $i_q$, the changes in field excitation were neglected, that is, $\Delta E_{fd} = \Delta E_{fq} = 0$. This assumption was of course unnecessary and the components of $i_d$ and $i_q$ due to the field excitation voltages, $E_{fd}$ and $E_{fq}$ can be determined in a similar manner to that used for determining these components due to $e_d$ and $e_q$. Since several readers of the paper have asked in regard to these components, it was deemed advisable that they be given in this closing discussion. The direct and quadrature axes components of armature current, including the components due to the field excitation are given below:

$$i_d = \frac{-\{[p^2 + (1-s)^2]Z_q(p) + px_c\}e_d - \{[p^2 + (1-s)^2](1-s)x_q(p) - (1-s)x_c\}e_q\{[(1-s)^2 + p^2]^2 x_q(p) + [(1-s)^2 + p^2]pr - [(1-s)^2 - p^2]x_c\} G_d(p)E_{fd} - (1-s)\{[(1-s)^2 + p^2]r + 2px_c\}G_q(p)E_{qd}}{A(p)} \quad (18a)$$

$$i_q = \frac{+\{[p^2 + (1-s)^2](1-s)x_d(p) - (1-s)x_c\}e_d - \{[p^2 + (1-s)^2]Z_d(p) + px_c\}e_q + (1-s)\{[(1-s)^2 + p^2]r + 2px_c\}G_d(p)E_{fd} + \{[(1-s)^2 + p^2]^2 x_d(p) + [(1-s)^2 + p^2]pr - [(1-s)^2 - p^2]x_c\}G_q(p)E_{fq}}{A(p)} \quad (19a)$$

It will be noted that all of the components of current have the same denominator $A(p)$. It can be further shown that when these expressions are rationalized the resulting denominator which determines whether or not self-excitation will exist will be the same. This means therefore that the results presented in the paper apply equally well for small changes in the field excitation voltages, as well as for changes in the armature voltage.

## Synchronous Machine With Solid Cylindrical Rotor

**Discussion of a paper by C. Concordia and H. Poritsky published in the January 1937 issue, pages 49–58, and presented for oral discussion at the synchronous machinery session of the winter convention, New York, N. Y., January 27, 1937.**

S. B. Crary (General Electric Company, Schenectady, N. Y.): This paper represents a valuable contribution to the theory of synchronous machines in that the effect of eddy currents in the main flux path of the solid rotor are included in the general equations. This makes possible more accurate analyses than have heretofore been made of the effect of the solid rotor on the short-circuit current, the torque slip characteristics, running out of and pulling into step, etc. Additional information as to the effect of saturation is also made available as the authors included the permeability of the rotor as one of the factors entering into their equations. The mathematical analysis of the effect of rotor eddy currents and main-flux saturation which the authors have made was essential in order that a better qualitative and quantitative understanding of the transient phenomenon involved in solid rotor synchronous machines be obtained.

The short-circuit current of turbogenerators has been calculated for some time based on rather empirical design constants which when compared with test data have not always checked very well. The reasons for these differences have been properly attributed to the difficulty in evaluating the effect of magnetic saturation and eddy currents in the magnetic parts.

It now seems desirable to consider in the light of the work by Concordia and Poritsky the present status of the problem of the determination of the magnitude of short-circuit currents of solid cylindrical rotor machines. They have found that the effect of main rotor body saturation and eddy currents is comparatively small, indicating that saturation and eddy currents in the leakage paths must play a predominant part in reducing the effective reactance to short circuit currents. In this analysis they assumed constant rotor permeability, an assumption which is likely to be questioned because the density actually may vary considerably. The importance of this assumption of constant permeability on the main flux path and the relative effect of leakage flux to main flux saturation may be more reasonably evaluated now on the basis of neglecting the effect of eddy currents, since Concordia and Poritsky have shown the relative unimportance of this factor in determining the short circuit current.

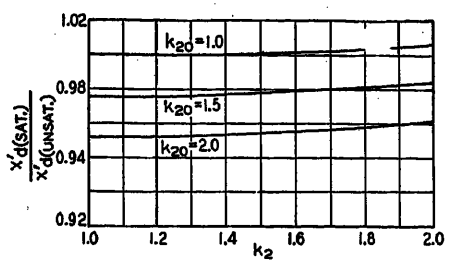

**Figure 1. Effect of rotor main-flux saturation**

If the effect of eddy currents is neglected, the comparative effect of main and leakage flux saturation can be approximately evaluated by equation 10 of a discussion given on page 1114 of the 1935 AIEE TRANSACTIONS. This equation is:

$$x_{d'(sat.)} = 2 \times \frac{\left(\frac{x_{afd}}{k_2} + x_l\right)\left(\frac{x_{afd}}{k_2} + \frac{x_{fld}}{k_3}\right) - \frac{x^2_{afd}}{k_2{}^2}}{\frac{1}{k_{20}}\left[\frac{x_{afd}}{k_2} + \frac{x_{fld}}{k_3}\right] + \frac{1}{k_2}\left[\frac{x_{afd}}{k_{20}} + \frac{x_{fld}}{k_{30}}\right]} \frac{1}{k_{20}}$$

$k_2$ = rotor main-flux saturation factor
$k_3$ = rotor leakage-flux saturation factor
$k_{20}$ = rotor initial main-flux saturation factor
$k_{30}$ = rotor initial leakage-flux saturation factor

Refer to the above mentioned discussion for more complete definitions of this and the remaining quantities.

Figure 1 of this discussion shows the ratio between $x_{d(satd.)}$ as calculated by this equation to $x_{d(unsat.)}'$ for the case when the leakage saturation is zero ($k_{30} = k_3 = 1.0$) for different conditions of initial saturation in the rotor main flux path ($k_{20} = 1.0, 1.5, 2.0$), while the saturation at the instant of maximum armature reaction varies ($k_2 = 1.0$ to 2.0). As shown by these results, the initial saturation in the main flux path has only a small effect, while changes in saturation from the initial to the value at the instant of maximum armature reaction has a still smaller effect. The magnitude of the effect of the initial saturation in the main flux path checks very well the results obtained by Kilgore ("Effects of Saturation on Machine Reactances," AIEE TRANSACTIONS., volume 54, pages 545–50, May 1935) and by Concordia and Poritsky for the laminated-rotor case. The additional fact, indicated by figure 1, that the effect of the change in rotor main-flux saturation is very small and tending to increase the effective reactance checks physical reasoning and further justifies the assumption of Concordia and Poritsky of constant permeability in the main flux path. Physically, increased saturation in the main flux paths under short-circuit conditions is due to an increase in density due to a required increase in the total flux near the base of the rotor teeth in the direct axis in order that constant field flux leakages be maintained. This interesting fact was pointed out sometime ago by Mr. P. L. Alger. Although this increase in density may increase the saturation in the rotor, it results in a very small increase in the effective transient reactance. This probably can be noticed more decidedly by its effect to increase the a-c component of induced field current rather than its effect on the magnitude of short-circuit current, the short-circuit current being limited chiefly by the leakage flux. Therefore, the conclusion is reached that the effect of rotor main-flux saturation on the magnitude of armature short-circuit current is small and that the effect of leakage-flux saturation is the important factor which should be further investigated.

Accordingly, letting $k_2 = k_{20} = 1.0$ in equation 1 and investigating the effect of changes in initial leakage saturation ($k_{30} = 1.0, 2.0$) and changes in leakage saturation at the instant of maximum armature reaction ($k_2 = 1.0$ to 4.0), the results shown in figure 2 of this discussion were obtained. It is seen from these results that the effect of saturation in leakage paths is appreciable.

These results indicate the very decided effect of saturation in the leakage flux paths in reducing the effective reactance, while very little effect is produced by saturation in the main flux path.

Because of the importance of saturation in the leakage flux paths on the short-circuit current, a possible explanation for the apparently inconsistent results sometimes obtained when attempting to obtain the transient and subtransient reactances from the oscillographic records presents itself. Maximum leakage flux exists when the rotor has moved 180 degrees after the instant at which the 3-phase short circuit was applied, this leakage flux decreasing to a minimum value at 360 degrees and then rising to a slightly reduced maximum value at 540 degrees, etc., until the d-c armature transients have died out. Therefore, if the envelope of the completely offset wave of armature current is measured, this effect will tend to yield lower values of short-circuit reactance than the envelopes which are not completely offset. If a completely offset wave is not obtained, the lowest possible value of short-circuit reactance may not be obtained. This leakage flux, which pulsates with respect to the rotor, disappears with the decay of the d-c components of armature current, so that if the d-c components of armature current have disappeared, the magnitudes of the envelopes of the different phases should be approximately equal and the saturation in the leakage paths considerably reduced even for the case of a long field time constant.

This suggests a modification of our present manner of defining and measuring subtransient and transient reactance of turbogenerators. Possibly, we should use the terms "maximum possible 3-phase short-circuit current" to apply to the first peak of the completely offset current wave and "transient symmetrical short-circuit current" to apply to the component of short-circuit current obtained from extending the slowly decaying components of armature current, after the d-c component of armature current has decayed, back to the zero time axis. These 2 values of current could have their corresponding values of reactance. The reactance determined after the d-c components of armature current had decayed could be used in calculating system short circuits where the d-c time constant is very small, which is practically true every place except on or just off a generator bus. This reactance could also be used in stability calculations.

The value of reactance used for determining "the maximum possible short-circuit current" could be used for determining the maximum short-circuit currents near or at the generator terminals. This method would have the advantage of giving more accurate answers and a clearer conception of the actual effect of saturation on the short-circuit current.

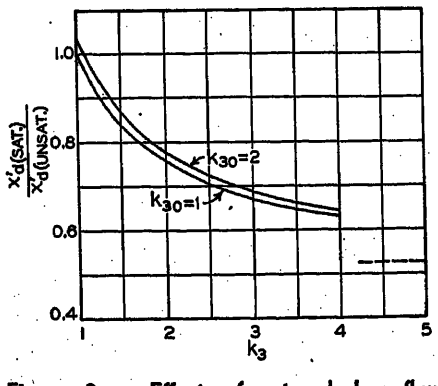

**Figure 2. Effect of rotor leakage-flux saturation**

## Contributions to Synchronous Machine Theory

**Discussion and author's closure of a paper by A. S. Langsdorf published in the January 1937 issue, pages 41–48, and presented for oral discussion at the synchronous machinery session of the winter convention, New York, N. Y., January 27, 1937.**

S. B. Crary (General Electric Company, Schenectady, N. Y.): Dean Langsdorf has presented an interesting paper which gives methods of obtaining the steady-state characteristics by graphical constructions. Such constructions have the advantage in that the work involved in calculating the steady-state performance of a machine may be materially decreased. The work that Dean Langsdorf has done suggests a further step, that of taking saturation more completely into account by modifying the present constructions based on no saturation. This would make the results considerably more practical as the steady-state performance of a machine is affected appreciably by saturation in the magnetic circuit under many normal and particularly under certain abnormal operating conditions. The effect of saturation on the steady-state performance is, in general, a more important factor than the effect of saliency.

If the effect of saturation is to be considered it is suggested that the assumptions in regard to it be critically reviewed. Saturation in the armature core is not negligible and there may arise conditions of operation in which saturation in the pole tip cannot be neglected. Dean Langsdorf presents in figure 16 a method for modifying V curves to account for the effect of saturation. This modification tacitly assumes that saturation in the field poles is only a function of the field excitation while actually saturation in the field poles is a function of the flux in the pole which is dependent on both the armature and field magnetomotive forces and not the field magnetomotive force alone.

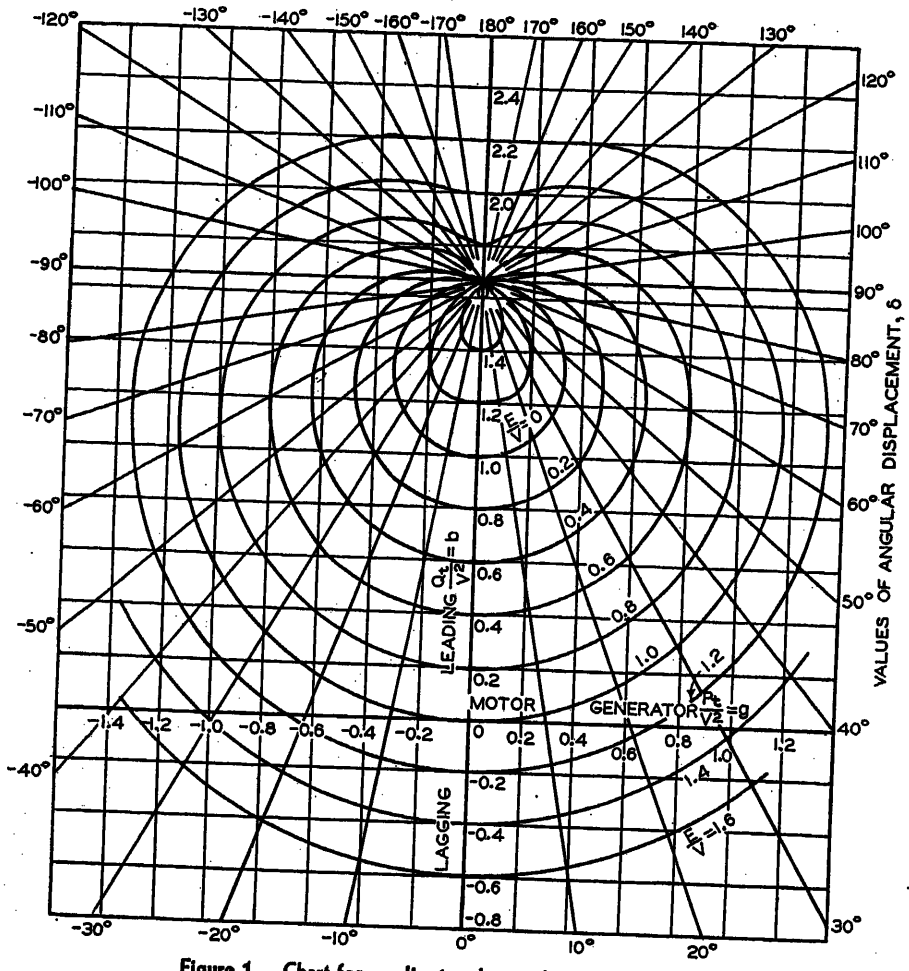

**Figure 1. Chart for a salient-pole synchronous machine**

$R_a = 0$ $X_d = 1.00$ $X_q = 0.60$

**H. E. Edgerton** and **Charles Kingsley, Jr.** (Massachusetts Institute of Technology, Cambridge): The writers, in collaboration with Professor W. L. Sullivan (now at Stevens Institute of Technology) developed several years ago a power chart for salient-pole synchronous machines which is very similar to the current chart, figure 10, of Professor Langsdorf's paper. The chart is illustrated in figure 1 of this discussion. The rectangular co-ordinates are

$$\frac{\text{power at the machine terminals}}{V^2} = \text{apparent conductance } g$$

= active component of armature current per-unit terminal voltage,

and

$$\frac{\text{reactive volt-amperes at the terminals}}{V^2} = \text{apparent susceptance } b$$

= reactive component of armature current per-unit terminal voltage.

Positive values of power are for generator action. Positive values of reactive volt-amperes are for leading-current generator action, or lagging-current motor action. The curves show the relation between the apparent conductance and susceptance for various constant values of the ratio $E/V$. The radial lines show various constant values of the load angle $\delta$. The chart shown is drawn for a machine having the following constants:

$R_a = 0$
$X_d = 1.0$ per unit
$X_q = 0.6$ per unit

The reactances are assumed to be constant, independent of saturation. This same assumption is made by Professor Langsdorf. Although resistance has been neglected in drawing this chart, it is not a difficult matter to include resistance, as will be shown subsequently in describing the method by which the chart is drawn. Practically, the effects of the resistance of the machine are usually very small.

This chart is very much like figure 10 of Professor Langsdorf's paper. In fact, if figure 10 of the paper were rotated counter-clockwise through 90 degrees, and the scale altered by dividing by the terminal voltage $V$, Professor Langsdorf would have obtained exactly these same curves for this machine. The advantage of altering the scale in this manner is that the chart now shows the vector loci of the armature current per unit terminal voltage. The chart can now be used at any terminal voltage, by correcting the readings taken from it in accordance with whatever the terminal voltage may be. This is a simple matter of multiplication. In addition to the curves for constant values of the ratio $E/V$, radial lines are drawn which show constant values of the load angle $\delta$.

The only essential differences between this chart and figure 10 of Professor Langsdorf's paper are the change of scale, making the chart applicable at any terminal voltage (saturation being neglected), and the addition of the radial angle lines. This chart can be used, as shown by Professor Langsdorf, to obtain practically any of the normal steady-state operating characteristics of the machine.

The chart is constructed by a different method than that used by Professor Langsdorf. The procedure is shown in figure 2 of this discussion. In this construction the armature resistance is included. The construction is as follows:

Compute the co-ordinates of the point $A$, which are

$$g = -\frac{R_a}{R_a^2 + X_q^2}$$

$$b = +\frac{X_q}{R_a^2 + X_q^2}$$

Draw the line $OA$, connecting point $A$ with the origin. Except for the change in scale and the rotation of the chart through 90 degrees, this line is the same as line $OC$ of Professor Langsdorf's figure 9 extended to the point $A$ where line $OC$ again intersects the reluctance circle.

Draw the perpendicular bisector of $OA$ and find point $G$, its intersection with the $b$-axis. The distance $OG$ should be equal to $\frac{1}{2} X_q$.

Draw the axis of symmetry $AGB$.

Draw the reluctance circle $ALC$ with its center $O'$ on the axis of symmetry $AGB$ and with its diameter equal to

$$\frac{X_d - X_q}{R_a^2 + X_d X_q}$$

Except for the change in scale, this is the same circle shown in figure 9 of the paper.

Draw in a number of radial lines $ALP$, $AL_1P_1$, etc., radiating from point $A$. These are the lines of constant load angle $\delta$. The load angle is equal to the angle which these lines make with the zero angle line $AO$.

From the intersections $L$, $L_1$, etc., of the angle lines with the reluctance circle, measure the distance $LP$, $L_1P_1$, etc., equal to

$$\frac{E}{V}\,\frac{Z_q}{R_a^2 + X_d X_q}, \text{ where } \frac{E}{V} \text{ is a chosen value.}$$

Draw the curve connecting points $P$, $P_1$, $P_2$, etc. This is the admittance locus for the particular chosen value of $E/V$.

By repeating this comparatively simple graphical construction for other chosen values of $E/V$, the complete chart can be constructed.

It can readily be shown by simple geometry that the points $L$, $L_1$, etc., are the same as the corresponding points which would be obtained by Professor Langsdorf's graphical construction.

Mathematically, the curves are limaçons, symmetrical about the line $AB$, and having the polar equation

$$\rho = a + b \cos\theta$$

where $a$ and $b$ are constants.

There have also been several articles

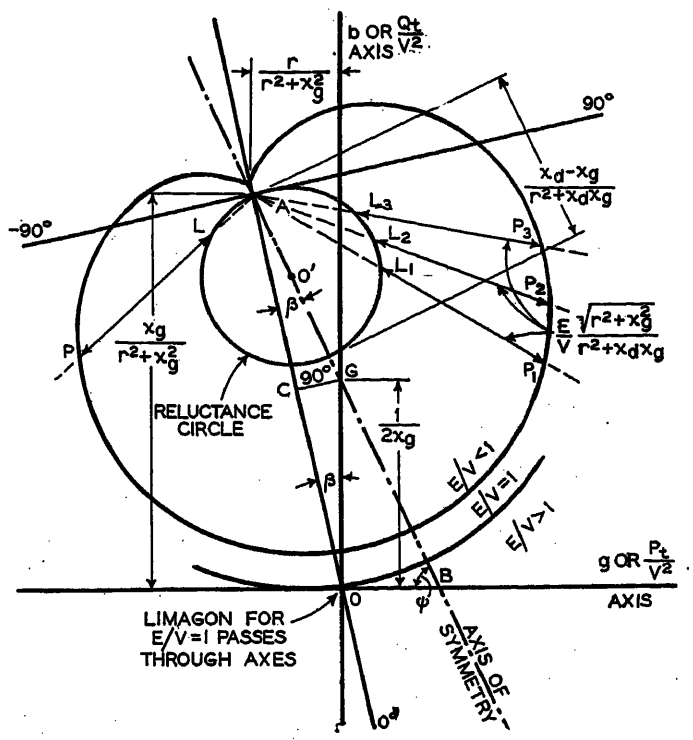

**Figure 2. Construction of the chart**

published in German ("Das Stromdiagramm der Synchronmaschine mit Ausgeprägten Polen in Symbolischer Behandlung," by Johannes Schammel, *Archiv für Elecktrotechnik*, volume 23, 1929, page 237). This article also gives a bibliography which may be of interest to those following the subject.

**Sterling Beckwith** (Allis-Chalmers Manufacturing Company, Milwaukee, Wis.): The relations and curves derived by Mr. Langsdorf are very interesting, and probably answer questions which have been wondered about by everyone who has worked with synchronous machines for any appreciable length of time.

There are 2 interpretations of the term "equivalent" impedance. One is the reactance which can be used to replace the varying reactance of a machine and which has the value that will give correct power limits for the machine when used with constant internal voltages in the usual formulas for power limits. Another is the reactance which will give the correct internal voltage of a machine. A point worth mentioning in connection with the 2 definitions, both of which appear in the literature on the subject, is that the first reactance will not give correct internal voltages, and that the second reactance will not give correct stability limits. In order to get correct stability results with the latter type of reactance, for example, it is necessary not only to take into account the magnitude of the reactance but also its rate of change and the rate of change of the internal voltage. Both reactances are useful for their purposes, but their shortcomings must not be overlooked.

Two questions occur to me after reading the article. One is whether the power circles in figure 10 are true circles, or whether they approximate circles as in the case of the circles for constant internal voltage $E$. The other is whether the assumption of negligible tooth saturation and the use of the no-load saturation curve in figure 16 are sufficiently accurate in view of the fact that stability is dependent on the rate of change of saturation.

**A. S. Langsdorf:** The excitation loci of figure 10, and their Cartesian representation in the manner indicated in figure 12, have been checked experimentally by slip tests made with a small 15-kva laboratory alternator. The accompanying oscillograms, all made by the usual slip-test method show the results of slip tests with zero excitation (curve number 9); with very small excitation (curve number 10); and with a larger, but less than normal, excitation (curve number 11).

In the case of oscillogram number 9, the theoretical polar current locus is the small reluctance circle $O'$ of figures 9 and 10. The current variation through the range from $\delta = 0$ to $\delta = 360$ degrees should theoretically show values of current which are less than the average through a range smaller than 180 degrees, and which are greater than the average through an angle of more than 180 degrees. This conclusion is amply supported by the oscillogram.

The second oscillogram, number 10, shows very clearly the humps predicted by figure 12 of the paper; and oscillogram number 11 shows how these humps are leveled with increasing excitation, and with the asymmetry to be expected because of the fact that the excitation loops of figure 10 extend below the zero-power circle more than they rise within it.

It is a further fact that the maximum power that can be developed by an unexcited motor (indicated by circle $P_1$, figure 10) is equal to the reluctance power

$$\frac{V^2(X_d - X_q)}{X_dX_q}$$

which appears as the coefficient of the second term of the coupling factor (equation 44), provided the resistance $R_a$ is neglected. The proof of this statement follows readily from the equations given in the paper.

There is no doubt that a critical study of the effect of saturation, as suggested by Mr. Crary, would be useful to designers, but it is nevertheless true (quoting from the original paper) that "the full effect of saturation of the magnetic circuit is apparently beyond the scope of any reasonably simple analysis." It was believed that such an open disclaimer, serving as an introduction to the "reasonably simple" construction of figure 16, constituted sufficient notice of the approximate nature of that construction. As a matter of fact, the approximations involved in figure 16 are precisely the same as those suggested in appendix *D* (part I) of Doherty and Nickle's paper,[1] (footnote refers to numbered references in the article) and which are there shown as modifications of the vector diagram, whereas the present author chose to represent them as modifications of the derived V curves. Mr. Crary is quite correct in his contention that saturation is not a function of field excitation alone; it is decidedly a function of the armature current and the phase displacement between current and voltage. If anyone knows how to bring these additional factors into the picture he has a clear field; pending the presentation of a complete analysis, it may merely be said that the method embodied in figure 16 tends in the right direction. In any case, the purpose of the paper was not to emphasize saturation effects, but (quoting from the opening paragraph of the paper) "to point out some features . . . which follow . . . from the 2-reaction theory." That theory is completely represented by the vector diagram figure 4, and any shortcomings in the deductions are inherent in the theory itself.

It is interesting to note that the method of Messrs. Edgerton and Kingsley leads to the same conclusions as those of the paper under discussion, though their analysis stops short of such deductions as those concerning the law of variation of reactance, the nature of the V curves, etc.

Mr. Beckwith mentions 2 different interpretations of the term "equivalent impedance," both of which refer to single-valued quantities. As the term is used in the paper, it refers to a variable impedance which is a function of the 2 constant reactances, $X_d$ and $X_q$, and of the variable phase angle $\psi$.

Mr. Beckwith raises the question whether the power circles of figure 10 are in reality true circles. Inasmuch as these circles are merely the geometrical representations of equation 1, the question is equivalent to asking (*a*) whether the power developed by the machine is really equal to the input minus the copper loss, and (*b*) whether the voltage $V$ and the current $I$ are the simple harmonic functions of time that they are tacitly assumed to be. The truth of (*a*) cannot be questioned, hence if (*b*) is satisfied the loci are truly circular, but with the understanding that $P$ represents power developed, not power usefully delivered at the shaft. The second question, concerning tooth saturation, has already been implicitly answered in reply to Mr. Crary; the method of figure 16 is confessedly somewhat approximate, that is, qualitative rather than quantitative.

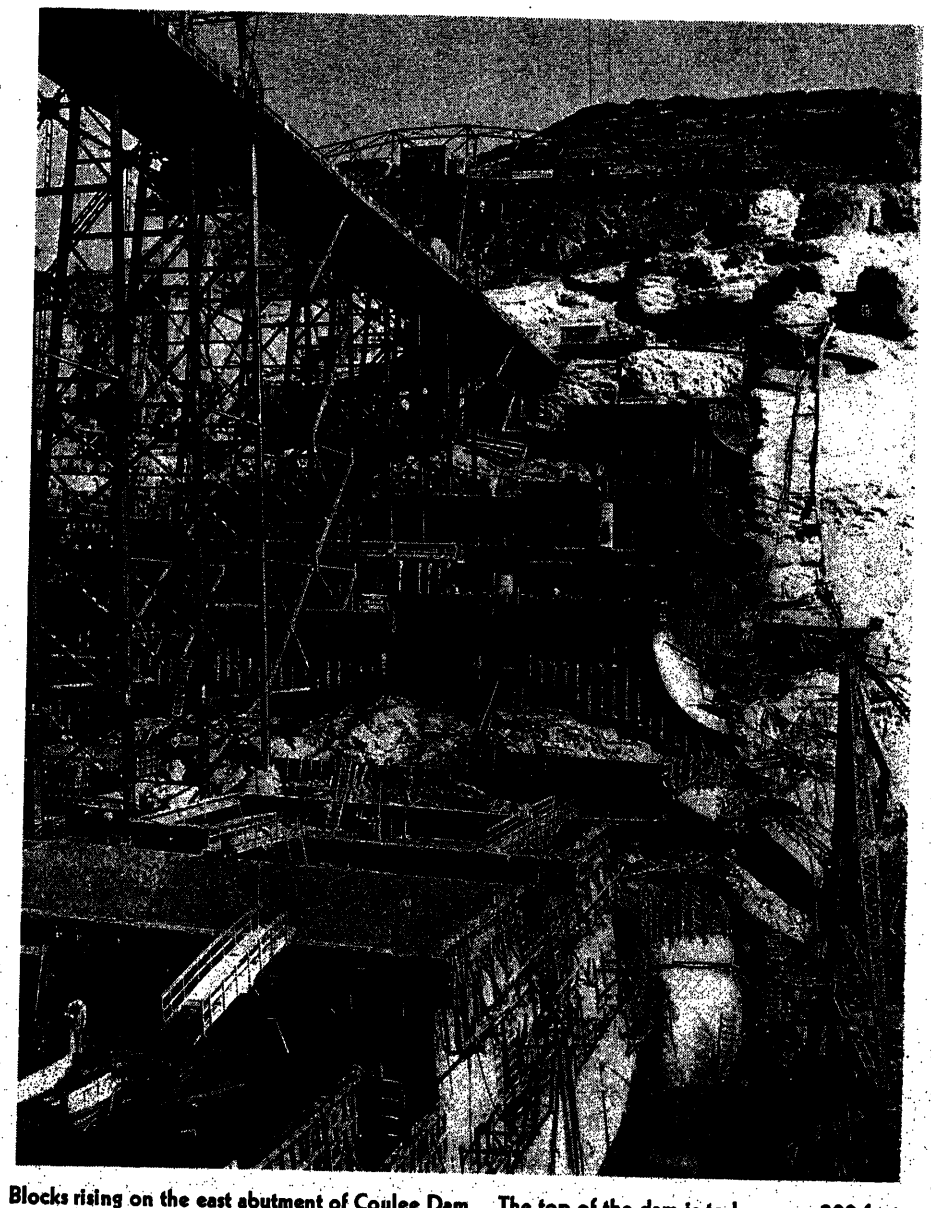
# Pacific Coast Convention Includes All-Day Trip to Grand Coulee

TO THOSE who have looked forward to the time when they might profitably visit the Pacific Northwest, the 1937 AIEE Pacific Coast convention to be held in Spokane, Wash., August 31–September 3, offers an excellent opportunity to combine business with pleasure. Not only is the city of Spokane itself a recreational center, but also within easy reach are many fine trout streams and mountain lakes, and several famous national parks.

A special feature of the high-class technical program that has been arranged is a joint session with the Institute of Radio Engineers, which organization is concurrently holding its first Pacific Coast convention. Other attractions include an all-day inspection trip to the Grand Coulee project on the Columbia river, and the usual sports competitions and special entertainment.

### Spokane a Recreational Center

A mountain river flows through the center of Spokane, and a big proportion of its banks has been, and is being, converted into State and City park areas. City and adjacent State parks total 4,920 acres, which is said to be the largest park area per capita of any city in the United States. Five golf courses, play grounds, the sunken gardens of Manito, all provide pleasant recreation.



For those who will combine either all or part of their vacations with attendance at the convention, Spokane offers a surrounding recreational area of mountain scenery, fine trout streams, and lakes. Within 50 miles of Spokane are located 76 clear mountain lakes. Only a little farther away is the famous Coeur d'Alene mining district with the Sunshine Mine, the Bunker Hill Smelter, and other new and old producers. Only a little farther, and all within easy reach of Spokane, are the national parks, Glacier, Yellowstone, Craters of the Moon, Mount Rainier, Mount Baker, and others.

### Technical Program

The technical program is comprised of a wealth of material, and some of the papers will deal with recent problems in the Pacific Northwest. Five technical sessions and one conference session on electric house heating will be held. The communication session will be a joint session with the Institute of Radio Engineers and papers also will be presented by well-known members of the IRE. According to F. E. Terman (A'23, M'34) of Stanford University, Calif., chairman of the IRE convention committee, present tentative plans call for a 2-day IRE convention to be held September 1 and 2 in the same hotel as the AIEE convention. Registration will be on the morning of September 1, followed by a technical session that afternoon. The jointly sponsored session is scheduled for Thursday morning and will be followed by another IRE session in the afternoon. The joint session and the IRE convention should prove an additional attraction for electrical engineers.

### Interesting Inspection Trips

As a special feature, it is planned to devote one entire day to an inspection of Grand Coulee, the world's greatest dam, and an address on its electrical features by Alvin F. Darland of the United States Bureau of Reclamation. This dam, which

**Blocks rising on the east abutment of Coulee Dam. The top of the dam is to be some 300 feet above the top of the trestle shown. Openings to the inspection and grouting galleries may be seen in some of the blocks. Approximately 500 cubic yards of concrete are used for a 5-foot lift on each block**

being built for the dual purpose of irrigation and of power generation, is of great interest to all engineers. Grand Coulee is only 92 miles from Spokane.

What is said to be the world's tallest unguyed radio tower, which has just been completed in Spokane by station KHQ, also is on the inspection-trip program. The main tower is 803 feet tall with a short wave and television spire extending up to a total height of 828 feet.

Another "world's greatest" scheduled for inspection is the new pumping plant of the City of Spokane. Each of the 2 vertical turbine-type pumps is driven by a 900-horsepower 1,200-rpm vertical hollow-shaft motor built into the pump head, largest ever built of this construction.

### Some Facts Concerning Grand Coulee

The Grand Coulee project, perhaps the most extensive of its kind every attempted, embraces the construction of a dam, power plant, and pumping plant on the Columbia River; a reservoir in Grand Coulee; and main irrigation canals and water distribution system on the project lands. The estimated cost of the dam and power plant is $178,790,000; of the irrigation system, $197,841,000. The dam is of the straight gravity type and will rise to a height of 550 feet, second only to Boulder Dam which is 727 feet. Thickness of the dam at the base will be about 500 feet and at the top about 30 feet. Length along the crest will be approximately 4,200 feet.

Some 11,250,000 cubic yards of masonry and 65,000,000 pounds of reinforcing steel will be required for the dam, power plant, and appurtenant works. The reservoir created by the dam will cover an area of about 82,000 acres and will contain approximately 10,000,000 acre-feet of water.

There will be 2 power houses, one at each end of the dam, each about 765 feet long. Ultimately, 18 generating units will be installed, each consisting of a 150,000-horsepower vertical turbine and a 120,000-kva 60-cycle 13,800-volt generator. Water will reach the turbines through 18 penstocks, each 18 feet in diameter, under an average head of 335 feet.

The pumping plant, which ultimately will contain 12 pumps each having a capacity of 1,600 cubic feet per second and driven by a 65,000-horsepower motor, will be on the west bank of the river adjacent to the upstream side of the dam. Normal pumping head will be 295 feet; maximum, 367 feet. Water from this pumping plant will be used to irrigate about 1,200,000 acres of land on the east side of the Columbia river.

The entire project is being constructed by the United States Government under the direction of the Bureau of Reclamation of the Department of the Interior. Excavation was begun in December 1933, and the placing of concrete in December 1935. If the present rate of progress is maintained, the dam and power plant will be completed in 1941. Initially, only 3 generating units will be installed; these are expected to be in operation during 1942. Present plans provide for bringing in irrigation areas in small units only, at such times as there is a demand for additional land. According to estimates, the irrigation project will be finally completed at the end of about 40 years.

### Sports

As usual, the high light of the sports events will be the golf tournament for the John B. Fisken cup. An interesting feature of the sports program this year is that Mr. Fisken himself, a resident of Spokane, is chairman of the convention's sports subcommittee. A variety of other competitions will round out the sports program.

### Special Entertainment for Women

For the women guests at the convention, one of the most interesting features will be the gardens of Spokane. During 4 years of participation in the nationwide contest of the National Yard and Garden Contest Association of America, Spokane gardens have won 4 first prizes. This is said to be more "firsts" than have been won by any other American city—in fact, as many as ever have been won by all the gardens within any other entire state.

## Tentative Program

**In this program, reference to the issue and, in so far as possible, to the page in ELECTRICAL ENGINEERING is given for all papers**

### Tuesday: August 31

**10:00 a.m.—Opening of Convention**

**10:15 a.m.—Selected Subjects**

Lighting the San Francisco-Oakland Bay Bridge, C. R. Davis, Department of Public Works, State of California. Scheduled for August issue

Present Day and Probable Future Electrical Applications in Aircraft, W. V. Boughton, Douglas Aircraft Company, Inc. Scheduled for August issue

Proposals for the Administration of Federal Power in the Pacific Northwest, H. V. Carpenter, State College of Washington. Scheduled for August issue

**2:00 p.m.—Development of Protective Equipment**

Relay Operation During System Oscillations, C. R. Mason, General Electric Company. July issue, pages 823–32

A Comprehensive Method of Determining the Performance of Distance Relays, J. H. Neher, Philadelphia Electric Company. July issue, pages 833–44

The Ultra-High-Speed Reclosing Expulsion Oil Circuit Breaker, A. C. Schwager, Pacific Electric Manufacturing Corporation. Scheduled for August issue

Capacitance Control of Voltage Distribution in Multi-Break Breakers, R. C. Van Sickle, Westinghouse Electric & Manufacturing Company. Scheduled for August issue

**9:00 p.m.—Reception and Informal Dance**

### Wednesday, September 1

**9:00 a.m.—Power Transmission and Distribution**

Empirical Method of Calculating Corona Loss From High-Voltage Transmission Lines, J. S. Carroll, Stanford University, and Mabel Macferran Rockwell, consulting electrical engineer. May issue, pages 558–65

Distortion of Traveling Waves by Corona, H. H. Skilling, Stanford University, and P. de K. Dykes, Cambridge (England) University. July issue, pages 850–7

Analysis of Series Capacitor Application Problems, J. W. Butler and C. Concordia, General Electric Company. Scheduled for August issue

**2:00 p.m.—Student Technical Session —Golf**

**8:00 p.m.—Banquet; Presentation of Prizes**

### Thursday, September 2

**9:00 a.m.—Joint Communication Session With Institute of Radio Engineers**

Magnetic Generation of a Group of Harmonics, Eugene Peterson, J. M. Manley, and L. R. Wrathall, Bell Telephone Laboratories, Inc. Scheduled for August issue

Radiotelephone Noise Reduction by Voice Control at Receiver, C. C. Taylor, Bell Telephone Laboratories, Inc. Scheduled for August issue

The Vodas, S. B. Wright, Bell Telephone Laboratories, Inc. Scheduled for August issue

Transmission Lines at Very High Radio Frequencies, L. E. Reukema, University of California Scheduled for August issue

The Developmental Problems and Operating Characteristics of 2 New Ultrahigh-Frequency Triodes, Winfield G. Wagener, RCA Radiotron Company. IRE paper

High-Efficiency Grid-Modulated Amplifiers, F. E. Terman and John Woodyard, Stanford University. IRE paper

**2:00 p.m.—Student Technical Session —Session on Electrical Machinery**

Tooth-Frequency Eddy-Current Loss, Paul Narbutovskih, Stanford University. February issue, pages 253–56

The Saturated Synchronous Machine, B. L. Robertson, T. A. Rogers, and C. F. Dalziel, University of California. July issue, pages 858–63

Transformer Current and Power Inrushes Under Load, E. B. Kurtz, University of Iowa. Scheduled for August issue

**8:00 p.m.—Conference on Electric House Heating**

Electric Heating of Residences, C. E. Magnusson, University of Washington.

Electric Heating of Residences, H. V. Carpenter, State College of Washington.

### Friday, September 3

**Coulee Dam Trip**

Address: The Coulee Dam Project, Alvin F. Darland, United States Bureau of Reclamation.

**Lobby of the Davenport Hotel, Spokane, Wash., headquarters of the AIEE 1937 Pacific Coast convention**

There will be sight-seeing trips for the women, a bridge luncheon at the Country Club, golf, putting contests, and other entertainment.

HOTELS AND REGISTRATION

Convention headquarters will be at the Davenport Hotel where registration desks will be open from early Tuesday morning, August 31. Accommodations of all types are available at the Davenport at prices beginning at $3 per day.

Accommodations at the Spokane Hotel will range from $2 to $6. The Desert Hotel, across the street from the Davenport, and the Coeur d'Alene have accommodations ranging from $2.50 upward. All members desiring accommodations are urged to make their reservations early. Special arrangements are being made for economical accommodations for Enrolled Students.

COMMITTEES

In the following list are given the members of the 1937 Pacific Coast convention committee, which includes the 10 subcommittee chairmen, as indicated.

H. V. Carpenter, *chairman*
R. D. Sloan, *vice-chairman*
M. F. Hatch, *secretary*
Reinier Beeuwkes
S. E. Caldwell
J. B. Fisken
L. R. Gamble
J. C. Gaylord
C. R. Higson
N. B. Hinson
R. H. Hull
H. S. Lane
F. O. McMillan
H. L. Melvin
H. S. Osborne
George Quinan
C. E. Rogers
R. W. Sorensen
A. Vilstrup
L. R. Gamble, meetings and papers
J. S. McNair, finance
L. A. Traub, transportation
H. W. Webbe, housing
J. R. Murphy, entertainment
J. B. Fisken, sports
H. B. Hodgins, publicity
R. H. Hull, student activities
D. H. Olney, registration
Earl Baughn, inspection trips

**Electric Power Markets in Washington.** This is the title of a 40-page bulletin (No. 93) of the University of Washington Engineering Experiment Station, prepared by Doctor C. E. Magnusson, professor of electrical engineering at the university, and director of the Engineering Experiment Station. This bulletin presents, largely in tabular and graphical form, the results of an extensive study of the electric heating of residences in Seattle. It is listed as being available from the University at 40 cents per copy.

## AIEE Directors Meet at Institute Headquarters

The regular meeting of the board of directors of the American Institute of Electrical Engineers was held at Institute headquarters, New York, on May 24, 1937.

Present: *President*—A. M. MacCutcheon, Cleveland, Ohio. *Past-President*—H. P. Charlesworth, New York, N. Y. *Vice-Presidents*—C. V. Christie, Montreal, Canada; Mark Eldredge, Memphis, Tenn.; C. Francis Harding, Lafayette, Ind.; W. H. Harrison, New York, N. Y.; A. C. Stevens, Schenectady, N. Y. *Directors*—F. M. Farmer, New York, N. Y.; H. B. Gear, Chicago, Ill.; F. Ellis Johnson, Columbia, Mo.; C. R. Jones, New York, N. Y.; P. B. Juhnke, Chicago, Ill.; W. B. Kouwenhoven, Baltimore, Md.; Everett S. Lee, Schenectady, N. Y.; K. B. McEachron, Pittsfield, Mass.; C. A. Powel, East Pittsburgh, Pa.; R. W. Sorensen, Pasadena, Calif. *National Treasurer*—W. I. Slichter, New York, N. Y. *National Secretary*—H. H. Henline, New York, N. Y. Present by invitation during discussion of one item—Past-President A. W. Berresford, New York, N. Y.

Minutes were approved of meetings of the board of directors held January 26–27, 1937, and the executive committee on March 25, 1937.

Announcement was made of the vacancies in the board of directors caused by the deaths of Past-Presidents J. Allen Johnson and E. B. Meyer and the filling of these vacancies by Past-Presidents H. P. Charlesworth (to August 1, 1937) and J. B. Whitehead (to August 1, 1938), in accordance with the board's interpretation, in May 1936, of section 35 of the constitution to mean that the 2 most recent living past-presidents shall be members of the board of directors.

Actions of the executive committee on applications for admission, transfer, and Student enrollment were reported and confirmed, as follows: As of February 19, 1937—1 applicant elected and 5 applicants transferred to the grade of Fellow; 12 applicants elected and 13 applicants transferred to the grade of Member; 76 applicants elected to the grade of Associate; 81 Students enrolled. As of April 16, 1937—2 applicants transferred to the grade of Fellow; 6 applicants transferred and 11 elected to the grade of Member; 470 applicants elected to the grade of Associate; 68 Students enrolled.

Reports were presented and approved of meetings of the board of examiners held April 14 and May 12, 1937. Upon the recommendation of the board of examiners, the following actions were taken: 2 applicants were transferred to the grade of Fellow; 14 applicants were transferred and 27 were elected to the grade of Member; 342 applicants were elected to the grade of Associate; 164 Students were enrolled.

Monthly disbursements as follows were reported by the finance committee and approved: April, $18,714.91; May, $20,679.11.

Upon recommendation of the committee on electrophysics, the board authorized a change in name of that committee to "committee on basic sciences," without change in function.

Approval was given to a recommendation of the membership committee that each District vice-chairman of that committee be added to the executive committee of his geographical District, if not already a member of the executive committee in another capacity. The wording of revisions of sections 32 and 76 of the by-laws, to bring them into conformity with this policy, was referred to the committee on constitution and by-laws.

Approval was given to the appointment, upon nomination by the standards committee, of Institute representatives, as

## Future AIEE Meetings

**Pacific Coast Convention**
Spokane, Wash., Aug. 30–Sept. 3, 1937

**Middle Eastern District Meeting**
Akron, Ohio, Oct. 13–15, 1937

**Winter Convention**
New York, N. Y., January 24–28, 1938

**North Eastern District Meeting**
Pittsfield, Mass., Spring 1938

**Summer Convention**
Washington, D. C., June 20–24, 1938

follows: T. H. Haines, on Sectional Committee on National Electrical Safety Code, and W. C. Goodwin, on Sectional Committee on Safety Code for Mechanical Refrigeration.

H. B. Gear was appointed an Institute representative on the Commission of Washington Award, for the 2-year term beginning August 1, 1937, to succeed L. A. Ferguson, whose term will expire at that time.

The board confirmed applications made by the AIEE committee on research to The Engineering Foundation for financial support for the year 1937–38 of the following research projects: investigation of electric shock, stability of impregnated paper insulation, and work of welding research committee.

Upon recommendation of the committee on research, it was voted "that the board approves in principle the idea of a contribution by the AIEE toward the specific research projects which the board recommends to The Engineering Foundation for financial support, of not more than $500 for any one project in a year, the total amount appropriated for all such projects during a budget year not to exceed one-half of one per cent of the total gross income of the AIEE for the preceding fiscal year."

Appointment by the president of the following committee of tellers to canvass and report upon the ballots for the election of Institute officers was approved: W. E. Coover (chairman), John T. Binford, George C. Brown, M. S. Mason, L. M. McCullough, L. A. Nelson, and A. M. Schoettgen.

A report, transmitted by Chairman F. B. Jewett of the committee on Iwadare Foundation, from E. H. Colpitts, covering his Iwadare lectureship itinerary in Japan in the spring of 1937, was received and ordered filed.

The report of the committee on award of Institute prizes, of the awards made by the committee for papers presented during 1936, was presented. (The report was published in the June issue of ELECTRICAL ENGINEERING, page 756.)

The annual report of the board of directors to the membership for the fiscal year which ended April 30, 1937, as prepared by the national secretary, was approved for presentation at the annual meeting of the Institute on June 21. This included reports in full or in abstract of general standing committees. The report appears elsewhere in this issue.

The annual report of the national treasurer was presented and approved.

In accordance with section 37 of the constitution, consideration was given to the appointment of a national secretary of the Institute for the administrative year beginning August 1, 1937; and National Secretary H. H. Henline was reappointed.

President A. M. MacCutcheon was appointed the official delegate of the Institute to the semicentennial of The Engineering Institute of Canada, June 15–18, 1937.

Other matters were discussed, reference to which may be found in this or future issues of ELECTRICAL ENGINEERING.

## Honorary Members Named at Summer Convention

Election of Bion J. Arnold and Alex Dow to honorary membership in the AIEE was formally announced at the opening session of the Institute's 1937 Summer Convention, which is being held in Milwaukee, Wis., as this issue goes to press. These 1937 elections are the first since 1933 when 6 prominent engineers and scientists were so honored. Doctor Arnold has been an independent consulting engineer since 1893 and has been active in Institute affairs, having served as the 16th president (1903–04). Doctor Dow is a pioneer in the electric utility field and was awarded the AIEE Edison medal for 1936 for outstanding leadership in that industry. Biographical sketches of both men are given in the "Personals" columns of this issue.

Neither Doctor Dow, who is in Europe, nor Doctor Arnold was present at the ceremony. Doctor Arnold was injured in an automobile accident on June 19, the Saturday before convention week, while on his way home from hospital confinement resulting from an earlier accident. Honorary Member certificates were sent to Doctor Dow by D. H. Baker, convention delegate from the Detroit-Ann Arbor Section, and to Doctor Arnold by his son.

As specified in sections 8 and 9 of the Institute's constitution,

**Honorary Members may be chosen from among those who have rendered acknowledged eminent service to electrical engineering or its allied sciences.**

**Honorary Members shall be proposed in writing by at least 10 members, and may be elected only by the unanimous vote of the board of directors, a ballot in writing to be forwarded by members absent from the directors' meeting. The election of an Honorary Member shall be deemed invalid if an acceptance is not received within 6 months after the date of his election.**

The grade of honorary member is the highest in the AIEE, and since the founding of the Institute in 1884 has been granted to only 33 men, including Doctors Arnold and Dow. Of those elected prior to this year, only the following are still living: Andrè E. Blondel, W. L. R. Emmet, Herbert Hoover, A. E. Kennelly, Guglielmo Marconi, R. A Millikan, Chas. F. Scott, and Motoji Shibusawa.

### NEW OFFICERS ELECTED

The report of the committee of tellers also was presented at the first session of the convention, and the following new officers were declared elected, each to take office August 1, 1937.

*President:*

**W. H. Harrison, assistant vice-president, department of operation and engineering, American Telephone and Telegraph Company, New York, N. Y.**

*Vice-Presidents:*

**I. Melville Stein, director of research, Leeds & Northrup Company, Philadelphia, Pa.**

**Edwin D. Wood, general superintendent, Louisville Gas & Electric Company, Louisville, Kentucky.**

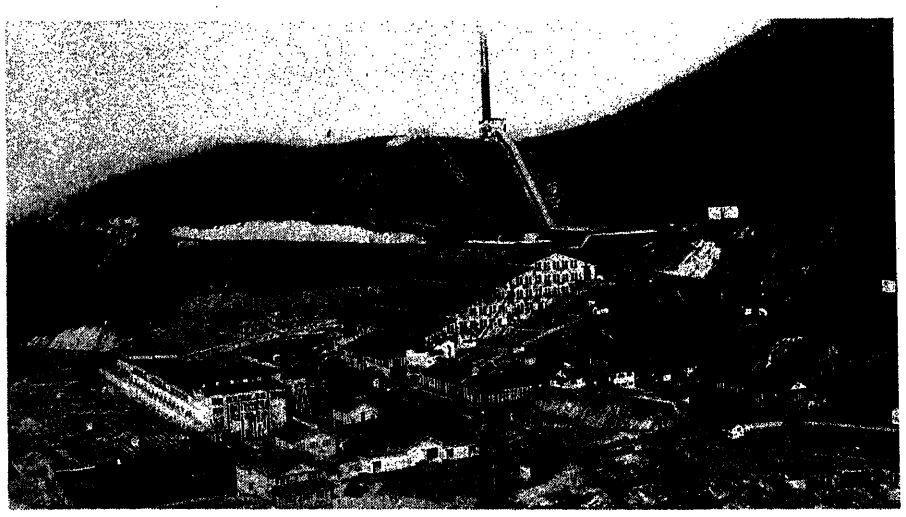
**L. N. McClellan, chief electrical engineer, U.S. Bureau of Reclamation, Denver, Colo.**

**J. P. Jollyman, hydroelectric and transmission engineer, Pacific Gas & Electric Company, San Francisco, Calif.**

**M. J. McHenry, manager, Toronto district, Canadian General Electric Company, Ltd., Toronto, Ont.**

*Directors:*

**C. R. Beardsley, superintendent of distribution, Brooklyn Edison Company, Inc., Brooklyn, N. Y.**



**Vannevar Bush, vice-president and dean of engineering, Massachusetts Institute of Technology, Cambridge.**

**F. H. Lane, manager, engineering division, Public Utility Engineering & Service Corporation, Chicago, Ill.**

*National Treasurer:*

**W. I. Slichter, professor of electrical engineering, Columbia University, New York, N. Y.**

The board of directors for the administrative year beginning August 1, 1937, consists of these newly elected officers, together with the following hold-over officers: A. M. MacCutcheon (retiring president), Cleveland, Ohio; J. B. Whitehead (junior past president), Baltimore, Md.; F. Malcolm Farmer, New York, N. Y.; N. E. Funk, Philadelphia, Pa.; H. B. Gear, Chicago, Ill.; F. Ellis Johnson, Columbia, Mo.; C. R. Jones, New York, N. Y.; W. B.

**The electrolytic zinc plant of the Sullivan Mining Company, a 2- or 3-hour drive from Spokane, will be an attraction to those attending the Institute's 1937 Pacific Coast convention who are interested in the application of electricity to ore mining and refining**

Kouwenhoven, Baltimore, Md.; K. B. McEachron, Pittsfield, Mass.; C. A. Powel, East Pittsburgh, Pa.; R. W. Sorensen, Pasadena, Calif.; A. C. Stevens, Schenectady, N. Y.; O. B. Blackwell, New York, N. Y.; C. F. Harding, Lafayette, Ind.; L. T. Blaisdell, Dallas, Tex.; C. E. Rogers, Seattle, Wash.

The first day's registration, which numbered 563 members and guests, presaged a highly successful convention. A detailed report of the various convention activities is scheduled for inclusion in the August issue.

## New Name for Electrophysics Committee

The name of the AIEE committee on electrophysics has been changed to "committee on basic sciences" by authorization of the AIEE board of directors, following the recommendation of the committee. The function of the committee remains unchanged.

The electrophysics committee was organized in 1911. Its scope, as defined at the present time, is: "Treatment of all matters in which the dominant factor is electrophysics, and which are of such novel character as to be unapplied in any apparatus or field of application within the scope of the other technical committees, or which are of such generality as to be significant within the scopes of several technical committees. Such subjects as general circuit theory, electrostatics, mathematical treatises, magnetics, general electrical units, and nomenclature are properly within the scope of this committee."

## Executive Committee of Pacific District Meets

A meeting of the executive committee of the AIEE Pacific District was held in the Engineers' Club at San Francisco, Calif., May 27, 1937. Members of the executive committee who attended were:

N. B. Hinson, vice-president, AIEE, Los Angeles
J. C. Gaylord, chairman, Los Angeles Section
E. F. Peterson, chairman, District committee on student activities, Santa Clara
H. S. Lane, chairman, San Francisco Section
F. S. Benson, secretary, San Francisco Section
Fred Garrison, secretary, AIEE Pacific District

Present by invitation:

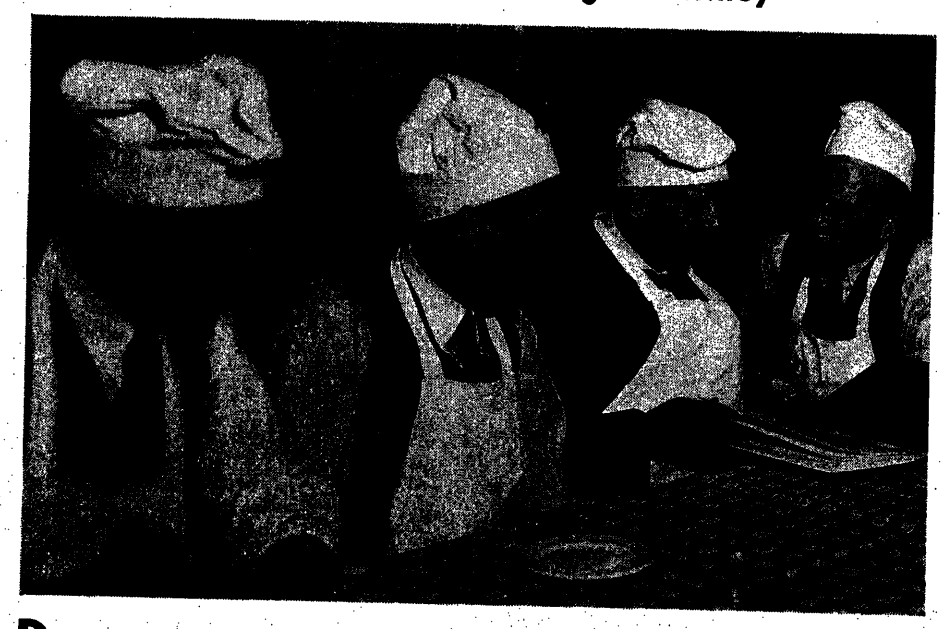
R. F. Monges, executive committee, San Francisco Section
W. H. Evans, executive committee, San Francisco Section
C. V. Fowler, executive committee, San Francisco Section
E. M. Wright, executive committee, San Francisco Section
R. O. Brosemer, chairman-elect, San Francisco Section
J. P. Jollyman, nominee for vice-president AIEE
J. S. Carroll, member-elect of executive committee, San Francisco Section

Vice-President Hinson presided. As the first item of business, chairman Gaylord of the Los Angeles Section read the following letter which he had written to Chairman Lane of the San Francisco Section:

At a recent meeting of the executive committee of the Los Angeles Section, it was unanimously voted that we should pledge to the San Francisco Section our wholehearted support in its effort to have San Francisco chosen as the convention city for the national summer convention of the AIEE in the year 1939.

It was also voted that should you be successful in obtaining the convention that year, we would do everything in our power to help make the convention a success.

After the reading of this letter, the committee voted to go on record as being in favor of holding the Institute's 1939 summer convention in San Francisco.



Promotion of greater interest on the part of students in preparing papers for District Branch paper competition was discussed. It was believed that the student counselors were in best position to encourage the preparation of such papers. It was thought also that the closer co-operation of student relations members on the executive committees of neighboring Sections with the students would encourage the students to prepare papers.

The proposed method of *inviting* Institute members to become Fellows, rather than leaving to the members themselves the initiation of applications for transfer to that grade, was discussed. It was the opinion of the committee that this plan should be adopted.

Much discussion centered about the proposed professional engineers licensing act, which was defeated in the California State Assembly at Sacramento this year. It was reported that a committee has been appointed from the San Francisco Engineering Council, which will co-operate with a similar committee from the Los Angeles Engineering Council, to frame a bill licensing professional engineers for possible introduction into the Assembly at their 1939 meeting.

After adjournment, those present attended the regular dinner and monthly meeting of the San Francisco Section.

## Electrical Industry Honors George Stickney

During a chef dinner given as part of the annual advanced lighting conference held recently at General Electric Institute, Nela Park, Cleveland, Ohio, tribute was paid by the electrical industry to G. H. Stickney (A'04, F'24) consulting engineer of the incandescent lamp department of the General Electric Company, Cleveland, in recognition of his numerous contributions to lighting progress during more than 40 years of service with the company. Formal presentation of an elaborate book in which the tribute was inscribed was made by E. E. Potter, eastern sales manager of the incandescent lamp department, in behalf of the hundreds of lighting men whose personal signatures the memento also contains. In the photograph reproduced above are shown John Arthur, Kansas City Power and Light Company; Ward Harrison (F'36) director of Nela Park engineering department; Mr. Stickney, examining his souvenir book; and Mr. Potter.

## Schenectady Section Sponsors Steinmetz Museum

The Schenectady Section of the AIEE, believing that the home of Dr. C. P. Steinmetz, including his library, laboratory, and personal effects, should be preserved to serve as an inspiration for the engineers of all time, is participating with other groups in a campaign to secure funds for its purchase. This property, when acquired, will be converted into a memorial museum to serve as a showplace for all the worthy Steinmetz mementos available, and will provide a point of great interest for all visitors, particularly to electrical engineers. An invitation to participate in the establishment of the museum has been extended to friends of Steinmetz throughout the United States.

## Membership—

Mr. Institute Member:

By bringing to the attention of your Section membership committee, the names of those who you feel are eligible for membership in the Institute, you help both the Institute and your fellow engineers.

Such co-operation on your part is very greatly appreciated by the Section membership committees.

John Banks

Vice-Chairman, District No. 9
National Membership Committee

This is the second activity to memorialize this noted electrical engineer to be engaged in by the Institute's Schenectady Section, the Steinmetz Memorial Lectures having been established by that Section in 1925. To date, 11 lectures in this series have been delivered, the last of which was published in the May 1937 issue of ELECTRICAL ENGINEERING, pages 510–17.

## Student Conference Held by North Central District

The tenth annual conference of Student Branches of the AIEE North Central District was held at the South Dakota State College, Brookings, April 23–24, 1937. The conference included 2 technical sessions at which 8 papers by student authors and a demonstration lecture were presented, a banquet, and 2 business sessions of the Student Branch counselors in the District. Although the official registration numbered only 68, it was estimated that more than 100 persons attended the technical sessions. All 9 Institute Branches within the District were represented.

President A. M. MacCutcheon of Cleveland, Ohio, was present for the entire conference and participated actively in all the technical and business meetings. His interest and advice was said to be very helpful in making this one of the most successful student conferences ever held in the District. He was the principal speaker at the banquet.

The meeting was opened by AIEE Vice-President R. H. Fair of Omaha, Neb., who introduced President MacCutcheon and Doctor H. M. Crothers, dean of engineering of the South Dakota State College, who made an appropriate address of welcome. After the opening address the first technical session began with T. J. Anderson, chairman of the University of Nebraska Branch, presiding. Lester C. Corrington of the South Dakota State School of Mines Branch presided at the second session. The following papers were presented at these sessions:

ARC WELDING AND ITS APPLICATION IN THE INDUSTRY, by James Landmesser, South Dakota School of Mines, Rapid City.

ELECTRON FOCUSING, by R. P. Buckingham and E. Pekhonen, University of North Dakota, Grand Forks.

THE DEVELOPMENT OF SOUND PICTURES, by John McKendry, University of Wyoming, Laramie.

X-RAYS AND THEIR APPLICATIONS, by Charles B. Minnich, University of Nebraska, Lincoln.

THE LIFE OF CHARLES PROTEUS STEINMETZ, by Everett H. Lee, South Dakota State College, Brookings.

SUN AND WIND AS POWER GENERATORS, by Howard McAllister, University of Colorado, Boulder.

SOME INVESTIGATIONS ON ELECTRETS, by John J. Shideler and Alfred R. Lee, University of Denver, Colo.

NEWTON'S DEVELOPMENT OF THE CALCULUS, by Kenneth Frolund, North Dakota State College, Fargo.

In addition to the foregoing papers, a demonstration relating to inductive co-ordination was given by S. B. Hughes and I. M. Ellestad (A'24) of the Northwestern Bell Telephone Company and A. A. Little of the Dakota Central Telephone Company. In this demonstration a miniature transmission line paralleled by a miniature telephone line was employed, and the effect of various conditions on the amount of noise induced on telephone circuits paralleled by power circuits was illustrated. The effectiveness of transpositions in mitigating interference effects was very clearly demonstrated.

Counselors present at the 2 business sessions were: W. H. Gamble, Branch counselor chairman, AIEE North Central District, South Dakota State College; H. S. Rush, North Dakota Agricultural College; H. F. Rice, University of North Dakota; J. O. Kammerman, South Dakota State School of Mines; L. A. Bingham, University of Nebraska; H. B. Palmer, University of Colorado; and G. H. Sechrist, University of Wyoming. President MacCutcheon and Vice-President Fair also attended. Chairman Gamble, who presided, first gave a report of the discussions at the conference of officers, delegates, and members held during the Institute's 1936 summer convention at Pasadena, Calif. Upon formal invitation of Professor Bingham, it was voted that next year's conference be held at the University of Nebraska, Lincoln. Following the usual custom, Professor Bingham then was elected District Branch counselor chairman for the coming term.

Concerning the conduct and scheduling of future student conferences, the following actions were taken:

1. Time allowed for delivering student papers is to be limited to 20 minutes each.
2. Each paper is to be discussed immediately following its presentation.
3. Discussions of student papers are to be limited to students, and the time allowed each discusser is to be limited to 10 minutes.

The proposition of obtaining an outside speaker for the annual conference was discussed and was viewed with favor. T. H. Granfield of Omaha, Neb., secretary of the AIEE North Central District, acted as secretary of the conference.

## Electrical Reports at NFPA Meeting

At the forty-first annual meeting of the National Fire Protection Association, held in Chicago, Ill., May 10–14, 1937, reports were presented by the electrical committee and by committees on static electricity and protection against lightning. H. S. Warren (A'03, F'13) attended the meeting as Institute representative on the electrical committee of the association, and the following information was received from him.

The report of the electrical committee, A. R. Small, chairman, was a summary report outlining the more important changes in the National Electrical Code which were adopted by the committee in March 1937. A minority report was submitted, but this did not prevent the acceptance of the electrical committee's report. The issue raised by the minority report was whether the use of a nontamperable type of plug fuse should be mandatory after July 1, 1937. The electrical committee's attitude was that such mandatory requirement would be premature because of the patent situation and because satisfactory types of nontamperable fuses embodying interchangeability have not yet been made available. Another item in the electrical committee's report which received extended discussion had reference to the classification of pyroxylin plastic manufacturing plants in respect to hazardous locations. The 1937 edition of the code will contain many changes, and will have an entirely new format and editorial arrangement.

The committee on static electricity, P. V. Tilden, chairman, presented a report consisting of 44 printed pages of text and diagrams. Sparks from static electricity constitute a very serious hazard where flammable liquids or gases are present. In many kinds of manufacturing establishments flammable or explosive materials are

involved, so careful safeguarding against sparks is essential. The report tells how accumulations of static electricity can be prevented most effectively by the interbonding and thorough grounding of all metal pipes, containers, and other equipment.

The report of the committee on protection against lightning, M. G. Lloyd (A'08, F'12) chairman, was devoted principally to an additional section covering the protection of reinforced concrete stacks. A similar addition was approved by the sectional committee on protection against lightning of the American Standards Association, which held a joint session with the NFPA on one of the days during the meeting. Doctor Lloyd is chairman of both committees, and Mr. Warren is a member of the ASA committee.

**National Adequate Wiring Program.** Appointments to a national adequate wiring committee have been completed, according to a recent issue of "Nema News," and the committee will now proceed to consider the details for the national adequate wiring program initiated by the National Electrical Manufacturers Association. The broad purpose of the program is to educate the householder to recognize and meet the need for adequate electrical wiring. Members of the committee are: M. E. Skinner and C. A. Eastman (A'35), Edison Electric Institute; E. G. May and S. J. O'Brien, National Electrical Contractors Association; W. E. Sprackling and G. C. Thomas, Jr., NEMA; and J. S. Bartlett and George R. Conover, International Association of Electrical Leagues.

# Current Items From American Engineering Council

## Engineers' Public-Employment Trends

Engineering employment by government agencies in Washington is somewhat disturbed by the threats of both Congress and the Administration actually to apply economy measures. The President has ordered all departments, administrations, and commissions including the Bureau of the Budget materially to reduce current expenditures and to limit future operations to be budgeted within the national income. Congress seems to have accepted the President's advice, and to have set itself to the task of reducing federal expenditures. Allowing for the application of political expediency in yielding to "certain pressures," a substantial reduction in the flow of public funds through the "emergency agencies" for "work relief" and "pump priming purposes" appears more like a certainty than ever before.

As evidence of the acceptance of the seriousness of these intentions, "administrative executives" are advising capable associates to transfer to other work within government service or seek opportunities in private enterprise. Rural electrification and the more permanent agencies are absorbing some of the engineers. Others will be re-employed by special activities similar to "the building materials study" scheduled to be started by the Bureau of Standards in July but a distressingly large number of competent engineers are leaving government work with its uncertainties and meagre compensation for the increasingly attractive private life. In recognition of operating difficulties likely to develop as more of the better engineers return to private employment and practice, the Civil Service Commission is planning to conduct an unassembled examination for engineers of the several grades of a dozen branches of engineering at an early date. Although civil service cannot be made more attractive in either classification or compensation until there is new legislation in that direction, an effort is being made to raise educational and experience standards for each grade, with the hope that engineers better fitted for public service may be induced to qualify for the design, construction, operation, and maintenance of public property, and for research, educational, or advisory and supervisory or inspection duty in the several lines of accepted public service.

Without becoming involved in anything leading toward the socialization of engineering or the standardization of either duties or salaries which might limit engineering initiative, Council through its staff and committees, is aiding the Commission and its "engineer examiners" in their efforts to improve the engineer personnel under civil service. This opportunity to forward engineering recognition and to act indirectly for the improvement of the economic status of the engineer in public service, comes to AEC as an invitation from the Civil Service Commission. Council is thus accepted as an instrumentality of organized engineering in position to express the united opinion of engineers regarding the qualifications for and conditions of the employment of engineers by those arms of the federal government of the United States whose employees are under civil service. In that position, Council may well be a stabilizing influence against unionization. Council is also given an opening to act for the engineering profession to further the use of the merit system in preference to patronage and in the public welfare.

## Government Reorganization

American Engineering Council has made its files available to both The President's Committee on Administrative Management and the Select Committee on the Investigation of Executive Agencies. Members of the staff have advised with both committees regarding the economies which might be attained by regrouping or reorganization of existing agencies. Council has also offered its services to the Joint Committee on Government Reorganization.

Each of the committees has studied Council's recommendation for the centralization of all public works under one qualified head and it is understood that ideas advanced by AEC have been incorporated in committee suggestions as representing the best thought on the subject available. None of the findings of the committees have been announced but all 3 committees are believed to have urged the creation of a public works department.

Four bills carrying the principal points in the President's reorganization program are scheduled for this session of Congress but it is doubted that any of them can pass under present circumstances. Even if departments of public work and social welfare should be established, Congress is not believed to be in a mood to delegate authority to the President over such important "arms" of government service as the comptroller general's office and Interstate Commerce, Federal Trade, Communications, and Power Commissions, or willing to relinquish control over the disposition of public works appropriations and authority. Feelings along these lines, in the Congress, are believed to be almost as deep seated as that involved in the present Supreme Court controversy.

## Rural Electrification Administration

The Rural Electrification Administration had its second birthday on May 11, 1937. As of that date REA had approved 310 projects involving $58,952,958. Of that amount, about $56,862,958 will be used for line construction; $1,980,000 for building generating plants; and $110,000 for financing wiring and plumbing installation. Loan contracts have been executed for more than $45,500,000 of the allotted funds. Projects totaling about $32,000,000 have reached some one of the several stages of construction and according to REA enough wire has been strung on projects which it has financed to reach twice around the earth at the equator.

Some of the new REA procedures will be of interest to engineers in contact with rural electrification: Rural electric co-operatives are now required to use consulting engineering services. The co-operatives may also employ skilled management even before the lines are built and charge such salaries against REA loans until the project is completed and in operation. Help in building load is being supplied by REA experts working in the field under the direction of a small headquarters staff in Washington.

Engineers interested in the production and distribution of electric energy may also be interested in knowing that Administrator John C. Carmody of the Rural Electrification Administration has just announced that a new order of the Kentucky Public Service Commission establishes a whole-

sale rate of about 11 mills per kilowatt-hour, to be made available to rural co-operative projects by 7 private utility companies operating in Kentucky. In a telegram to Governor Chandler, Administrator Carmody states that the Kentucky action "might well serve as a model for other state commissions."

## National Rivers and Harbors Congress

The outstanding feature of the April 1937 meeting of The National Rivers and Harbors Conference was the attention given to various features of water use and control in our river basins other than navigation. In past sessions of this congress, the emphasis has been placed upon navigation and water transportation. At this session, consideration was given to such factors as flood control, stream pollution, power development, water supply for municipal and industrial purposes, and biological and recreational uses.

After a series of addresses and discussions on each of these factors, the following resolution was unanimously adopted: "Ample funds should be provided at once to construct flood control projects already authorized by Congress—There should be no stint where human life and human misery are involved—Nothing substantial has been undertaken to prevent a recurrence of these catastrophies, largely through lack of appropriation—At this very moment another flood is generating at Johnstown, Pittsburgh, and the upper Ohio valley and still there is delay and lethargy."

Two diametrically opposite plans for water resources development received emphasis in this meeting. The first plan is exemplified by the Tennessee Valley Authority and the recent legislation proposed by Senators Barkley, Bulkley, and Norris providing for a series of similar projects throughout the country. The second plan contemplates the co-ordination of federal, state, and local agencies according to the recommendations of the National Resources Committee in the development of basin plans and programs for the various phases of water use and control including navigation, water power, municipal and industrial water supply, sanitation, irrigation, drainage, soil conservation, and the biological and recreational uses.

Council's present attitude favors the plan of co-ordination but the matter is before the AEC committee on the conservation and utilization of natural resources and its recommendation is yet to have consideration by the executive committee and the assembly. In the meantime Council shall be glad to have both opinions and suggestions from individual engineers and member engineering organizations on these questions of such vital social and economic implication.

# Letters to the Editor

CONTRIBUTIONS to these columns are invited from Institute members and subscribers. They should be concise and may deal with technical papers, articles published in previous issues, or other subjects of some general interest and professional importance. ELECTRICAL ENGINEERING will endeavor to publish as many letters as possible, but of necessity reserves the right to publish them in whole or in part, or reject them entirely.

ALL letters submitted for consideration should be the original typewritten copy, double spaced. Any illustrations submitted should be in duplicate, one copy, to be an inked drawing but without lettering, and other to be lettered. Captions should be furnished for all illustrations.

STATEMENTS in these letters are expressly understood to be made by the writers; publication here in no wise constitutes endorsement or recognition by the American Institute of Electrical Engineers.

## A Power Scale for the Instant Heavisidion

*To the Editor:*

At the AIEE winter convention in 1923 the writer demonstrated and described a computing kinematic device for long transmission lines which he named the "Heavisidion" ("The 'Heavisidion,' "AIEE TRANSACTIONS, volume 42, 1923, pages 42–53). With this device, the desired current and voltage having been set in their proper vectorial relationship at one end of the line, the corresponding quantities anywhere on the line, including the other end, could be obtained by a simple rotation of certain portions of the linkages. Moreover, the device was adjustable for any desired line constants and length of the line. Later, the author designed and built a simpler device, suitable only for a particular line and with the electrical quantities indicated only at the 2 ends of the line, but not at intermediate points ("The Instant Heavisidion," *General Electric Review*, volume 28, 1925, page 746). Both these devices indicate the current, the voltage, and the power factor, so that the power may be readily computed. However, it is convenient to have the real, reactive, and apparent power indicated directly on the device, in order to see at once their approximate magnitude and note the sense in which they vary as the load is varied. This is of particular importance in studies of static stability of a line, for which studies the device is particularly suited.

During the spring of 1937, a large heavisidion was built by 2 of the writer's students (figure 1) to illustrate the electrical relationships which may be expected on the 275-kv line between Boulder Dam and the city of Los Angeles. The device was quite carefully and accurately made out of steel bars and so proportioned that the electrical quantities could be scaled off from no load to short circuit within quite a wide range of operating voltages. The measured currents and voltages agreed with those analytically computed by means of hyperbolic functions of a complex variable to within better than one per cent. It was therefore deemed opportune to add a power scale to the device to enable true kilowatts, reactive kilovolt-amperes and apparent power to be read off directly.

The principle upon which the power scale is based is shown in figure 2. The line $CO$ is the same as that in figure 2 in the article in the *General Electric Review*, referred to above. The line $CD$ is drawn at an angle $\theta$ to it, $\theta$ being the same as in that article. $CB$ is the current vector whose correct phase angle $\phi$ is with respect to $CD$, and not $CO$. $CDFG$ is a piece of ruled paper (ordinary cross-section paper with decimal divisions will do). $HJ$ is a guide, and $CK$ is a straightedge whose lower side, $UMN$, passes through $C$ and is used in measuring power. The straightedge can be fastened at any point of the guide by means of the thumbscrew at $L$. $S$ and $T$ are 2 markers which can slide along $CG$ in grooves or along straight guides, to fix the values of the real and reactive power until the next reading. The kilovolt scale along the edge $FG$ is a nonuniform scale, computed as is explained below. The setting at $U$ must be the same as the value of the voltage $OC$. Thus, if $OC$ is 300 kv, the straightedge must be set for the division 300 at $U$. If, however, $OC$ is read in centimeters and not in kilovolts another scale along $FG$ must be used, also calibrated in centimeters, but in reality a nonuniform scale.

The use of this attachment is as follows: Having set the Heavisidion for some desired currents and voltages, read $OC$ (in centimeters or in kilovolts) and set the straightedge $CK$ accordingly. Follow the ruled line $BN$ to point $N$ and set the marker $S$, following the ruled line $NS$. $CS$ gives the real power, on the scale marked on $CG$, directly in kilowatts. With a pair of dividers transfer the reactive component of the current, $CR$, into the position $CR'$. Follow $R'M$ with the eye, and set the marker $T$ accordingly. $CT$ will give the reactive kilovolt-amperes, to the same scale as the real power. If the total kilovolt-amperes

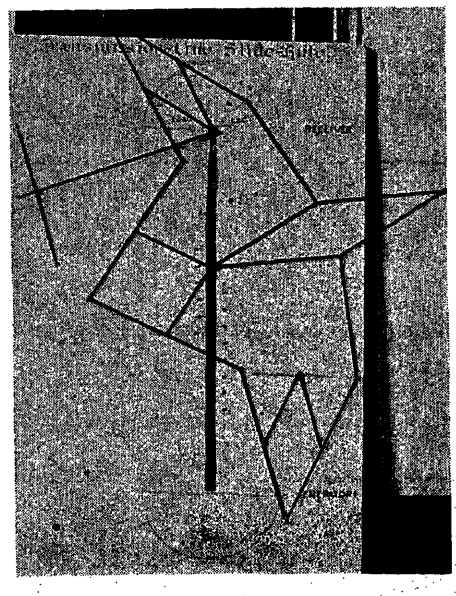


Figure 1

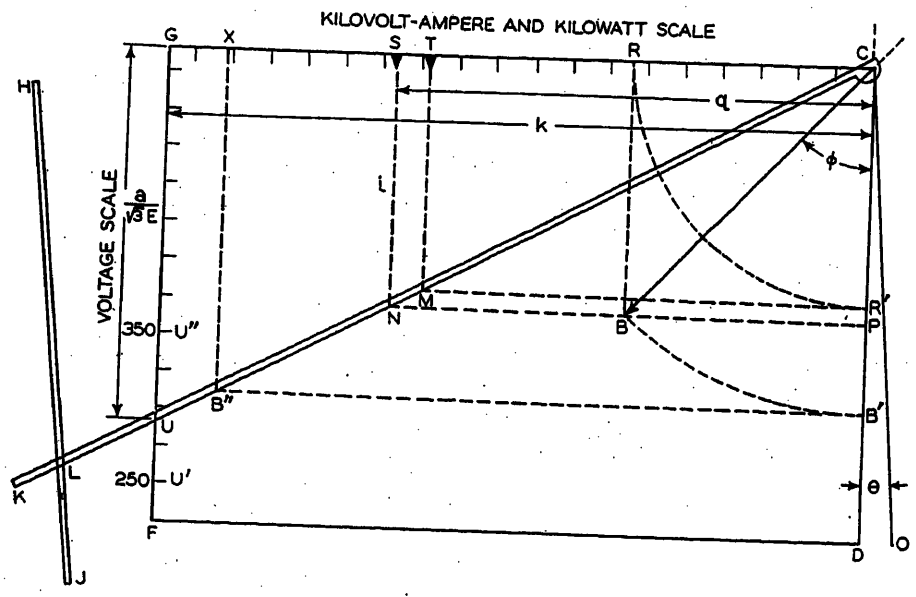

**Figure 2**

are desired, transfer $B$ to $B'$, follow $B'B''$ to its intersection with $KC$, and read $CX$ on the kilowatt scale, as before.

The foregoing arrangement is based on the similarity of the triangles $UGC$ and $NSC$. We have

$$UG/GC = NS/SC \qquad (1)$$

Make $UG = a/(E\sqrt{3})$, where $a$ is a convenient arbitrary constant, and $E$ is the line voltage $OC$. $GC$ is an arbitrary length denoted by $k$. $NS$ is the power component, $i$, of the line current. $SC$ must be the value of the real power, $iE\sqrt{3}$; let it be denoted by $q$. Equation 1 may therefore be rewritten in the following form:

$$a/(Ek\sqrt{3}) = i/q \qquad (2)$$

from which

$$q = Eik\sqrt{3}/a \qquad (3)$$

Since $a$ and $k$ are arbitrary constants, they can be so chosen that $q$ will give the 3-phase power, $Ei\sqrt{3}$.

The following example illustrates the choice of the scales. Let the range of operating voltages be from 250 to 350 kv. Choose arbitrarily $a = 25 \times 35 \times \sqrt{3}$. For $E = 250$ kv, the length $GU'$ will be 35 centimeters, but the division marked there will be 250 kv. For $GU''$ the length will be 25 centimeters, but the voltage marked there will be 350. Any number of intermediate divisions may be similarly computed, and a fairly detailed nonuniform scale drawn. Let the current scale be 1 centimeter = 50 amperes, and let us compute the conditions for an in-phase component $i = 400$ amperes, or 8 centimeters. Let the line voltage be 350 kv, so that the real power is 242,500 kw. To pick out a convenient value for $k = CG$, we reason as follows: $NS$ is 8 centimeters, and $GU$ is 25 centimeters (assuming $U$ to be at 350 kv). Hence, the division of the power scale at $G$ must be (25/8) 242,500 = 758,000 kw. It is therefore convenient to choose 1 centimeter = 20,000 kw, making the length $CG$ = 37.9 centimeters. The same power scale will be correct, by construction, for any other value of the line voltage.

One could establish theoretical equations for the interdependence of the scales, but it seems that a few trials, such as the foregoing example, will readily permit to choose the most convenient proportions within the available space on the board. The power scale is shown in the upper left corner in figure 1. The board on which the Heavisidion is mounted is 42 by 64 inches; this will give the idea about the size of the device.

The writer wishes to express his appreciation of the help rendered by his 2 former students, Robert R. Gay (Enrolled Student) and Paul H. Hunter, both Cornell '37, who computed the sizes of the linkages and actually built and assembled the device following the writer's instructions in the 2 abovementioned articles.

Very truly yours,

VLADIMIR KARAPETOFF
(A'03, F'12, Life Member)
Cornell University, Ithaca, N. Y.

## Articles on Radio in "Electrical Engineering"

*To the Editor:*

This is just a note to let you know how attractive the June issue of ELECTRICAL ENGINEERING is with its cover lettered in red. I am sure that the combination of color printing and the unique paper which is used makes this publication by all odds the most pleasing in appearance of the 20-odd periodicals which reach my desk every month.

I will also take this opportunity to tell you how pleased I was to find not just one but 2 articles on radio in the June issue. When it is remembered that the radio industry produced about 8-million receivers last year, the importance of this branch of electrical engineering stands out. I trust that this field will continue to receive the attention it so clearly deserves in ELECTRICAL ENGINEERING.

Very truly yours,

ALBERT R. HODGES (A'37)
Associate, Ralph H. Langley,
Consulting Engineer
165 Broadway, New York, N. Y.

## Induction Motors on Unbalanced Voltages

*To the Editor:*

I wish to point out some errors in my discussion which appeared in the May 1937 issue of ELECTRICAL ENGINEERING on page 621.

In the center column the equation appears,

$$I_c = I$$

This should be

$$I_c = -I$$

Lower down in the same column the equation

$$V_{bc} = j(\sqrt{3}\ V_{s1} - V_{s2})$$

is shown. This should be

$$V_{bc} = j\sqrt{3}\ (V_{s1} - V_{s2})$$

Equation 1 reads

$$I_{s1} = I_{s2}$$

This should be

$$I_{s1} = -I_{s2}$$

The second line of equation 4 appears as,

$$V_b = \alpha^2 I_1 Z_1 + \alpha I_2 V_2 - (I_1 + I_2)\ Z_0$$

This should be,

$$V_b = \alpha^2\ I_1 Z_1 + \alpha\ I_2 Z_2 - (I_1 + I_2)\ Z_0$$

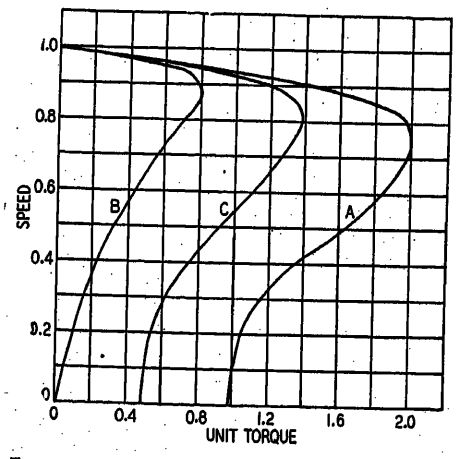

**Figure 4. Speed-torque characteristics of a 5-horsepower 220-volt 3-phase 60-cycle 6-pole induction motor**

*A*—Normal 3-phase operation
*B*—Single-phase operation, line-to-line voltage
*C*—Operation on 2 of the 3 phases
The motor constants in unit values are as follows:

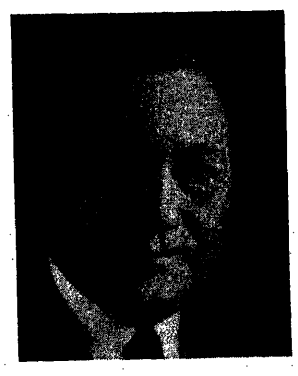
$r_{s1} = 0.044$
$r_{r1} = 0.057$
$Z_0 = 0.044 + j\,0.140$
$Y_{m1} = 0.023 + j\,0.380$
$X_{s1} + 0.140$
$X_{r1} = 0.140$

The speed-torque curves of figure 4 were not published in the May issue and are therefore given here.

Very truly yours,

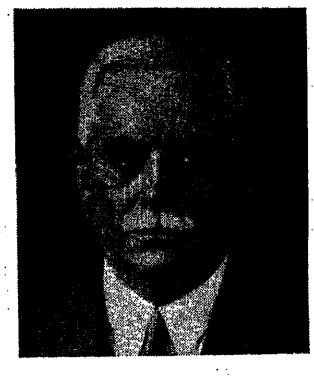
H. J. REEVES (A'30)
PAUL AND REEVES,
Spokane, Wash.

# Personal Items



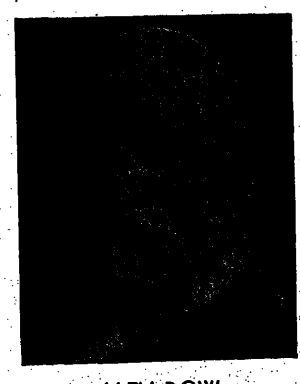
B. J. ARNOLD (A'92, F'12, past-president, member for life) consulting engineer, Chicago, Ill., has been elected an Honorary Member of the Institute. Colonel Arnold was born at Casnovia, Mich., in 1861, and received the degrees of bachelor of science (1884) and mechanical engineer (1887) at Hillsdale College; later, he took a graduate course in electrical engineering at Cornell University, in 1897 received the degree of electrical engineer from the University of Nebraska, and at various times has received several honorary degrees. One of Colonel Arnold's first important engineering projects was the design and construction of the Intramural Elevated Railway at the Columbian Exposition in Chicago, in 1893. This was the first commercial demonstration of the third rail on a large scale. Later he did pioneer work of construction for such railroads as the Chicago-Milwaukee Electric Railway and the Lansing, St. Johns, and St. Louis Railway in Michigan. For the latter company he devised, in 1900, a single-phase a-c system. Colonel Arnold electrified the Grand Trunk Railroad through the St. Clair Tunnel from Port Huron, Mich., to Sarnia, Ont., Canada, and used for the first time a single-phase high-voltage system for heavy electric railway work. Among his other important commissions were the electrification of the Grand Central Terminal, New York, N. Y., and the development of the subway system in New York. He has been a consultant on surface and underground traction problems for cities throughout the United States and consulting engineer for numerous railroad commissions. During the World War Colonel Arnold served in various capacities, being assigned as lieutenant colonel in the aviation section in 1917, to make a complete survey of aircraft supply and production facilities for the United States Army and Navy, and to take charge of the development and production of aerial torpedos. He has served the Institute as manager, 1895–98; vice-president, 1902–03; and president, 1903–04. In addition, he has served as a member of the committees on education, 1924–26; meetings and papers (now technical program), 1902–03 and 1908–09; executive, 1924–26. He was a member of the American Committee on Electrolysis (1914–21 and 1922–32) and of the John Fritz Medal board of award during 1905–08. Colonel Arnold received the Washington Award of the Western Society of Engineers in 1929, and is a member of many technical and engineering societies, including the American Society of Civil Engineers, The American Society of Mechanical Engineers, and the American Society for the Promotion of Engineering Education.

P. S. MILLAR (A'03, M'13) president, Electrical Testing Laboratories, Inc., New York, N. Y., has received the 1936 AIEE national prize award for best paper in engineering practice for his paper "The Qualities of Incandescent Lamps." Mr. Millar was born at Andover, N. J., in 1880, and obtained his formal technical education at Paterson Classical and Scientific School and through the International Correspondence Schools. In 1897 he entered the employ of the Lamp Testing Bureau (now Electrical Testing Laboratories, Inc.) and in 1899 became assistant manager of that organization. He became general manager in 1914, and has been president since 1930. Mr. Millar has done much original work in illumination research, being co-inventor of the Sharp-Millar photometer, and has contributed liberally to the technical press. He has been a member of the Institute's committees on electrophysics, 1917–18; meetings and papers (now technical program), 1925–28; and production and application of light (chairman, 1925–28) since 1924. Recently he was elected president of the United States National Committee of the International Commission on Illumination. Mr. Millar is a fellow of the American Physical Society, member of the council of the Association of Consulting Chemists and Chemical Engineers, secretary-treasurer of the Association of Edison Electric Illuminating Companies, member and past-president of the Illuminating Engineering Society, and a director of the Thomas Alva Edison Foundation.



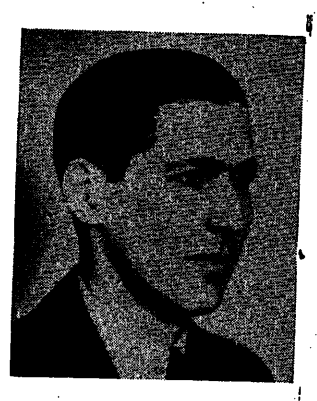
ALEX DOW (A'93, F'13, member for life) president, Detroit (Mich.) Edison Company has been elected an Honorary Member, the highest grade of membership in the Institute. The petition proposing his election as Honorary Member stated: "Doctor Dow's responsible guidance has developed one of the great utility companies, which has, throughout this long period [Doctor Dow has been President of the Detroit Edison Company for 24 years] been in the van of technical progress and which has maintained a high standard of service in the public interest." He has been a leading pioneer in the United States in the engineering, rate making, and general operation of the electric light and power utility, and is given credit for both the engineering and financial success of his enterprises. He is considered the father of the so-called "big" steam boiler in the United States and was the first to adopt the underfeed stoker for large installations. A more complete biographical sketch of Doctor Dow was published in the January 1937 issue of ELECTRICAL ENGINEERING (page 197) upon the occasion of the award to him of the AIEE Edison Medal for 1936 "for outstanding leadership in the development of the central station industry and its service to the public."

W. J. LYMAN (A'25) electrical planning engineer, Duquesne Light Company, Pittsburgh, Pa., has received honorable mention in the 1936 AIEE national prize awards for best paper in engineering practice for his paper "The Relation Between Load, Capacity, and Service Continuity on an Electric Power System." Mr. Lyman was born August 30, 1901, at Cambridge, Mass., and received the degree of bachelor of science in electrical engineering at Carnegie Institute of Technology in 1924. Prior to his enrollment at that school he was affiliated briefly with the Turners Falls Power and Electric Company, Greenfield, Mass., and the Automatic Transportation Company, Buffalo, N. Y. In 1924 he entered the employ of the Duquesne Light Company as an apprentice engineer, but in the following year was transferred to the planning division of that company, where his work has consisted of engineering and economy planning for the entire system. Mr. Lyman has been electrical planning engineer since 1929, in which capacity he has been in entire charge of the electrical planning section. From 1927 to 1932 he served as a member of the lightning arrester subcommittee of the AIEE protective devices committee, and was active in committee work of the former National Electric Light Association. In addition to his regular duties, Mr. Lyman has taught technical subjects in the night school at Carnegie Institute of Technology since 1924. He has written several technical papers and articles, including 2 papers presented before the Institute.

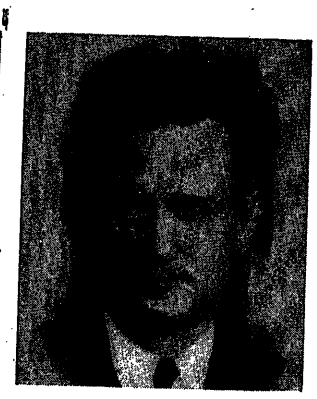


H. P. SEELYE (A'19, M'28) engineer for The Detroit (Mich.) Edison Company, has received honorable mention in the 1936 AIEE national prize awards for best paper in engineering practice for his paper "Modernization of Power Distribution Systems." Mr. Seelye was born June 27, 1890, and was graduated from the University of Michigan

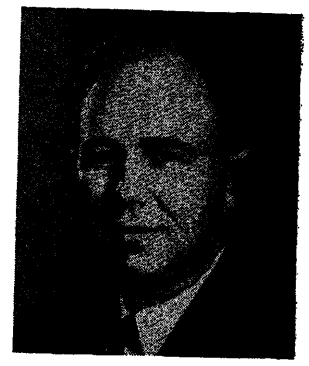
P. S. MILLAR



B. J. ARNOLD



ALEX DOW



with a degree in civil engineering in 1912. After 4 years of varied engineering training, he entered the employ of The Detroit Edison Company in 1916, and since that time has been engaged in transmission and distribution engineering problems and design. Mr. Seelye now is in active charge of the transmission and distribution section of the Company. He was chairman of the AIEE Detroit-Ann Arbor Section during 1935–36, and is a member of the distribution subcommittee of the AIEE committee on power transmission and distribution and the electrical standards committee of the American Standards Association. In addition, he is a sponsor of the group on standards and specifications of the transmission and distribution committee of the Edison Electric Institute. Mr. Seelye is the author of 2 books: "Electrical Distribution Engineering" and "Economics of Electrical Distribution."

D. H. ROWLAND

H. R. WOODROW

H. E. EDGERTON

H. R. WOODROW (A'12, F'23) vice-president, Brooklyn (N. Y.) Edison Company, Inc., has been elected vice-president of the Consolidated Edison Company of New York, Inc., New York, N. Y. Mr. Woodrow was born April 15, 1887, at Luverne, Minn., and received the degrees of bachelor of science (1909) and master of science (1911) at Drake University and University of Illinois, respectively. Following his graduation in 1911 he joined the engineering staff of The New York Edison Company, Inc., as assistant to the chief electrical engineer, and held that position until he was appointed assistant chief electrical engineer in 1917. In 1920 he became affiliated with Stone and Webster, Inc., as an electrical engineer, but remained with that company for only one year before transferring to the Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa., as a general engineer. Mr. Woodrow entered the employ of the Brooklyn Edison Company in 1922 as an assistant electrical engineer. Four years later he was promoted to electrical engineer, and since 1932 he has been vice-president. He served the Institute as a director from 1931 to 1935, and is at present serving as its representative to the United Engineering Trustees for the term 1934–37, just ending. He has also served as a member of many of the Institute's technical committees.

H. E. EDGERTON (A'27, M'32) assistant professor of electrical engineering, Massachusetts Institute of Technology, Cambridge, has received the 1936 AIEE national prize award for best paper in theory and research for his paper "High Speed Motion Pictures." Doctor Edgerton was born April 6, 1906, at Fremont, Nebr., and was graduated in electrical engineering from the University of Nebraska in 1925, following which he entered the test course of the General Electric Company, Schenectady, N. Y. In 1926 he enrolled in the graduate school of Massachusetts Institute of Technology and received from that institution the degrees of master of science (1927) and doctor of science (1931). During 1927–28 Doctor Edgerton served as a research assistant, and in the following year was appointed to the faculty of MIT as an instructor in electrical engineering. He became assistant professor in 1932. His graduate work for his doctor's degree consisted of research on synchronous machines and stroboscopes, and much of his subsequent research has been of a similar nature. He has become widely recognized for his accomplishments in studying motions of machines and moving parts by means of high-speed motion pictures. Doctor Edgerton served as a member of the Institute's committee on electrical machinery from 1931 to 1935.

D. H. ROWLAND (A'26) research engineer, Locke Insulator Corporation, Baltimore, Md., has received the 1936 AIEE national prize award for initial paper for his paper "Porcelain for High Voltage Insulators." Mr. Rowland was born December 25, 1898, at Baltimore, and received the degree of bachelor of science in electrical engineering at The Johns Hopkins University in 1922; however, his college training was interrupted by his service in the United States Army during the World War, and at the conclusion of the war Mr. Rowland went to Paris, France, to study physics and mathematics at the Sorbonne University before returning to the United States. Following his graduation he was employed in the statistical department of Stone and Webster, Boston, Mass., but shortly thereafter he entered the lightning protection department of the Western Union Company, New York, N. Y. In 1922 Mr. Rowland became affiliated with the Locke Insulator Corporation and in various capacities has since served that company continuously. He is the author of several technical articles on ceramics as related to insulators. He is a member of Tau Beta Pi and Omega Delta Kappa honorary fraternities.

W. L. SMITH (M'22) professor and head of the department of electrical engineering, Northeastern University, Boston, Mass., recently retired from active duty, after more than 40 years of service. Professor Smith was born September 6, 1867, at Concord, Mass., and was graduated in electrical engineering from Massachusetts Institute of Technology in 1890. Following his graduation he was appointed to the faculty of the same institution as an assistant in physics; later, he became an assistant in electrical engineering and an instructor in electrical engineering, but resigned in 1902 to pursue experimental and consulting-engineering work. Professor Smith has been head of the department of electrical engineering since the incorporation of Northeastern University in 1916.

A. A. LOW (M'37) executive vice-president, Brooklyn (N. Y.) Edison Company, Inc., has been elected vice-president of the Consolidated Edison Company of New York, Inc., New York, N. Y. Mr. Low was born August 1, 1889, at Saratoga Springs, N. Y., and received the degree of bachelor of arts at Yale University in 1911. He entered the public utility field in 1928 as organizer and president of the Old Forge (N. Y.) Electric Company. In 1931 he became affiliated with the Utica (N. Y.) Gas and Electric Company as executive vice-president, which position he held for 3 years before being elected president of that company in 1934. Mr. Low became identified with the Brooklyn Edison Company in 1936 as executive vice-president in responsible charge of operations.

W. R. HARRY (A'37) Bell Telephone Laboratories, Incorporated, New York, N. Y. has received honorable mention in the 1936 AIEE national prize awards for Branch paper for his paper "A High-Speed Vibration Analyzer." Mr. Harry is a native (1912) of Detroit, Mich., and an electrical engineering graduate of Cornell University. Prior to graduation, he was employed during summer vacations by The Detroit Edison Company and radio station CKLW, Windsor, Ont., Canada. Since the beginning of his association with the Bell Telephone Laboratories, in 1936, he has been engaged in the derivation of a new microphone for broadcast use.

W. P. GRAHAM (A'02, F'23) acting chancellor, Syracuse University, Syracuse, N. Y., has been appointed chancellor. As stated in a biographical sketch of Doctor Graham published in the December 1936 issue of ELECTRICAL ENGINEERING (page 1404) he has been affiliated with the university for almost 40 years, and was vice-chancellor for 15 years prior to his appointment as acting chancellor in 1936.

W. J. WALSH (Enrolled Student) graduate student in electrical engineering at Oregon State College, Corvallis, has been awarded the 1936 AIEE national prize award for

Branch paper for his paper "Heat Transfer Efficiency of Electric Range Surface Units." Mr. Walsh was born February 7, 1915, at Portland, Me., and received the degree of bachelor of science in electrical engineering at Oregon State College in 1936. In addition to his regular scholastic work, Mr. Walsh serves as a research assistant in the Oregon State College Engineering Experiment Station. He is a member of Tau Beta Pi, Eta Kappa Nu, Phi Kappa Phi, and Sigma Xi.

G. H. JONES (A'02, F'12) for many years power engineer for the Commonwealth Edison Company, Chicago, Ill., recently was appointed manager of power sales. Mr. Jones was born at Fond du Lac, Wis., in 1874, and received the degree of bachelor of science in electrical engineering at the University of Wisconsin in 1897. He became affiliated with the Commonwealth Edison Company in 1909.

E. S. SIEVERS (A'34) who has been a sales engineer in the New York (N. Y.) offices of the Weston Electrical Instrument Corporation, has been transferred to Los Angeles, Calif., as assistant to the Weston company's representative in that area. Mr. Sievers has been associated with the Weston organization continuously since his graduation from Purdue University in 1934.

T. H. HAINES (A'23, M'31) superintendent, distribution department, Edison Electric Illuminating Company of Boston, Mass., has been appointed a representative of the AIEE on the Sectional Committee on National Electrical Safety Code.

W. C. GOODWIN (M'33) air conditioning department, Westinghouse Electric & Manufacturing Company, Mansfield, Ohio, has been appointed a representative of the AIEE on the Sectional Committee of Safety Code for Mechanical Refrigeration.

H. B. GEAR (A'01, F'20, director) vice president in charge of operating and engineering, Commonwealth Edison Company, Chicago, Ill., has been appointed a representative of the AIEE on the Commission of Washington Award for the 2-year term beginning August 1, 1937.

J. F. LAMBIAS, JR. (A'36) formerly a distribution draftsman for the Brooklyn (N. Y.) Edison Company, now is a junior engineer in the evaluation bureau of the New York and Queens Electric Light and Power Company, Long Island City, N. Y.

S. P. SAWYER (A'30) formerly assistant district engineer, New England Power Service Corporation, Northampton, Mass., now is assistant superintendent of distribution, Central Massachusetts Electric Company, Palmer, Mass.

L. L. ROBINSON (A'31) who has been employed by the Kinnear Manufacturing Company, Columbus, Ohio, now is associated with the production division of the Marion Steam Shovel Company, Marion, Ohio.

S. A. SMITH, JR. (A'24, M'31) resigned recently from the Public Service Electric and Gas Company, Newark, N. J., to become affiliated with the engineering department of the General Cable Corporation, New York, N. Y.

F. W. MEYEREND (A'34) electrical engineer, John A. Roebling's Sons Company, San Francisco, Calif., has been transferred to the Trenton, N. J., offices of that Company.

FRANK MANSUR (A'35) local agent for the Southern California Edison Company, Placentia, Calif., has been appointed commercial and industrial lighting specialist for that company, with offices at Santa Ana.

M. M. DE LASCURAIN (A'36) recently resigned his position in the engineering department of the General Electric Company, Mexico City, Mexico, to become sales manager of Cía Comercial Ericsson, Mexico City.

K. C. HOLLISTER (A'35) assistant sales engineer, Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa., has been transferred to the New York (N. Y.) offices of that company.

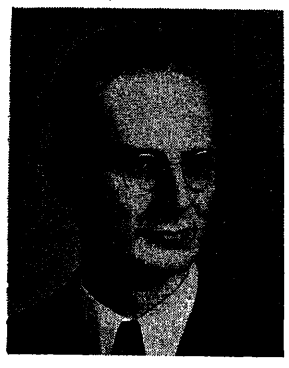
JOSEPH GLADIS (A'27) who has been employed by the Board of Transportation, City of New York, N. Y., now is affiliated with the switchgear engineering department of the Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.

C. H. ANDERSON (M'34) formerly general superintendent of the Ontario division of the Niagara, Lockport, and Ontario Power Company, Medina, N. Y., now is general superintendent of the Niagara Falls division of the Buffalo and Niagara Electric Corporation, Niagara Falls, N. Y.

NATHAN FRIEDLAND (A'36) formerly production manager of Belmet Products, Inc., Brooklyn, N. Y., now is employed in the office of the signal engineer of the Interborough Rapid Transit Company, New York, N. Y.

W. C. STEWART (A'28) formerly an engineer in the data division of the General Electric Company, Schenectady, N. Y. has become technical adviser to the American Institute of Bolt, Nut, and Rivet Manufacturers, Cleveland, Ohio.

PAUL SHAAD (A'34) student engineer, General Electric Company, Schenectady, N. Y., has been transferred to the San Francisco, Calif., offices of that company.

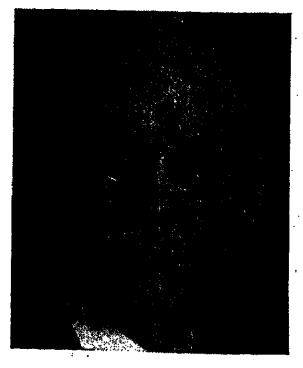


H. W. GIESECKE (A'35) formerly employed in the electrical department of the Federal Shipbuilding & Dry Dock Company, New York, N. Y., now is an engineer in the general engineering department of the Standard Oil Development Company, Elizabeth, N. J.

B. V. HOARD (M'36) who has been an engineering assistant in the plant bureau of the Consolidated Edison Company of New York, Inc., New York, N. Y., now is with the Westinghouse Electric & Manufacturing Company, Newark, N. J.

TALIAFERRO MILTON (A'11, F'20) has been appointed special representative of the K. W. Battery Company, with headquarters at Chicago, Ill.

## Obituary



AMBROSE SWASEY (HM'28) chairman of the board, The Warner and Swasey Company, Cleveland, Ohio, died at his summer home in Exeter, N. H., June 15, 1937, in his 91st year. Doctor Swasey was born at Exeter, N. H., December 19, 1846. During the period 1869–80 he was with the Pratt and Whitney Company, Hartford, Conn., where he gave special attention to problems of gearing. In 1880 he formed a partnership with W. R. Warner, the firm being incorporated in 1900 as The Warner and Swasey Company. The company engaged in the manufacture of machine tools and astronomical instruments at Chicago, Ill., moving later to Cleveland, Ohio. Doctor Swasey has been chairman of the board since the death of Mr. Warner. In 1914, he established the Engineering Foundation, research agency of the 4 national societies of civil, mining and metallurgical, mechanical, and electrical engineers. He has contributed gifts totaling more than $750,000 to the Foundation. Doctor Swasey's many

W. J. WALSH

A. A. LOW

W. P. GRAHAM

honors include: The John Fritz Gold Medal, 1924; Franklin Medal, highest award of the Franklin Institute; Washington Award, 1935; The Second Hoover Gold Medal, 1936; and the Medal of Honor of the Verein Deutscher Ingenieure, 1936. In addition to honorary membership in the AIEE, which was awarded him June 27, 1928, he is an honorary member of The American Society of Mechanical Engineers (president 1904), American Society of Civil Engineers, Institution of Mechanical Engineers (Great Britain), Institution of Mining Engineers (Great Britain), and the Society of Civil Engineers. He is a chevalier and officer of the French Legion of Honor, and has received several honorary degrees in the United States.

ARTHUR LANGLEY MUDGE (A'01, M'12, F'12) consulting electrical engineer, Toronto, Ont., Canada, died April 29, 1937. Mr. Mudge was born October 17, 1873, at Montreal, Que., Canada, and was graduated in mechanical engineering at McGill University in 1894; in 1895 he received a degree in electrical engineering at the same institution and almost at once joined the Canadian General Electric Company, Peterborough, Ont., as an instructor in the student training course. In 1897 Mr. Mudge became affiliated with the Royal Electric Company, Montreal, where he remained for 2 years as a test engineer before being appointed electrical engineer for the Grand Trunk Railway Company. In 1901 Mr. Mudge became engaged as a test engineer for the Stanley Electric Manufacturing Company, Pittsfield, Mass., but in 1904 he began a series of brief associations with the Allis-Chalmers Manufacturing Company in the United States and the Allis-Chalmers-Bullock Company and the Crocker-Wheeler Company, Ltd., in Canada, which lasted until 1908. At that time he joined the consulting engineering firm of Smith, Kerry, and Chace, Toronto, and was placed in charge of the electrical department. He remained with that company until 1925, when he was appointed senior electrical engineer with the joint board of engineers in the Canadian section of the St. Lawrence waterways project. In 1927 Mr. Mudge was appointed senior electrical engineer of the Welland Ship Canal and remained in charge until construction was completed. He was chairman of the AIEE Toronto Section during 1911–12, was a past-vice-president of the Canadian Electrical Association, and a member of the Association of Professional Engineers of Ontario.

HARRY MILTON DEARMIN (A'22, M'28) supervising draftsman, Pacific Gas and Electric Company, San Francisco, Calif., died recently. Mr. Dearmin was born September 16, 1895, at Hillsboro, Texas, and received the degree of associate in electrical engineering at the Polytechnic College of Engineering. Following brief periods of association with the Pacific Gas and Electric Company, the Marconi Wireless Telegraph Company of America, and the Western Electric Company, he entered the employ of the United Electric Vehicle Company, Oakland, Calif., and was placed in charge of plant maintenance. He was affiliated with that company for only one year, however, before enlisting in the United States Navy, in 1917, as an electrician. Later he was promoted to the rank of ensign, and was made an inspector of machinery at the Union Iron Works, San Francisco. At the end of the World War Mr. Dearmin joined the engineering staff of the Pacific Gas and Electric Company as a designer, and had been a supervising draftsman since 1924.

ELDEN S. CODE (A'11, M'20) electrical engineer, Westinghouse Electric & Manufacturing Company, Seattle, Wash,. died January 1, 1937, according to word just received at Institute headquarters. Mr. Code was born January 15, 1883, at Carleton Place, Ont., Canada, and received the degree of bachelor of science in electrical engineering at Queens University in 1907. Following his graduation, he entered the electrical engineering apprenticeship course of the Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa., and upon completion of the course was transferred to the switchboard engineering department of that company. In 1910 he was sent to the Seattle offices of the Westinghouse company. His work there comprised sales and design work for industrial, power, railway, and lighting projects, and his service extended over more than 25 years.

MICHAEL ROMANO (A'20) manager and treasurer, Hackett Products Company, Inc., Providence, R. I., died March 21, 1937. Mr. Romano was born in Italy, February 15, 1886, and attended Lowell Institute and Massachusetts Institute of Technology. From 1908 to 1914 he served the General Fire Extinguisher Company, Providence, first as an electrician and later as maintenance engineer. In 1914 he entered the employ of the General Electric Company, Schenectady, N. Y., as a test engineer and remained there for 4 years before becoming an inspector for the United States Navy. He became associated with the Hackett Products Company, Inc., in 1925.

ZELLA A. MCBERTY (A'24) secretary and treasurer of The Federal Machine and Welder Company, Warren, Ohio, and one of the few women members of the Institute, died May 24, 1937. Mrs. McBerty was born August 27, 1878, at Mineral Ridge, Ohio, and received her formal technical training through private instruction. In 1913 she became interested in electric welding, and began to design low-voltage transformers and electric welding machines. In the following year she became affiliated with the National Electric Welder Company, Warren, and her service with that company and its successor, The Federal Machine and Welder Company, was continuous for more than 22 years. Mrs. McBerty had retired from active service on the day of her death.

EMIL M. KAEGI (M'36) electrical engineer for the Allis-Chalmers Manufacturing Company, Milwaukee, Wis., died recently. Mr. Kaegi was born June 21, 1900, at Zurich, Switzerland, and received his technical education by serving an apprenticeship with the Trueb Tauber Company, Zurich, from 1915 to 1919. In 1919 he became a designer of d-c control apparatus for the Brown Boveri Company, at Baden, Switzerland, but in the following year came to the United States, where he secured a position with the Hoskins Manufacturing Company, Detroit, Mich., and remained 2 years. After a brief association with the F. B. Electrical Company and the Premier Radio Corporation, Detroit, Mich., he joined the Brown Boveri Company, Camden, N. J., and was placed in charge of the drafting department for rectifiers and auxiliary equipment. In that capacity Mr. Kaegi supervised the design of several large substations in the United States and Canada, and when the Brown Boveri Company was purchased by the Allis-Chalmers Manufacturing Company in 1931, he was retained in the same position, but with the title of electrical engineer.

THOMAS HOSKINS KETTIG (A'34) construction superintendent, Southern Bell Telephone and Telegraph Company, Louisville, Ky., died February 12, 1937. Mr. Kettig was born at Louisville, August 2, 1889, and received his education in the public schools there. He served the Southern Bell Telephone and Telegraph Company in various capacities for 31 years, and was superintendent of construction in the Kentucky division for more than 12 years.

# Membership

## Recommended for Transfer

The board of examiners, at its meeting on June 16, 1937, recommended the following members for transfer to the grade of membership indicated. Any objection to these transfers should be filed at once with the national secretary.

**To Grade of Fellow**

Bailey, R. Cooper, system control engineer, Virginia Electric and Power Company, Richmond.
Spurck, R. M., manager, circuit breaker sales, General Electric Company, Philadelphia, Pa.

2 to Grade of Fellow

**To Grade of Member**

Blevins, Edward, assistant superintendent, Tampa Electric Company, Plant City, Fla.
Burroway, A. C., division plant superintendent, Cincinnati and Suburban Bell Telephone Company, Cincinnati, Ohio.
Carlin, P. J., superintendent of distribution, Florida Power and Light Company, Miami.
Concordia, C., engineer, General Electric Company, Schenectady, N. Y.
Coursey, R. W., underground engineer, Oklahoma Gas and Electric Company, Oklahoma City.
Crary, S. B., member central station department, General Electric Company, Schenectady, N. Y.
Dean, C. E., radio engineer, Hazeltine Service Corporation, New York, N. Y.
Fife, S. T., professor of electrical engineering, and head of department, University of Louisville, Louisville, Ky.
Holton, J. L., assistant distribution engineer, New York and Queens Electric Light and Power Company, Flushing, N. Y.
Houchens, J. M., co-ordinator (assistant professor), University of Louisville, Louisville, Ky.
Howes, J. C., electrical engineer, General Electric Company, Pittsfield, Mass.
Jones, J. Coleman, superintendent of transmission, Florida Power and Light Company, Fort Pierce.
Lea, R. A., distribution engineer, Union Electric Light and Power Company, St. Louis, Mo.
Loeffler, B. T., division equipment engineer, Indiana Bell Telephone Company, Indianapolis, Ind.
Macalpine, William W., communication engineer, Federal Telegraph Company, Newark, N. J.
McMorris, William A., electrical engineer, General Electric Company, Pittsfield, Mass.

Miller, C. W., sales engineer, Westinghouse Electric & Manufacturing Company, New York, N. Y.
Mulligan, J. F., superintendent, transmission division, Consolidated Edison Company of New York, Inc., New York, N. Y.
Parker, William W., technician, switchgear engineering department, Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.
Skone, R. C., resident engineer, Diablo Project, Rockport, Wash.
Southworth, H., assistant manager, Lawrence Gas and Electric Company, Lawrence, Mass.
Tadlock, W. L., supervising engineer, Commonwealth and Southern Corporation, Birmingham, Ala.
Town, G. R., research engineer, Stromberg-Carlson Telephone Manufacturing Company, Rochester, N. Y.

23 to Grade of Member

## Applications for Election

Applications have been received at headquarters from the following candidates for election to membership in the Institute. If the applicant has applied for direct admission to a grade higher than Associate, the grade follows immediately after the name. Any member objecting to the election of any of these candidates should so inform the national secretary before July 31, 1937, or Sept. 30, 1937, if the applicant resides outside of the United States or Canada.

Ashbaugh, E. G., Westinghouse Electric & Manufacturing Company, Sharon, Pa.
Byers, J. F., Libbey-Owens-Ford Glass Company, Charleston, W. Va.
Caldwell, C. A., Houston Lighting and Power Company, Houston, Texas.
Carter, R. C., Jr., Company 1843, Camp *NP-5-C*, Mesa Verde, Colo.
Coates, R. E., General Electric Company, Pittsfield, Mass.
Cooley, M. C. (Member), W. N. Matthews Corporation, St. Louis, Mo.
Corves, G. S., Southern New England Telephone Company, West Haven, Conn.
Dimmitt, E. H., Federal Power Commission, Washington, D. C.
Elmer, E. R., Jr., Underwriters' Laboratories, Inc., Chicago, Ill.
Fetherolf, J. M., in care of Edward J. Cheney, New York, N. Y.
Fox, C. E. (Member), 806 North Fifth Avenue, Knoxville, Tenn.
Goodburn, R. A., Florida Power and Light Company, Miami.
Harmon, L. B., Westinghouse Electric & Manufacturing Company, Los Angeles, Calif.
Hubbard, R. R., J. A. Adams Company, Indianapolis, Ind.
Jabour, E., Department of Light, Los Angeles, Calif.
Kearns, J. J., Crucible Steel Company of America, Harrison, N. J.
Kimball, A. L. (Member), Otis Elevator Company, Buffalo, N. Y.
Klumb, R. K., Southern California Edison Company, Ltd., Chino, Calif.
Lickey, H. F., State College of Washington, Pullman.
Madsen, R. V., Southern Pacific Golden Gate Ferries, San Francisco, Calif.
Mathes, R. E., RCA Communications, Inc., New York, N. Y.
McCormick, F. J. (Member), Wisconsin Telephone Company, Milwaukee, Wis.
Mellor, A. G., Buffalo, Niagara and Eastern Power Company, Buffalo, N. Y.
Miller, M. I., Carolina Power and Light Company, Raleigh, N. C.
O'Neal, F. C., Jr., Texas Electric Service Company, Eastland, Texas.
Parsons, C. W., Johnson Electric Supply Company, Cincinnati, Ohio.
Power, R. B., Jr., Kennecott Wire and Cable Company, Phillipsdale, R. I.
Ramsay, H. B., New Orleans Public Service, Inc., New Orleans, La.
Rogers, H., Jr., Western Electric Company, San Francisco, Calif.
Rossrucker, E. A., Ohio Bell Telephone Company, Cleveland, Ohio.
Scheer, G. B., San Francisco-Oakland Bay Bridge, San Francisco, Calif.
Selman, M. H., housing division, Public Works Administration, Washington, D. C.
Shannon, S. R., Jr., General Electric Company, Erie, Pa.
Sheblak, V. B., Bureau of Power and Light, Los Angeles, Calif.
Simmons, E. E., Jr., California Institute of Technology, Pasadena.
Sinnott, J. F., San Diego Consolidated Gas and Electric Company, San Diego, Calif.
Smith, C. J., Charles H. Smith and Company, Engineers, Inc., New York, N. Y.
Soares, Glen J., 5482 Kales Avenue, Oakland, Calif.
Stafford, D. E., National Electric Coil Company, Columbus, Ohio
Stahler, L. L., Florida Power and Light Company, Miami.
Taylor, W. F. (Member), New England Allis-Chalmers Manufacturing Company, Boston, Mass.
Tellez, J. S., Pipe Trades Service Company, Toledo, Ohio.
Thomson, W. T., 1224 Park Avenue, Alameda, Calif.
Vesely, S. M., Chicago Electric Company, Chicago, Ill.
Waidhas, G., Allis-Chalmers Manufacturing Company, West Allis, Wis.
Ward, S. J., Houston Light and Power Company, Houston, Texas.
White, E. L. (Member), Federal Communications Commission, Washington, D. C.
Willis, J. D., Canadian General Electric Company, Ltd., Toronto, Ont., Canada.
Witzke, R. L., Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.
Woolley, H. P., Woolley Welding and Machine, Houston, Texas.

50 Domestic

**Foreign**

Apte, S. V. (Member), College of Engineering, Poona, India.
Geltz, F., South American Development Company, Guayaquil, Ecuador.
Gordon, F., Cerro de Pasco Copper Corporation, La Oroya, Peru.
Madahar, G. D., Modern Electric Works, Lahore, Punjab, India.
Page, F. W., British Electrical and Allied Industries Research Association, London, England.
Shivapuri, P. R. N., Punjab Electric Power Company, Ltd., Gujrat, Punjab, India.

# Engineering Literature

## New Books in the Societies Library

Among the new books received at the Engineering Societies Library, New York, recently are the following which have been selected because of their possible interest to the electrical engineer. Unless otherwise specified, books listed have been presented gratis by the publishers. The Institute assumes no responsibility for statements made in the following outlines, information for which is taken from the preface of the book in question.

CONTRIBUTIONS from the PHYSICAL LABORATORIES of HARVARD UNIVERSITY for the Years 1933, 1934, and 1935. Series II, 2 volumes. Cambridge, Mass., Harvard University Press, 1936–1937. Illustrated, 11x8 inches, volume 1, 628 pages; volume 2, 469 pages, leather, $2.50 each. Collections of 65 and 57 papers, respectively, on work done in the physics laboratories of Harvard University.

First Course in STATISTICAL METHOD. By G. I. Gavett. 2 edition. New York and London, McGraw-Hill Book Company, 1937. 400 pages, illustrated, 9x6 inches, cloth, $3.50. A textbook for use as a foundation course in "statistical method" for all fields in which the mathematical representation of facts is desirable.

ZERO to EIGHTY, being My Lifetime Doings, Reflections and Inventions, also My Journey around the Moon. By E. F. Northrup. Princeton, N. J., Scientific Publishing Company, 1937. 280 pages, illustrated, 10x6 inches, cloth, $3.00; foreign countries $3.50. Devoted to a presentation of the possibilities in the production of high linear velocities by the use of traveling waves of electric force. Cast in the form of the autobiography of a scientist living from 1920 to 2000 A.D.

(The) WORLD of ATOMS. By A. Haas. 2 edition, translated by G. B. Welch and H. S. Uhler. New York, D. Van Nostrand Company, 1937. 183 pages, illustrated, 9x6 inches, cloth, $3.00. A translation of the revision of a series of lectures intended to present to a lay public the achievements of modern atomic physics in as brief and yet thorough a manner as possible.

VALUATION of PROPERTY. 2 volumes. By J. C. Bonbright. New York and London, McGraw-Hill Book Company, 1937. 1271 pages, 9x6 inches cloth, $12.00. A presentation of the results of a research in legal and economic theories of property valuation. Volume 1 covers concepts of value, methods of valuation, and valuation for specific legal purposes. Volume 2 covers specific cases of valuation under certain rules, tax restrictions, and other legal considerations.

TECHNIQUE of MARKETING RESEARCH. Prepared by the Committee on Marketing Research Technique of the American Marketing Society. New York, McGraw-Hill Book Company, 1937. 432 pages, illustrated, 9x6 inches, cloth, $4.00. A review of methods for investigating problems in marketing policies, salability of products, markets, and selling.

SAE HANDBOOK, 1937 edition. New York, Society of Automotive Engineers. 774 pages, illustrated, 9x6 inches, cloth, $5.00 to SAE nonmembers ($2.50 to members). Contains specifications covering parts and fittings, materials, and small hardware in the automotive field. Also covers standard tests, ratings, and codes.

RELATIVITY THEORY of PROTONS and ELECTRONS. By Sir A. S. Eddington. New York, Macmillan Company; Cambridge (England) University Press, 1936. 336 pages, tables, 11x7 inches, cloth, $5.50. A companion volume to "Mathematical Theory of Relativity." The central problem is concerned with the conditions which fix the amount of mass and electric charge carried by protons and electrons.

PASCAL, the Life of Genius. By M. Bishop. New York, Reynal and Hitchcock, 1936. 398 pages, illustrated, 10x6 inches, cloth, $3.50. Biography of a man whose life had many interests and contacts.

NATIONAL PHYSICAL LABORATORY REPORT for the YEAR 1936. Great Britian, Department of Scientific and Industrial Research. London, His Majesty's Stationery Office, 1937. 144 pages, tables, 10x6 inches, paper. (Obtainable from British Library of Information, 270 Madison Avenue, New York, $0.80.) Contains a résumé of the research work done in 1936 in the departments of physics, electricity, radio, and engineering.

MOTOR and CONTROL APPLICATIONS. By G. H. Hall. New York, McGraw-Hill Book Company, 1937. 259 pages, illustrated, charts, tables, 9x6 inches, cloth, $3.00. Contains information for the machine designer; also presents data and dimensions of motors as standardized by the National Electrical Manufacturers Association.

MARCONI, the Man and His Wireless. By O. E. Dunlap, Jr. New York, Macmillan Company, 1937. 360 pages, illustrated, 9x6 inches, cloth, $3.50. A "biography" of wireless telegraphy, from infancy to maturity, combined with personal information concerning Marconi.

FUNDAMENTALS of VACUUM TUBES. By A. V. Eastman. New York and London, McGraw-Hill Book Company, 1937. 438 pages, illustrated, 9x6 inches,, cloth, $4.00. Discusses the basic theory underlying the operation of all types of modern vacuum tubes. Discusses at length high-vacuum tubes, mercury-vapor tubes, and several special varieties, with engineering analyses of their more important applications.

ELECTRIC POWER DEVELOPMENT in the U.S.S.R., edited by U.S.S.R. Committee for International Scientific and Technical Conferences, Krzizhanovsky Power Institute of the Academy of Sciences of the U.S.S.R. London, Lawrence and Wishart, Ltd., 1936. 496 pages, illustrated, 9x6 inches, cloth, $3.00. An exposition of the principal technical and economic problems of electrical development in the Soviet Union, and of the plans for meeting them.

**Engineering Societies Library**
29 West 39th Street, New York, N. Y.

MAINTAINED as a public reference library of engineering and the allied sciences, this library is a co-operative activity of the national societies of civil, electrical, mechanical, and mining engineers.

Resources of the library are available also to those unable to visit it in person. Lists of references, copies or translation of articles, and similar assistance may be obtained upon written application, subject only to charges sufficient to cover the cost of the work required.

A collection of modern technical books is available to any member residing in North America at a rental rate of five cents per day per volume, plus transportation charges.

Many other services are obtainable and an inquiry to the director of the library will bring information concerning them.

# Industrial Notes

**New Rod Mills in Operation.**—The two parallel continuous rod mills of the American Steel & Wire Co. at Joliet, Ill., have been completed and were formally dedicated on June 23. These mills, designed by the wire company's own engineers, embody all modern improvements and a number of new developments never before used in such mills. Every 40 seconds a No. 5 rod, nearly a mile long, comes off the final pass at a speed of 3428 ft. per minute, as compared with 1500 ft. per minute in the old Joliet mills. Speed practically eliminates temperature drop in the rod during rolling and assures greater accuracy as to contour, and physical properties which improve wire quality. The new project is part of a $5,000,000 development which includes improvements in the South Chicago and Gary billet mills, as well as the wire mills in Illinois. Local power companies supply power at 6600 volts for the new mill. Direct current is supplied by a 4 unit motor-generator set, one generator supplying direct current for general use, the other two generators providing power to the reel motors which must be run in step with the mill at the final pass. One 4500-hp motor drives all the rolls on one mill.

**New High Speed Electric Locomotives.**—Six new streamlined electric locomotives, more powerful than any of the 53 already in operation between New York and New Haven, have been ordered by the New Haven Railroad and will be built in the General Electric plant at Erie, Pa. Each 3600-hp unit will weigh approximately 130,000 pounds, capable of a speed of over 80 miles an hour. Power will be supplied by six motors on as many driving axles, with each motor having two armatures geared to the one axle.

**Cutler-Hammer Appointment.**—E. J. Gove has been placed in charge of a new Cutler-Hammer office recently opened in Youngstown, O., at 1106 Central Tower. The new office is a branch of the company's Pittsburgh office.

**Ohio Brass Appointment.**—E. C. Thompson, formerly supervisor of transmission for the Alabama Power Co., has joined the Ohio Brass Co., Mansfield, O., as sales engineer in the power utilities department. He will spend considerable time in the field contacting utility engineers in connection with transmission problems.

**New Resistors.**—Electrical resistors of an improved type have been developed by the Ohmite Manufacturing Co., 4835 W. Flournoy St., Chicago. Among the features emphasized are evenness of windings and special vitreous enameled covering.

**New Oil Filter Press**—A new line of oil filter presses for cleaning and drying insulating oils has been announced by the Westinghouse Elec. & Mfg. Co. These presses are light in weight, have low power consumption and are quiet in operation. Their features include a pump bypass through a $^1/_4$-inch needle valve to test the suction line for leaks; a small tank providing a primary gas trap; a discharge flow taken from the bottom of the filter sections providing a secondary gas trap. Standard outfits are rated 5, 10 and 30 gallons per minute for 60 cycle, 220 volt supply.

**New Cable Insulation.**—A new synthetic cable compound has been introduced by the General Electric Co. under the trade name of "Flamenol." While similar to rubber in its characteristics, it contains no rubber and will not support combustion. It is also highly resistant to moisture and acids, alkalies and oils, and has excellent aging qualities. The properties of the new material are such that it can be made a very soft and flexible compound, or one with celluloid-like rigidity. Flamenol-insulated cable is recommended by the manufacturer for power and control circuits at 600 volts and less, and is well adapted to machine tool wiring, switchboard wiring, and battery and coil leads.

# Trade Literature

**Lighting Equipment.**—Bulletin, 112 pp. Describes lighting equipment for theatrical, architectural, photographic and special purposes. Prices are listed. Century Lighting, Inc., 419 W. 55th St., New York City.

**Residential Wiring.**—Bulletin, 12 pp. Describes "Durax" non-metallic sheathed cable for residential and similar circuits and interprets its use according to the National Electric Code. Anaconda Wire & Cable Co., 25 Broadway, New York City.

**Bus Supports.**—Bulletin 34B, 32 pp. Describes outdoor bus supports and fittings. With the parts listed, approximately 50,000 bus support combinations are available. Delta-Star Electric Co., 2400 Block, Fulton St., Chicago, Ill.

**Instruments.**—Bulletin. Describes instruments for measuring coils, condensers, dielectrics and insulators at radio frequencies; covers the Q-Meter, QX-Checker, the new dielectric unit, the converter test oscillator, Hi-Q parts and inductors. Boonton Radio Corporation, Boonton, N. J.

**Motors.**—Bulletin. Describes manufacturer's method of integrally-casting end rings, fans and rotor bars of a-c squirrel-cage induction motors, whereby all possibility of bad contacts or loose connections is eliminated, and uniformly high performance is assured. The Reliance Electric & Engg. Co., 1086 Ivanhoe Rd., Cleveland, O.

**Detachable Instruments.**—Cat. Sec. 43-600, 10 pp. A description of these detachable instruments includes outline dimensions; application data; economic advantages; construction details of the socket and the instrument; accuracy and permanence of calibration; performance characteristics; multiple installations, etc. Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

**Insulating Paper Sample.**—A novel figure cut from "Manning 300" insulating paper,—a high quality, high density paper for slot insulation and other uses, characterized by extreme toughness, heat aging qualities and extreme dielectric strength. The purpose of the paper character, trade-named "Tuffy," is to illustrate the toughness of the product and unusual resistance to tearing. Insulation Manufacturers Corp., 565 W. Washington Blvd., Chicago, Ill.

**Motors.**—Bulletin 1032, 8 pp. Describes slip ring motors, 1 to 350 hp., designed for continuous duty, open and enclosed ratings, or for intermittent reversing application, short-time duty rating. Available in open, drip proof, splash proof, fully enclosed and gear head types for horizontal and vertical operation. Century Electric Co., 1806 Pine St., St. Louis, Mo.

**Lightning Arresters.**—Catalog 390, 116 pp. A comprehensive volume aiming to provide essential data on lightning protection for distribution systems and on Crystal Valve lightning arresters. Much new and up-to-date information has been included in the engineering section. Chapters are devoted to lightning protection for distribution systems, for rural distribution lines, performance characteristics of arresters, and theory of operation of CV lightning arresters and complete descriptions of the various types. Electric Service Supplies Co., 17th and Cambria Sts., Philadelphia, Pa.

**Electrical Steel Sheets.**—Bulletin, 32 pp. Describes development of electrical steel sheets and modern mill technique in producing this material. Ten grades of USS electrical steel sheets are discussed and many applications are detailed. Conversion tables are included as well as a new table on guaranteed maximum core losses and information on magnet wire and varnished cambric insulated cables made by the American Steel & Wire Co. Terms commonly used, including normal magnetism, hysteresis loss, etc., are treated and explained. The uses of electrical sheets in different types of electrical apparatus are illustrated. United States Steel Corp. Subsidiaries, P. O. Box 176, Pittsburgh, Pa.

**Arc Welding Design Chart.**—A newly-revised engineering drafting room chart to provide, in concise ready reference form, data necessary for producing arc welded designs. The chart includes the latest weld symbols adopted by the AWS in May. Additional data covers particulars regarding the 16 types of joints for arc welding; illustrated suggestions for better arc welded design; sketches explaining the nomenclature of welds; and a comparison of welded and riveted drawings. Tables are included giving properties of base metals, weld metals, electrode metals, etc. The Lincoln Electric Co., Cleveland, Ohio.

**The Engineer and Society.** Two stimulating addresses on the general subject of the engineer and his relation to society were delivered at the Institute's 1937 summer convention in Milwaukee, Wis.; both of these addresses are published in this issue. The first address, on the subject of "The Engineer and His Relation to Government," stresses the need for a more effective expression of the engineer's viewpoint on important public questions (*pages 928–36*). The second address discusses the position and duties of "The Engineer in a Changing World" and emphasizes the necessity for engineers to exercise their responsibilities more for the sake of society as a whole than for the sake of themselves or the private interests of the businesses with which they may be connected (*pages 937–41*). In a third article on this same general subject, an electrical-engineering student urges engineers to "interest themselves in something outside their narrow technical field . . . and become human and humanitarian" (*pages 943–4*).

**Circuit Breakers.** Simply dividing a circuit breaker into several units will not raise its interrupting capacity as a multiple of the number of breaks, because the voltage distribution across the breaks is not uniform. Capacitance shields will give a satisfactory distribution of duty in multibreak circuit breakers (*pages 1018–24*). Ultrahigh-speed reclosing of oil circuit breakers is said to provide an effective and economical solution to the problem of reducing transmission-line outages and thereby improving continuity of service (*pages 968–70*).

**Federal Power in the Northwest.** The federal administration of a public utility is a new idea in the United States; consequently, the formulation of some ultimate plan of administration has become a problem of major importance. The Tennessee Valley Authority and the plans proposed for the public administration of power from the Bonneville and Grand Coulee projects have been compared with the Ontario Hydro-Electric Commission and the British Grid (*pages 964–7*).

**Summer Convention Reports.** Reports covering the various activities of the Institute's 1937 summer convention held in Milwaukee, Wis., June 21–25, are published in the news section of this issue. Included are reports of the annual business meeting, the presentation of the Lamme Medal, conference of officers, delegates, and members, 2 technical conferences, prepared discussions on Institute activities, board of directors meeting, and other features (*pages 1042–52*).

**Radiotelephone Noise Reduction.** Several conventional methods, such as the use of higher power, directive antennas, and selective filters, may be used to increase the intensity of the signal with respect to the noise level in transmitting speech over radiotelephone circuits. Another method, somewhat unconventional in character, consists of diminishing the noise during the intervals of no speech (*pages 971–4*).

**Resonant Lines.** Transmission lines, composed of either parallel or concentric wires, provide a stable means of frequency control for ultrahigh radio frequencies of 30 megacycles or more. Radiation resistance has been found of dominant importance in determining the selectivity factor and input impedance, and therefore materially changes the optimum design of the line (*pages 1002–11*).

**Electricity on Aircraft.** Applications of electricity in modern aircraft construction are manifold, because electrical operation is convenient and the equipment required is relatively light in weight. The electrical system of a modern transport ship is described in a paper in this issue (*pages 959–63*).

**Power Inrushes Under Load.** "Starting" currents in transformers have been studied by several investigators, but most of such tests have been conducted under the special condition of no load. A paper in this issue presents the results of a study of starting currents in transformers connected to loads having various power factors (*pages 989–94*).

**Electric Range Units.** Several types of surface heating units are used in electric ranges, the heat being transferred by radiation, conduction, or both. The efficiency of heat transfer varies with the type of unit, and may be improved, particularly for radiation, by the use of black-bottom utensils (*pages 953–8*).

**Eta Kappa Nu Recognition.** An honorary electrical-engineering society has established awards to recognize outstanding young electrical engineers; statistics for the nominees for the 1936 awards reveal significant information concerning the leading American engineers under 35 years of age (*pages 945–9*).

**Cooling Transformers.** Units composed of a radiator and fan, commonly used for heating industrial buildings, have been found suitable by an eastern power company for cooling transformers by circulating oil from the transformer through the unit. A water spray further increases its effectiveness (*pages 950–2*).

**Pacific Coast Convention.** Plans are nearing completion for the AIEE 1937 Pacific Coast convention to be held in Spokane, Wash., August 30–September 3. The Pacific Northwest offers splendid opportunities for combined vacation-convention trips (*page 1053*).

**Harmonic Generation.** A harmonic generator circuit, suitable for the supply of carrier currents to multichannel telephone systems, for synchronization of carrier frequencies in radio transmission, and for frequency comparison, has been developed (*pages 995–1001*).

**Series Capacitors.** Improved voltage regulation in power circuits may be obtained by the insertion of capacitors in series with the line. Sometimes, however, difficulties such as hunting of synchronous machines and self-excitation of induction motors arise which require investigation (*pages 975–88*).

**The Vodas.** Suppression of feedback and singing in the interconnection of ordinary telephone systems by means of radiotelephone links requires a special type of apparatus known as the "vodas" (*pages 1012–17*).

**The Engineer of Tomorrow.** Some thought-provoking questions were propounded by President MacCutcheon concerning the engineer of tomorrow, in his 1937 summer-convention address (*pages 941–3*).

**New AIEE Officers.** Nine officers were newly elected at the recent AIEE summer convention to serve the Institute during the ensuing year (*page 1049*).

# DISCUSSIONS

Appearing in this issue are discussions of the following papers:

## Electrical Machinery

A Suggested Rotor Flux Locus Concept of Single-Phase Induction Motor Operation—Button 1028
Operational Solution of A-C Machines—Miller and Weil 1028

## Protective Devices

A New Service Restorer—Sixtus and Nodder . . . 1033
A New Thermal Fuse for Network Protectors—Nettleton 1031
A Single-Element Polyphase Directional Relay—McConnell 1025
The Control Gap for Lightning Protection—Higgens and Rorden 1036
Ultrahigh-Speed Reclosing of High-Voltage Transmission Lines—Sporn and Prince 1033

## Tensor Analysis

Complex Vectors in 3-Phase Circuits—Sah . . . 1030
Dyadic Algebra Applied to 3-Phase Circuits—Sah 1030

Statements and opinions given in articles and papers appearing in ELECTRICAL ENGINEERING are the expressions of contributors, for which the Institute assumes no responsibility. Correspondence is invited on all controversial matters. ¶ Subscriptions—$12 per year to United States, Mexico, Cuba, Porto Rico, Hawaii, Philippine Islands, Central and South America, Haiti, Spain, Spanish Colonies; $13 to Canada; $14 elsewhere. Single copy $1.50. ¶ Address changes must be received by the fifteenth of the month to be effective with the succeeding issue. Copies undelivered because of incorrect address cannot be replaced without charge. ¶ ELECTRICAL ENGINEERING is indexed annually by the Institute, weekly and monthly by *Engineering Index*, and monthly by *Industrial Arts Index*; abstracted monthly by *Science Abstracts* (London).

# A Message From the President

**Fellow Members of the Institute:**

I SHOULD LIKE to take this opportunity to say to all of you what I had the privilege of saying to those at the summer convention in Milwaukee in response to notification of election as president:

"Instinctively I feel sure you understand how wholly inadequate words of mine are to express appreciation of the great honor the membership of the Institute has conferred upon me.

"I am mindful of the responsibility that goes with the high and cherished office of president, and with humility I confidently look forward to this distinguished opportunity further to serve the profession in which we are spending our lives.

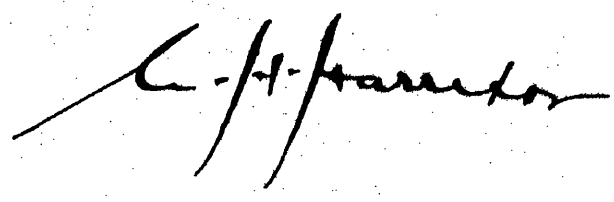
"It has been my privilege for many years to participate in the affairs of the Institute, and I am familiar with its high ideals, its traditions—its responsibilities to the profession at large.

"No period has ever afforded our organization a greater opportunity to be of service.

"One need but recall the many new developments looming on the horizon in almost every phase of the industry to visualize the important part the Institute will play in the period ahead. Perhaps even more immediate and bearing on the profession as a whole is the situation presented by the changing social and economic order of the world in which we live. In this we as engineers face a stiff challenge—a broadened horizon. The engineering societies can do much to point the way.

"The joy and satisfaction one gets in service to the Institute is the opportunity afforded for associations and acquaintanceships with the membership, and I am eagerly looking forward to this through the coming year.

"The life of the Institute is in the Districts, Sections, Student Branches, and committee activities. No organization, year in and year out, has ever had a more enthusiastic, loyal, and effective group of workers. Then there is an equally able headquarters staff, headed by our effective national secretary, Mr. Henline.



"As I think of all of these I look forward to the year with confidence.

"Last year District 2 of which I was then a member was accorded great distinction by having elected from its ranks our president, Mr. MacCutcheon. You need no reminder as to how faithfully he has carried out his responsibilities. Under the impetus of the enthusiasm he has generated I am sure we will continue to go forward. I want to take this opportunity to express great admiration for him, and for the work he has done in the past year.

"Again my deep thanks for the great honor you have conferred upon me. Milwaukee, 1937, is a milepost in my life."

The summer convention is over. Those of us who were fortunate enough to be there will long carry in mind the interesting, instructive sessions, the inspiring talks by Doctor Bush and Doctor Flanders, the inspection trips, the courtesy of those who made the trips possible, the entertainment, and in particular the consideration shown our families.

The Institute has gained new honors from the really superb manner in which the Milwaukee convention program was carried out. As host the Milwaukee Section earned high praise. It is a privilege to express appreciation.

# The Engineer and His Relation to Government

By VANNEVAR BUSH
FELLOW AIEE

**Whether democracy in America can endure depends in no small measure upon the attitude of the great professional classes in general, and in particular upon the attitude and effectiveness of the engineer in his relation to government, says this well-known engineer and educator, who states further that although there is an enormously complex system of organizations of scientists and engineers in the United States, this mechanism is not utilized to the full in expressing the viewpoints of engineers generally upon important public questions. To meet this need, Doctor Bush suggests that the organization of engineers should be integrated, simplified, and strengthened.**

WHATEVER one may conceive to be the future of civilization, whether one is pessimistic or optimistic in regard to the long pull, one thing stands out—we are certainly on our way. The world is full of change. Our systems of government, not only in Europe, but here in America, are in a state of flux. We live faster, occasionally longer, and always in a new pattern of relationships between man and man. We are headed somewhere in a hurry, whether that somewhere be a grand crash, a reversion to a long sleep, or a more abundant life.

The scientist and the engineer started us on this path. They wakened us from the semipeaceful somnolence of a century ago, shrunk the world to a fraction of its former size, and placed the well-oiled wheels of the scientific method under us; and we roar forward in a crescendo of tumult toward the unknown. Now it is suggested that some attention should be paid to the steering gear.

Much attention has been paid to equipping and speeding up the conveyance in which civilization rides, and comparatively little devoted to safety devices. The medical profession has conquered one plague after another, engineers and health officers have extended sanitary measures, and the mentally defective benefit along with everyone else, breed rapidly, and may inherit the earth. Bringing science to agriculture makes possible the production of food by fewer men on less acreage, and our farmers have no place to go. Individual transportation is cheapened, and automobile accidents kill 30,000 people a year. The airplane applies a multiplying factor to the useful lives of busy and creative men, and brings hostile nations within grasp of one another's throats.

Since the dawn of history the acquisition of skill and knowledge has rendered more complex the relationships between man and man. It is the function of government to control these relationships. Today the burdens and responsibility thrown upon government are increasing by leaps and bounds, and government everywhere is staggering under the load. The kaleidoscopic changes we have witnessed in governments of the nations are a direct result of the growing technical complexity of our lives. Every advance increases the rate of advance, in accordance with the law of acceleration of Henry Adams.* Whether democracy in America can successfully carry the modern burden and the burden to come, and endure, remains to be demonstrated. Certainly this depends in no small measure upon the attitude of the great professional class in general, and in particular upon the attitude and effectiveness of the engineer in his relation to government. It is this relationship that is examined in this address.

First, what really is this government of ours? I am not going to review the history of our democratic system, or the details of its organization. Certainly I am not interested at the moment in the affairs of individuals or parties. The important point is that we have a government which is responsive to public opinion. Sometimes, it is true, this is only haltingly effective; but by and large the course of our affairs is determined by what the great bulk of the public thinks and feels. As we all know, small minorities, through effective organization and pressure, can dictate the course of events in limited areas; but not the major trends. We have had striking illustrations of this power of public opinion in recent times. It first, in a reflection of the war enthusiasm, placed prohibition in the Constitution; and then, in a revulsion of sentiment, forced it out again, in spite of a complex legal situation and the strong resistance of well-knit groups. There is no doubt that, in 1936, public sentiment generally desired a continuance of federal social activity, and obtained what it wanted. More recently public sentiment has turned a tide that was running strongly against the power of the judiciary. The final outcome of the present labor movement similarly will depend upon what all the people think.

This is the essence of democracy, and of a government responsive to the will of the people. This we have and this we hope long to maintain. It is the most beneficent type of government that has yet been created by the mind of man. Yet it has its disadvantages and dangers in a complex modern world; and there is serious question as to whether it can be maintained indefinitely under modern conditions. I make this statement with no implications

* "The Education of Henry Adams," Houghton Mifflin Company.

An address delivered at an evening session of the AIEE summer convention, Milwaukee, Wis., June 22, 1937.

VANNEVAR BUSH is vice-president of the Massachusetts Institute of Technology, Cambridge, and dean of the school of engineering. He was graduated from Tufts College in 1913; in 1916 he received the degree of doctor of engineering from MIT and Harvard University, and in 1932 the honorary degree of doctor of science from Tufts. He is known for both his achievements in research and his contributions to engineering education. He has long been interested in the design of analyzing instruments, and for his work in this field he was awarded the Levy Medal of the Franklin Institute in 1928 and the AIEE Lamme Medal for 1935. Doctor Bush is one of the newly elected directors of the AIEE and has served on many AIEE committees. He is the author of many technical articles, and of "Operational Circuit Analysis" and, jointly with W. H. Timbie (A'10, F'24), of "Principles of Electrical Engineering."

whatever in regard to any individuals or isms. We have proceeded far in this country along the road of democracy. This republic started its career with great detail in its representative form, expressly designed so that the primary opportunity of the electorate would be to select trusted representatives who would then be somewhat removed from immediate pressure. The loss of real significance of the electoral college, the direct election of senators, the introduction of the referendum, have been some of the steps toward that complete democracy in which the people themselves decide on the important questions of the moment. This trend began with the election of Jefferson and has continued ever since.

Yet this enormous country, with its heterogeneous population and interests, is one of few remaining democracies. We witness a movement in the world at large toward absolutism. It has made little difference in the end result whether this has come about by reason of a first move toward the left or the right. We see many nations turning toward the placing of absolute power in the hands of one man, with consequent suppression of individual freedom. Democracies elsewhere have proved unstable. No small factor in this situation is to be found in the fact that the questions of the day are too complex for the people truly to grasp in time.

Doctor Bush

There is a pessimistic philosophy of government which holds that the trend of democracy toward breakdown and succeeding absolutism by an individual or a class is inevitable. According to this theory, democracies tend to become increasingly more direct, checks and balances gradually are thrown aside, the dependence of the governing group on public whim leads to weakness in law enforcement, respect for law decreases, and finally chaos ensues, to be followed by seizure of arbitrary power by a closely organized minority. Shall this be true of America? Not necessarily. All these dire results were predicted to follow promptly upon Jefferson's accession; and in fact many seriously expected that the Reign of Terror of France would be repeated here. But it was not, and over a century has passed while this republic has gone through stress of the most intense form. There is a counter influence which has saved us from catastrophe. This is the gradual increase in the standard of living, and the intelligent grasp of large affairs on the part of the people. We have also developed in this country a resistance to the forces of propaganda which occasionally manifests itself. So we may yet go on.

For present purposes, it is sufficient to note that our government is now of rather extreme democratic form, and that public opinion controls its trends in large affairs. Its governing bodies and executives, therefore, are bound to be men who are sensitive to, and able to cope successfully with, this opinion of the public.

In this form, our government is called upon to decide momentous technical matters, most of which are so complex that they can be fully understood, if at all, only by experts. Such questions involve finance, sociology, economics, engineering. They cannot be grasped completely and intelligently by the general public. They cannot be grasped by the elected representatives of that public, who must in the nature of things, be specialists principally in the political art. How then are they to be decided wisely in a democracy?

Much depends upon the answer to this question. We are in competition with nations in which absolutism and intense nationalism control. The maintenance of our position, our relative standard of living, depends upon the skill with which our affairs are handled. Under an absolute ruler all specialists of every sort become government specialists. A dictator can make final, binding, prompt decisions upon weighing their recommendations. Will we, with our exceedingly loose system, be similarly able to bring to bear the best of intelligent judgment upon the technical problems of the day? We must do so, if we are to hold our place. Our frontiers have vanished; the surge of a pioneering people cannot indefinitely carry us forward; we are making rapid inroads upon our unique national resources. The day is coming when our progress will lean heavily on the intelligence with which we treat our public questions.

The age-old struggle between those who have and those who have not is distinctly modified by advancing standards of living. A greater proportion of the people become property holders, and this tends toward stability and orderly processes. Yet the trend proceeds slowly, and the struggle is far from termination. We still face a clash of interests which is as old as history, between those who control our social and industrial systems, and the great mass of people who labor. Whatever the political system, whatever changes in the character of our institutions may come, this situation will always be with us, for someone must always control; there must always be those who issue orders, benignly or harshly, if the industrial mechanism is to function. It is the proper sphere of government to control and regulate; to set up and enforce the rules that will insure efficiency and equity, to protect minorities, and to deal with other nations. For government to step in and itself become the manager of industry is a mistake. There is no longer an umpire in the field. The lines become drawn between the people and government itself, and this is the beginning of disaster. We cannot afford, in this country of ours, to have an umpire who also plays on one of the teams.

## What Distinguishes a Professional Man?

Standing aside from the industrial system, and yet intimately connected with it, are the great professional classes, of which the engineer forms a part. What renders a man a member of this professional group? It is much more than the possession of special knowledge, although this is a necessary attribute. The skilled machinist possesses special knowledge, as does indeed the man who owns and manages a machine shop; yet neither thereby is constituted a professional man. It is more than the nature of the source of income. True, many professional men, physicians and lawyers especially, derive their income from fees from clients. Yet a clergyman is usually on a salary. The majority of scientists are similarly paid by universities and scientific institutions. The great proportion of engineers are employed regularly by industry on a salary basis. Definite association with a specific organization on a salary basis does not bar a man from rightful membership in the professional class. The distinguishing characteristic is the possesssion of a philosophy and a point of view. The true criterion lies in the basis of motivation of the individual.

In any society there are 4 primary classifications of individuals. First is the great body of artisans who carry on the work of the world. Second are those who manage and direct, deriving their power rather directly from the possession of the facilities for production, or indirectly by delegation from the actual owners. Third stand those who govern. Finally come those whose primary mission in life is to acquire learning and render it usefully available to those in every classification. These last form the professional group.

It is possible for an individual to belong simultaneously to several groups. The farmer is often a worker and a manager. The owner, to whom management is at least formally responsible, may comprise hundreds of thousands of stockholders in all walks of life. He who governs may derive from any group. Similarly, the professional man may adhere also to other classifications. But if he loses his philosophy, if he ceases to regard the acquisition of knowledge for the public welfare and rendering it available to all groups as his primary mission in life, he no longer is truly a professional man.

The late Arthur D. Little in an essay* delivered before the Franklin Institute, defined the "fifth estate" as: "those having the simplicity to wonder, the ability to question, the power to generalize, the capacity to apply. It is, in short, the company of thinkers, workers, expounders, and practitioners upon which the world is absolutely dependent for the preservation and advancement of that organized knowledge which we call science. It is their seeing eye that discloses, as Carlyle said, 'the inner harmony of things; what Nature meant.' It is they who bring the power and the fruits of knowledge to the multitude who are content to go through life without thinking and without questioning, who accept fire and the hatching of an egg, the attraction of a feather by a bit of amber, and the stars in their courses as a fish accepts the ocean."

It is the high privilege of the engineer to aspire to genuine membership in this distinguished category. The possession of an academic degree is not sufficient to admit him. Success, as measured by his income, does not admit him either. The humble Jesuit parching amid the sands of the desert that he may bring light to the lowly, and the country physician struggling through the storm to relieve suffering, need no decoration of material success to mark them as honorable members of the group. Recognition by colleagues, based upon true scholarship, untainted by self-advertising—this is the reward. Completely free from prejudice as to class or race, laboring for the ultimate good of society at large as he envisages it, above passion, secure in the possession of special knowledge which the world needs and hence independent of the whims of individuals and groups, the true professional man is and should be a figure apart, wherever he may be placed. It is his duty to merit that confidence which alone will permit him to operate with effectiveness.

## Government Needs Influence of Engineer

There is all too little respect for law in this country. There is also all too little respect for genuine scholarship. Fundamentally the influence of the professional group depends upon the development of this respect. Only thus can its influence be effective. The trend of affairs can be molded by those who have seen the light only in so far as they are welcomed into the counsels of the groups of the population. The influence of the professional man is sorely needed in these times. Managers of industry have been keen to grasp its peculiar advantages, and there is no lack of contact at this point; but unfortunately it often arises under conditions that render difficult the maintenance of true professional status by the professional man. But government most needs the influence. At this point in this country we proceed haltingly. The influence of the engineer upon the processes of government is especially necessary if there is to be sanity in public affairs. How then may it be enhanced?

The professions of law and medicine exert strong and generally beneficial group influence through their national professional organizations. The profession of engineering does not. No great legal change occurs without scrutiny and pressure from the American Bar Association. No move for the regulation of medical practice proceeds without the prompt, effective participation of the American Medical Association. Great engineering works are constructed in this country, and the group opinion of the body of engineers thereon is not even expressed, with results that are sometimes ludicrous. We have no reason to be proud of the influence of engineers on the course of government as it affects engineering. By and large our efforts have been pitiful.

There is a striking difference in the relationships of these 3 great professional groups to government. Many members of the legal profession are essentially part of government itself, since they fill our legislatures, sit on the judicial bench, and practice as elements of the court. At

* Centenary celebration of the founding of the Franklin Institute, September 17, 1924.

the opposite extreme is the medical profession, most of whose members shudder at the thought of governmental medicine and have their heels dug into the ground to resist the present tug in that direction. In between are the engineers, who are more and more becoming closely allied with government as the technical aspects of government activity intensify. We do not know whether, as a group, they resist this trend or not. Apparently they haven't even begun to think about it.

## Organization of the Engineering Profession Is Highly Complex

It is said that, where 3 Americans foregather, there soon will emerge a president, a treasurer, and a secretary. One might add to this that often when learned men associate themselves there will be found an intangible complex organization beyond the mind of man to fathom. There seems to be direct correlation between the scholarly attainments of individuals, and the looseness and ineffectiveness for action of the associations they create. The greater the grasp by a group of the intricacies of a social problem, the less likely is it to present a united front on anything whatever. The rate of progress of a group toward a single objective varies inversely with the number of members thereof, and inversely as the square of their special knowledge. The scheme of organization of the professional groups in this country is a marvel to behold. Those of the lawyers and the physicians have effective elements which have been noted. That of the scientists and engineers is a tangled maze in which most of the participants become lost. I think I can fathom something of the way in which our complex political system operates. I have been a member of many professional organizations for many years, and I have yet to form a rational picture of their activities. Their journals get a quick glance as they zip across my desk toward the sagging shelves. They collect dues with growing persistency. Yet the government digs a hole in the sands of Florida to no proved good purpose, and I hear no voice raised to say that we, the engineers of this country, insist that we be told authoritatively what the economic and engineering complexion of that particular hole really is. Much less do I gather that the hole will not be dug except when it has the blessing of the organized engineers of the country. The trouble is they are not really organized for this effective purpose.

In 1933, the *Technology Review** attempted to sort out the 900 scientific and technical societies listed in a handbook of the National Research Council, and to present something of an organization chart and family tree of the engineering societies included. The tree developed into something of a forest. True, one might construct an imposing list of medical or legal societies devoted to special interests. The difficulty is that the engineering group of societies does not head up anywhere. We are especially interested in the way in which this situation influences the relationship between engineers and government, so it will be examined somewhat in detail.

* *Technology Review*, July 1933, page 330, "Engineering Societies, their Multiplicity, their Relatives, their Duplication."

It is right and proper that there should be many organizations devoted primarily to special technical interests, and the increase of these is inevitable as the interests of engineers fan out. Yet it is far better that this development should occur by subdivision of large national societies, rather than by the creation of new groups with consequent increase in overhead costs, and lack of coordination of interests. The American Institute of Electrical Engineers, last of the 4 Founder Societies,† was founded in 1884. Since then have appeared the American Electrochemical Society, the Illuminating Engineering Society, the Institute of Radio Engineers, and others representing special interests within this general field. A similar disintegrating tendency appeared in the group of societies dealing with all aspects of physics, but in 1931 the creation of the American Institute of Physics regrouped these to secure closer interrelation, and economies in publication. No comparable integrating tendency among the Founder Societies has yet appeared. The most important question however, is that of attempts to integrate engineering societies as a whole.

The 4 Founder Societies are associated, through the United Engineering Trustees, Inc., for the purpose of managing a building used in common, for the maintenance of a library, and to sustain the Engineering Foundation "for the furtherance of research in science and engineering, and for the advancement in any other manner of the profession of engineering and the good of mankind." Excellent as is this joint effort, it is directed in practice primarily toward the attainment of technical objectives, and does not properly touch the relationships of engineers generally to government.

The Founder Societies, together with the American Institute of Chemical Engineers, the Society for the Promotion of Engineering Education, and the National Council of State Boards of Engineering Examiners, joined in 1932 to create the Engineers' Council for Professional Development. This "aims to co-ordinate and promote efforts and aspirations directed toward higher professional standards of education and practice, greater solidarity of the profession, and greater effectiveness in dealing with technical, social, and economic problems." Its activities have been pointed primarily toward young engineers, through the certification of engineering schools in connection with state licensing programs, and the postacademic education of engineers. It is doing excellent work in these fields, but does not aim to ascertain and impress group opinion of engineers on governmental or social problems.

## Central Engineering Organizations Already Exist

The nearest approach to a mouthpiece for engineers generally on important matters is the American Engineering Council founded in 1920 "to further the public welfare wherever technical and engineering knowledge and experience are involved, and to consider and act upon

† The others are:. American Society of Civil Engineers; American Institute of Mining and Metallurgical Engineers; and The American Society of Mechanical Engineers.

matters of common concern to the engineering and allied professions." This is exactly what we have in mind. Yet the engineer, with all his supposed genius for organization, has not rendered this the effective instrument that is sorely needed. Every country doctor knows of the American Medical Association. He may quarrel with its dicta; but he knows that with a host of others he influences its pronouncements, and he is proud that it represents him. I would be willing to wager that a survey would show that a large fraction of engineers in this country do not even know of the existence of the AEC. Certainly the average engineer has no feeling that his influence is brought to bear even indirectly upon their considerations of important public questions. It has not the intense interest and support of the profession generally, and its expressed opinions are to this extent ineffective. A devoted group of engineers deals meticulously with the affairs of AEC, and undoubtedly the situation is not their fault. It is none the less regrettable. There are some evident contributing factors to the situation: The average engineer pays no dues to AEC, sees no direct publication of AEC, and takes no direct part in the selection of this body of men who convene to decide upon the problems of the day. Pronouncements have not been strikingly timely. The engineering profession has held important group opinions, but has not seen them forcibly enumerated and spread on the front pages of the newspapers.

If the engineers of this country do not recognize and support their spokesman in the AEC, still less do they recognize that they have a duality of spokesmen. The American Association of Engineers was founded in 1915 "to accomplish for the unity, welfare, standards, and public recognition of the engineering profession what such organizations as the American Bar Association and the American Medical Association have accomplished for their respective professions." It has the slogan "proper recognition to the engineer and the engineering profession," awards a medal, provides group insurance for its members, and has been active in vocational guidance.

There are 3 laudable ideas involved in this matter of a central engineering organization. First is the furtherance of the interests of the profession. Second is the bringing to bear of the influence of the profession upon public matters. There should be no confusion between these. While it is highly fitting and proper that engineers should be active to guard their own interests, such activity is apart from the higher mission of influencing public trends for the benefit of the entire public. These are combined in the same organization only at the risk of weakening the latter. The attention of the AAE is primarily devoted to the former. The third laudable idea is that of direct advice to government departments or agencies on their specific problems.

## National Academy of Sciences Was Founded to Advise Government

On this third aspect the engineering societies function primarily only through a more general organization of scientists. The National Academy of Sciences was founded in 1863, by act of Congress, approved by President Lincoln "to advance science and especially to investigate, examine, experiment, and report on any subject of science or art whenever called upon by any department of the Government of the United States." It is a limited-membership self-perpetuating body, similar to the scientific academies of the old world. One of its many sections is composed of engineers. In 1916 its activities were implemented when it formed, at the request of President Wilson, the National Research Council for "the promotion of research in the physical and biological sciences, and the encouragement of the application and dissemination of scientific knowledge for the benefit of the nation." After the war the NRC was perpetuated by an executive order of May 11, 1918. Still later, and again in time of emergency, this organization was extended by the creation, under the Academy, of the Science Advisory Board, which reported on many important matters referred to it by government departments. The term of this board now has expired, and it has been superseded by a committee of the Academy. This whole organization is itself extremely complex.

By the very nature of this organization, it does not function to bring to bear upon great public questions the opinions of scientists, except when called upon and then in connection with definite scientific problems. In such matters it has rendered important aid and advice. One important aspect of its affairs has been to set up advisory committees for scientific bureaus of the government. Its active arm in research, the NRC, administers research funds for government and large groups, and correlates and promotes scientific research generally.

This is the official established mechanism by which government may call for the opinion of scientists generally, and engineers in particular, upon technical problems, for it was created by government for this specific purpose. Government does so call, and does thus receive advice and counsel. Questions involving important engineering matters, such as recently the problems of ship stabilization, and of lighter-than-air craft, thus are given the benefit of review by distinguished men. Such a controversial matter as the economic and engineering justification of building a tide-power plant on the coast of Maine, however, does not travel by this route. If government asked the question, it would obtain an answer; but it does not ask the question. The mechanism is available, but the pressure necessary to ensure that it will be used is absent. True, engineers are here joined with all types of scientists, but nevertheless the query would result in the gathering of a distinguished group of engineers and economists to deliver the answer. Later, I will discuss the function of the independent consulting engineer in this connection, but at this point I merely note that his services, under proper fee, are not at all inconsistent with the presence of distinguished voluntary committees of review.

One more organization remains to be mentioned. The American Association for the Advancement of Science, founded in 1848, is the great democracy of science in this country. This loosely knit organization comprises about 150 member societies, with half a million members. One

section with many member societies, is devoted to engineering, but engineers generally take no part in its activities. It serves the very useful purpose of bringing together diverse scientific groups for great annual meetings at a common point. Its council occasionally adopts resolutions on public questions, but legislators do not hang on its words. Its membership is too casually affiliated to render it a powerful voice in national affairs.

The engineer, who applies science in an economic manner for the benefit of mankind, certainly has as close common interests with the social scientist as with the physical scientist. Yet the organizations of the social scientists are not greatly participated in by engineers.

Since the beginning the engineer has co-operated closely with the physical scientist; and in fact many engineers are themselves physical scientists of no mean accomplishment. We have reached the point where engineers are learning to work in similar co-operation with social scientists, but the relationship must proceed much further than this. It is necessary, in connection with many of the problems that come to him, that the engineer be himself a social scientist —not a dilettante but a deep student and scholar in his own right in various branches of the social sciences. Only thus may he be properly cognizant of the source from which his activity derives, and also properly cognizant of the social conditions under which it becomes applied. Long familiar with applied economics, he now finds pressing upon him other branches of the broad science of human relationships. The colleges have a duty to perform here, and so have the professional engineering societies. Certainly their meetings and publications should generously reflect this growing need and interest.

## Integration, Not Another Society, Needed

To summarize this matter of organization: Real attention is being given to the professional advancement and the technical interests of the profession. We have an enormously complex system of organization of scientists and engineers in this country, and yet no effective single central organization representing *all* engineers and expressing their viewpoint on public questions. We have an elaborate mechanism for bringing advice to bear on scientific and engineering problems as they arise in government, and this mechanism is not utilized to the full.

What is to be done about it? Certainly no solution lies in forming one more society to join the throng. Integration is indicated; and since societies now exist for all the express purposes we have considered, a duplication of effort by a newcomer would simply complicate matters. Rather, the existing mechanism should be simplified and strengthened.

Would it be of aid if the great national organizations, such as the AIEE, were to take official and definite positions on public questions involving engineering? I do not think this is their proper function, for reasons I will discuss. This is being done in some such organizations, and the effect so far has not been especially helpful. It is another thing entirely for the AIEE to provide a forum for the frank discussion of important questions by men of all shades of opinion. In this I believe it has a duty to perform. So far it has not been done, and the reason seems to be that those in control have not had the courage to take a step which they fear would split the society. Perhaps a frank and fearless discussion on the floor of an AIEE convention of such a problem as that of the proper sphere of activity of government in the generation and distribution of electric power would split the society. I do not think it would. This is certainly a matter of present interest to electrical engineers. If those who are best able to approach it dispassionately and intelligently fear to open the question at all, how is public opinion to be influenced? In the membership of the Institute are men who hold all sorts of opinions on this subject, many of them violently. Many will not express their honest opinions because of their affiliations with government or with public utilities. But there are many more who can and will bring light upon the subject, and, like all subjects of great controversy, it has at least 2 sides. When I speak of a free forum in this connection I do not mean one where the floor is open to the public. I have in mind one where the participants are carefully chosen for their ability to present their views clearly and calmly, and carefully chosen to bring out all shades of opinion. Such an airing of views on this and many other matters would do a great deal of good. A similar benefit will result when professional publications carry powerful expositions and arguments on the live issues of the day, again with an opportunity for accomplished representatives of all sides to be heard. But the Institute itself should express no opinion on this or any other controversial question where its membership holds diverse views. It cannot at once be the guardian of a free forum and an advocate. Still it should certainly not be an ostrich.

This taking of stands should be left to a body having that as its primary function. That body should be made up of men of great distinction in the profession, chosen for the purpose by the membership of the profession directly. It should use every legitimate means to be well known to the membership, by questionnaires, publications, and by reasonable publicity in regard to its deliberations and findings. It should be absolutely without fear and without prejudice. Its pronouncements should be front-page news in every corner of the land. It should enter into any public question involving engineering as a right and without invitation. It should not hesitate to swing public opinion by rousing the profession when such action is indicated. In order that it may speak with a single voice it should represent engineers only, with deference, of course, to the opinions of other professional groups. We do not have this situation today. The metamorphosis of existing organizations, under the guidance of public-spirited engineers, may bring it to pass. As it proceeds it should have the aggressive support of every engineer who has the good of his country at heart, whether or not he agrees with its findings in every respect.

The technique of applying the pressure of engineering opinion on great public questions is only one aspect of our problem. Another aspect involves the advice by engineers to government on specific technical problems. This is a

large question and one that involves many of us in one way or another, as citizens and taxpayers as well as engineers.

## Government Needs Independent Consulting Engineers

That there is an elaborate mechanism by which government departments may secure the advice of scientists and engineers, has been shown. For several reasons, this is not sufficient for the purpose. First, the way is indirect, through an organization that is preponderantly scientific. With the best intentions in the world such an organization cannot function precisely and promptly to bring to bear on a great national engineering problem the best engineering brains to be had anywhere; only a few of the great engineers of the country are directly affiliated with it; and the indirect path is cumbersome. The complexities and inertia of this situation were overcome in time of war and in time of great depression, but during normal times the mechanism works feebly. Second, to wait to be called upon in a busy world is not enough, and the present organization has a natural and proper hesitancy to press itself into controversies. Third, the setting up of distinguished boards of review on a voluntary basis is not enough.

One cannot give sound advice on important engineering matters without spending considerable time and money. This is the function of the independent consulting engineer. We will not be on sound ground in this country until government, on a basis of adequate and dignified fees, calls for the opinions of independent consulting engineers whenever it has an important engineering problem. This it does not do at the present time to any determining extent. If, when the subject has been deeply studied and reports have been presented, the government wishes review by distinguished boards, it always will find men ready to give their services as a matter of public duty. The main reliance, however, must be upon independent consulting engineers, and I wish to make a plea on their behalf.

There are many engineers—many able engineers—in government itself, and these are utilized by government when it has an engineering project to carry out. Army engineers have carried forward on a high plane many outstanding engineering works. The Reclamation Service conducts a research laboratory that is second to none. But the government engineer is not an independent engineer and the latter is sorely needed. Given a definite project the government engineer can carry it forward; but he cannot at the same time say that it is a foolish thing to carry out at all, even if his engineering studies convince him that it is. Here is a point at which a democracy is at an advantage compared with an absolute government. The dictator has *only* government engineers—units in a rigid machine. Independence of thought and speech there cannot be tolerated. Yet, having the advantage as a democracy of the presence of engineers of real independence, we do not make use of them. This is partly because truly independent engineers are becoming rare; partly because unfortunately government is sometimes not anxious that the full truth be known; partly the fault of the engineers themselves. This matter is worth discussing briefly, for it is truly unfortunate if one of assets of a democracy is being thrown away.

The rise of great industries in this country, own engineering organizations, has restricted operation of independent consultants. The extend free engineering services as part of the grams of large companies similarly has encroached tunately, industry by and large cannot maintain neering departments capable of coping with the and these peaks are surmounted by calling in porary services of independent engineering organ Yet the way of the consultant has not been easy number of men who are truly independent, seasoned opinions based upon wide experience fields, is not large. This is distinctly the fault ment. There should be more utilization of the type of John F. Stevens called for service at the Canal. If it were our practice in this country ment to employ independent engineers frequently number of such engineers would be greater. When ment calls on the engineer at all, it usually does so on a niggardly basis. It appears to starve out a group upon which it distinctly needs

But part of the fault lies with engineers themselves. While we deplore any reluctance on the part of ment to let the full light of reason play on its engineering works, we must admit at the same the approach of engineers often has not been based sufficiently broad consideration of these very To show that a government engineering work will an adequate financial return on the original investment not necessarily sufficient to condemn it; yet engineers prone to limit their considerations to a strict cost basis. The building of a battleship cannot be justified this basis. The setting aside of a national forest not be thus approached with limited logic.

Do not think that I advocate letting down the strict reasoning to which all engineering works subjected. I have no sympathy with any waste money. To build a great dam to supply electric a region already amply supplied with power, to land in a region of no inhabitants while farm lands idle close by, to render navigable a stream that into a wilderness, are fool pieces of work in any Yet I would have the engineer join with the the sociologist, the student of government, that grasp problems in their entirety.

Is it foolish to clear slums, and to cause living to be built by subsidy from public monies, for previous slum dwellers on a rental basis that returns a portion of the direct investment? It may or may be, and the answer can come only when the works with the sociologist. It may be a decided investment on the part of government from a financial point of view, if the decrease in costs of health hazards, hospitalization, and social decay follow slum clearance, offsets the direct cost of But merely because the problem involves more matter of direct costs and direct revenues, does the government for proceeding without independent

it merely emphasizes the need for analysis by professional men of diverse types.

## Consulting Engineers in Educational Institutions

Both government and industry should support the independent consultant in this country, that he may be available in time of need. A duty also rests upon our educational system in this same connection. This duty may rest lightly, for the consultant with university affiliations can bring strength to the educational system itself. Much has been said on this subject, and some would block consultation by members of college faculties. This always would be a catastrophe, but especially so at present when the consulting engineering profession needs to be enlarged and supported. Moreover engineering education must be real, conducted in an atmosphere of success, and in close contact with industrial and governmental advance; and the consultant on the faculty can aid greatly in this regard. There are dangers in the relationship, of course, but they can be avoided and the benefits secured. The use of the name of university affiliation, without the substance of educational duties and responsibilities on the part of the consultant, is a perversion. Encouragement of consulting by university administrations should be accompanied by insistence that such contacts be on a high plane and such as to advance the professional standing of both the individual and his institution. The fees charged should be on a dignified basis and such that there is no unfair competition with consultants who do not combine educational activities. There should be no use of university laboratories in consulting connections except where the institution is fully reimbursed for all costs of having the facilities present, and then only when there is no interference with the use of these facilities for their primary purposes. Educational institutions that have unique research facilities not available elsewhere, should make them available as far as possible without impeding educational use, either directly or through those commercial organizations which perform research services for industry. This certainly does not mean, however, that an educational institution should do routine testing for industry where there is a commercial organization capable of performing the work. Industrial research within an educational institution may be a fine thing, when it carries its full costs, when its results become published, and when its presence adds to the educational process of training men capable of coping with industrial research problems after graduation. But neither the educational institution itself, nor the consultant who is a member of its faculty, should carry on activities that tend to lower the plane of independent consultants or independent commercial research laboratories. When these matters are realized, the presence of a consultant on a faculty may be of benefit to the institution and render available one more independent engineer for advice to government and industry.

There are many ways in which the individual engineer makes contact with government, and several in which a more intimate contact would be of benefit. One important way lies in the growth of the commission form of activity. These commissions usually, as in the case of the Federal Communications Commission, the United States Shipping Board, and the Tariff Commission, are essentially groups of experts within the frame of government itself. So also are such units as port authorities, irrigation district authorities and the like, set up within our still flexible frame of government to unite the administration of regions having common technical character. These and similar units offer one promising mechanism by which to implement the specific actions of government in technical affairs. The engineer is an important member of all such bodies. By and large they have been decidedly effective. An important element, however, appears to be generally lacking in the movement. Usually such boards depend upon the technical knowledge of their own membership, supplemented only by the examination of witnesses who come before them. They are not amply enabled, by the act which establishes them, to increase their grasp and power by temporarily joining to their membership outstanding consultants with special knowledge of the particular problems before them. The independent engineer would find in such association many opportunities to be of genuine service.

## Engineers and the Legal System

Another important way in which the engineer makes contact with government is in connection with the legal system, both in law enforcement and in the administration of justice in the courts. This is too large a matter to be treated adequately in an address having a broader subject, yet the point comes up inevitably. There is a real need for close association of scientists and engineers with the legal system at many points, especially in the patent system. The reason is clear. The determination of any legal question depends jointly upon the law and the facts. In a modern technical world the facts are beyond the comprehension of the layman. When dealing with a scientific or engineering subject, the most eminent jurist or attorney is usually decidedly a layman. The result is often sad. Decisions are rendered by judges to whom the facts of a case are in essence imcomprehensible. Present procedure is expensive, indeterminate, and sometimes ludicrous. Details of procedure aside for the moment, the real reason for this situation is the unwillingness of the legal profession to admit to a basis of partnership the scientist who understands the technical facts of modern civilization, with the attorney who understands the law. We have the spectacle of opposing experts, cross-examined by lawyers who have a week's cramming as a background in the subject under consideration, for the benefit of a judge whose scientific training ended at "Physics I." The childlike faith of most attorneys in this process of elucidating technical facts is beyond comprehension. To the technical man on the sidelines it is often evident that the discussion proceeds to about page 20 of an elementary text, when the true answer lies on page 500 of an advanced treatise. The general atmosphere, charged with suspicion, progressing at a snail's pace, is such that the majority of scientific men engage in legal matters just as little as

possible. To expect men of great scientific attainment generally to be willing to take part in this procedure is expecting a great deal from the human race. Yet the members of the legal profession generally regard the presence of a technical adviser to the court, not subject to cross-examination, as an anachronism, and they are perfectly sincere and honest in the opinion. The dilemma is clear. The legal profession, which controls the system, cannot itself or through its artifices deal justly in the type of world in which we now live. It will not have the true co-operation of the best scientific and engineering minds in expeditiously arriving at justice until it welcomes them to something besides a subordinate status. In some of its phases, the legal system has been dangerously close to breakdown, and no small portion of this situation is the extent to which it is bogged down in a scientific morass. If breakdown comes, it will be the fault of the profession that molds its affairs and determines its form. Scientists and engineers stand always ready to aid in a matter of public concern and on a basis of professional partnership. In this connection the independent consulting engineer can be of real service in many ways, but space does not permit a detailed examination of them.

Throughout this address I have emphasized the value of independence. So long as this is maintained and there is the effective guidance of affairs by an independent professional class, I have no fear for the future. A true democracy, given this support, can compete with dictatorship and prevail.

## Frontiers of Science Still Remain

It was independence of thought, freedom of action, the opportunity of a vast untamed domain that built this country and gave it the highest standard of living in the world. The geographical frontiers have disappeared, but the frontiers of science and technology still remain. Those qualities which built a trail into the wilderness can still build trails in the technological advance. The same qualities of courage, resourcefulness, and independence which opened the nation, are as necessary today as ever.

The growing complexity of life tends to make men cogs. The world is growing smaller, and it is becoming crowded. We "rub elbows" and find increasing dependence upon the activities of our fellow men. The race for economic domination becomes a race, from which we only partially are separated, for military supremacy. The burden on government increases, and the problems arising are more and more beyond the true comprehension of the proletariat. Intense nationalism is in the saddle, and everything, including freedom itself, toward which the human race always has aspired, is being sacrificed for a momentary advantage in the struggle. Nations are turning toward absolutism as a refuge.

Gladstone predicted the decay of democracy if the indigent voter found the power of his vote sufficient to seize arbitrarily and unreasonably the fruits of production. Jefferson himself, the father of American democracy, postulated as a necessary feature of a democratic régime that the bulk of the voters must be tillers of their own land. Whatever we may wish to modify in these opinions, one thing should be added in view of modern conditions. As the social machine becomes more complex and interdependent, it becomes increasingly easy for an aggressive group to disrupt it. The need for discipline is greater, the necessity for restraint of the asocial individual or group is more pressing. Individual freedom, always circumscribed, from the clan up, by the necessity of consideration of the rights of others, becomes inherently narrowed. The right to do this or that ceases to be a right when its performance injures a neighbor; and the ways in which each individual's acts reflect upon the security of his fellows are constantly multiplied. The democratic form of government is adapted to the maintenance of discipline only to the extent that great groups of varied peoples are ready and willing to discipline themselves. The failure to do so in other countries is the primary reason that the people have reverted to absolutism in the hope that it would prove benign. The immediate result of course, has been to impose discipline, often harshly and in the extreme, to curtail radically individual freedom, and thus to create a state in which efficiency is secured at the sacrifice of much that makes life worth living. The plunge into absolutism is abrupt. The winning of individual liberty is a slow and painful process. Must all democracies go through this cyclic process? Can the great populace, which is governed by its intuitions, its emotions, its mass psychology, grasp this trend and preserve its stability? Moved by the persuasion of those with ulterior interests, who play upon their emotions, can they yet understand the voice of reason? It depends upon whether those who would bring to the people the accumulated wisdom of the ages speak in words that are powerful, genuine, and capable of being truly understood; and then it depends only upon whether the people listen and are willing to be guided by reason.

## Professional Man Should Make Himself Heard

The free operation of professional classes, motivated by public zeal and altruism, is an anchor upon which our democracy depends to hold it through the storm. There is a great obligation upon the professional man to speak clearly, to insist upon being heard, to maintain his independence. This obligation rests heavily upon engineers.

To be a professional engineer in the true sense, does not require that we have some special set of relationships to society and to the organizations of which it is made up. It does require that the primary motivation be the acquisition of scholarship and its generous application to the needs of man.

To be an engineer in these days is to bear a proud title. To be able and willing to speak true opinions on the complex technical affairs of the day, without prejudice and free from control, is a privilege that is becoming rare in the world. Insistent upon his prerogatives, kowtowing to no man, respected because he speaks a truth the country needs to know, the independent engineer stands as an important member of the professional class—a strong bulwark against disaster, which can guide our steps into the ways of pleasantness and into the paths of peace.

# The Engineer in a Changing World

By RALPH E. FLANDERS

**What can and should engineers do about the social and economic problems that beset the modern world? In answering this question, Doctor Flanders says: "We must exercise our responsibility more for the sake of society as a whole than for the sake of ourselves as individual engineers or for the private interests of the businesses with which we may be connected." He states further that: "It is an inescapable duty that we each make of ourselves centers of education and influence, to the end that our useful offices may continue, and our civilization fulfill its destiny of an ever-growing service to the needs of mankind."**

THE WORLD in which we are living is changing in many ways, and those changes are rapid. The physical frontier has disappeared from this continent and, except for the antarctic regions, it has practically disappeared from the earth as a whole. With the occupation of the frontier has gone one of the powerful automatic stimuli to private enterprise and material progress.

Much of the progress we are making is so based upon elaborate research and requires such extensive and expensive provision of facilities that it is best carried out by large corporations or well-financed research groups, rather than by individual scientists, engineers, and inventors of the old type. This is another influence that tends to restrict the expansion of individual initiative and tends to throw the burden of further social progress onto aggregations of capital and of men.

A further element in our increasing socialization is the recent rapid sensitizing of the social conscience and a resulting expansion of social activity into fields of action which in past generations had been considered reserved for the individual or for small social groups. The severity of the depression was so great and the social responsibility for it seemed to be so definite that both our relief measures and our recovery measures have tended to be social and political, rather than individual and philanthropic.

Finally, though without exhausting the list of recent developments, we have become aware of the fact that in our banking, credit money, and general aggregate of financial institutions, we have a useful but delicately balanced, and at times unbalanced, mechanism difficult to control and tending on the whole greatly to increase the violence of business fluctuations and economic distress, rather than to provide a dampening effect on them. All these phenomena and others not mentioned pose a new set of problems to the engineer and to the engineering societies in which they are organized.

In their beginnings and until recent times, engineering societies had the purely technical purposes of bringing to the attention of their members all the latest technical developments in their fields and offering a forum for criticizing them, advancing them, and disseminating knowledge about them.

Even while this type of activity remained almost the sole object of society action, the problem nevertheless began to be complicated by the numerous divisions into which engineering work began to elaborate itself. Engineers were no longer simple engineers. Some were in control of their own businesses as consultants or manufacturers of engineering apparatus; others were employees of various grades. Some were engaged in teaching; others in research, design, construction, sales, operation, and administration. This multiplication of function brought a host of new problems to the engineering societies, on the one hand opening new opportunities to usefulness, and on the other tending so to elaborate engineering activities as to lose much of the harmonious directness and strength of the earlier days.

As a result of the tendency for engineering advance to be focused in and to be carried out by large aggregations of men and of money, the problem of the engineering society has been complicated further by widespread sentiment in favor of entering employer-employee relations, so that in the extremes of such policies the societies might be tending to take on some of the aspects of trade-union organizations.

This continuous elaboration of function is here described and emphasized so that we may realize that the problems facing us are no longer simple, and that any endeavor forcibly to keep them within too simple lines may result in giving to the societies a cloistered and sterile outlook, devoid of vital function and social usefulness. We are in fact faced with the problem of maintaining our social usefulness and finding out just what are the spheres in which it most clearly may be demonstrated and exercised.

## World of Today a Product of the Engineer

The world we know has been made by the engineer so far as its physical aspects are concerned, and his influence has had no small part in determining its spiritual environment.

---

An address delivered at the general session on the economic aspects of engineering and Institute activities held during the AIEE summer convention, Milwaukee, Wis., June 23, 1937.

RALPH E. FLANDERS is president of the Jones and Lamson Machine Company, Springfield, Vt. He began his technical career as an apprentice machinist in 1897, and became president of the Jones and Lamson company in 1933. He has received several honorary degrees. Doctor Flanders has devoted much time to engineering-society activities, having served as president of the American Society of Mechanical Engineers, and as member or chairman of many ASME committees. He is a vice-president of American Engineering Council and chairman of the AEC committee on relation of consumption, production, and distribution; since 1932 he has been active in the public works program of Council. During 1936 he was chairman of the AEC committee on engineering economics and has been a director of the Social Science Research Council. He has written numerous technical papers and 2 books.

Perhaps some remember the epitaph of Sir Christopher Wren, the architect, engraved on the walls of his masterpiece—St. Paul's Cathedral in London. It reads: "Si monumentum requiris, circumspice," or, in English, "If you seek his monument, look about you." In like manner, if we wish to inquire as to the material influences of the engineer, we have but to look about us. We will see thousands of daily reminders of the fact that our material civilization has at the bottom an engineering foundation.

Its useful services are many. Our profession has filled the world with a profusion of comforts and luxuries which were denied to kings a short century ago, but are now enjoyed by the average citizen. Flowing water in the kitchen and bathroom, brightly lighted streets, and the radio, are all ordinary conveniences for the ordinary citizen. They were nonexistent when Queen Victoria began her reign.

There is no need to multiply instances. The tale has been told and retold; but told and retold, as well, has been the story of the problems an engineering civilization has posed for the solution of its citizens. The perils of drought and pestilence have been exchanged for the mischances of technological unemployment. That unemployment may be transitory and a part of a process which history shows to be benevolent in its total results, but it is as yet a serious and sometimes insoluble personal problem.

Worst of all, our engineering civilization proves to be less stable than the older forms based upon subsistence agriculture. It gives us more, but its gifts are more irregular. There are seasons of outpouring and seasons of withholding. Boom follows depression, and depression follows boom, and this relentless alternation leaves much human wreckage in its wake. What can and should we engineers do about the evil features of this world we have made?

## Engineers Should Not Intrude Into Alien Fields

It is not my intention to go into the details of this problem. I believe that the engineer's work has been healthy and constructive. I believe that the maladjustments have come from our narrow and selfish activities as industrialists, workers, farmers, and financiers, and from the imbecilities of our politics. In particular, I do not believe, as so many have urged, that the remedy lies in the intrusion of engineers with engineering methods into the alien fields of politics, economics, and finance. This subject will be discussed briefly, because in popular opinion our profession alternately has been damned for causing all the ills of our era on the one hand, and on the other for not curing them by still more radical engineering activity.

This question was raised some months ago in an address by Walter Lippmann, and I take the liberty of quoting here in part from his criticisms and in part from a reply to them:

> There were several years, I should say roughly from the crash of 1929 to the end of 1933, from the breakdown of prosperity to the beginning of recovery, when the ideal of an engineered and planned economy had almost completely captured the imagination of the Western World. Every one who raised his voice—the Chamber of Commerce, the heads of big corporations as well as the New Dealers and the Progressives—talked about planning something. No doubt they had different ideas of how to plan and what to plan for, but the underlying image dominated most minds. The notion finally reached its grand climax, and its *reductio ad absurdum*, in the vogue of technocracy.
>
> The point I wish to make is that the conception of government as a problem in engineering is a false and misleading conception, that the image of the engineer is not a true image of a statesman, and that society cannot be planned and engineered as if it were a building, a machine, or a ship. The reason why the engineering image is a bad image in politics, a bad working model for political thought, a bad pattern to have in mind when dealing with political issues, is a very simple one. The engineer deals with inanimate materials. The statesman deals with the behavior of persons.
>
> The notion that society can be engineered, planned, fabricated, as if men were inanimate materials, becomes in its extremist manifestations a monstrous blasphemy against life itself.

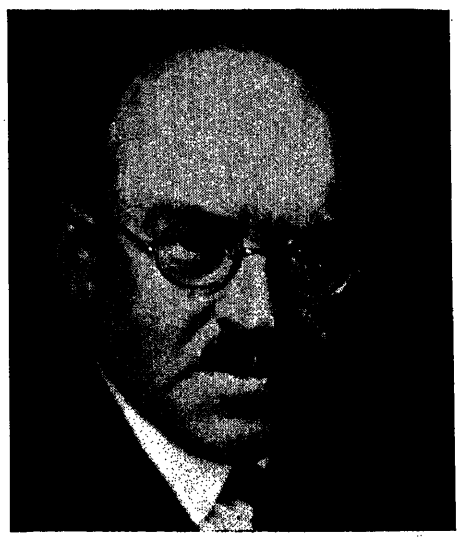
These statements are a challenge to the engineer's training, his state of mind, and his usefulness to society. That challenge should be accepted and an answer given.

## Engineer Can Contribute to Government

Engineers never have been convinced, in great numbers or for long, of the effectiveness of their technique as a main reliance of government. In fact, the clearest, most reasoned, most convincing demonstration of its inapplicability is the work of an engineer. Those interested will find it in an article by David Cushman Coyle entitled "The Twilight of National Planning," published in *Harper's Magazine* for October 1935. In all this we are at one with Mr. Lippmann.

But it will not do to leave the matter in this negative state. The engineer has positive contributions to make to the processes of effective government. He cannot make them unless certain misconceptions expressed in Mr. Lippmann's address are removed and the real nature of his contribution is revealed. There are 2 primary misconceptions: (1) The engineer cannot "dictate to nature." He is the humble disciple of nature, serving society by virtue of that discipleship. (2) His undertakings grow ever farther removed from the completely material realm, and must perforce deal ever more and more with the realization of human ends, whereby the completed structure or mechanism is a joint product of material science on the one hand, and human desires, needs, and possibilities on the other. In no branch of engineering does this appear more clearly than in the modern forms of "scientific management," of which the foundation is a fundamental and sincere comprehension of the human and personal element. Engineering is science applied to human needs. It is both a science and an art. If it is not both, it is not engineering.

Another characteristic of engineering is derived from the fact that it is an applied science. It is science applied to definite purposes; and definition of the purpose becomes the ruling factor in engineering design. In government a similar definition of fundamental purpose is sadly needed. Our national policies are guided by such sec-



ondary and derivative purposes as raising the price level, restoring the freedom of international trade, raising wages, shortening hours, controlling production, restraining competition. Each of these confidently is put forward as a good in itself, with small pains taken to see that each is related to some larger, general set of purposes.

Good engineering is based upon a careful statement of the problem to be solved; and it happens that our profession has formulated such a statement of the economic problem and has publicly offered it for the consideration of government and governed. It is to be found in the first progress report of the committee on economic balance of American Engineering Council. It reads as follows:

> The problem is "the selection and recommendation of such governmental, financial, and business policies as will maintain in the United States a standard of living that is high, broadly distributed, and free from severe fluctuations."

At first sight such a statement appears trite and sterile; but when we take the trouble to examine the infinitude of partial and conflicting policies that go to make up our total program at this moment, the need becomes clear for some such statement of fundamental purposes, to which all policies must be referred.

A third contribution of our profession—and the last to be suggested in this connection—is a certain knowledge, and a particular faith. The knowledge is that the physical requirements are now at hand for a material standard of living far higher than the human race ever before has enjoyed. There are no physical obstacles. The engineer has removed them. He has played his part. If fault there be, it lies at some other door than this.

**Doctor Flanders**

With the knowledge goes a faith. He has faith that the complicated social and political problems involved in reaching our objective can be solved—not immediately nor completely, but in such wise and with such speed as may lead to a continuance of our old progress toward a higher and more widely distributed material prosperity. This knowledge and this faith we would share with others.

It is a privilege to belong to a profession that combines the practice of a science and an art. The combination is essential for leadership and achievement. For some time, it has seemed that at least 3 branches of education and professional practice are well fitted to prepare men for life in our present troubled world. They are the doctors, the engineers (to an extent and for reasons I have endeavored to explain), and the graduates of the first-rank schools of business administration, together with the practitioners of business who have attained professional first rank without grace of formal education.

Not only is each of these professions at once a science and an art, but they have another property in common. Each has to face the harsh judgment of ascertainable fact. For the doctor, the patient gets worse or better, lives or dies. For the engineer, the dam endures and serves its economic purposes, or it goes out under the pressure of the flood, scattering death and destruction. The business man faces the grim entries on the balance sheet. Each is in touch with reality. Society needs the touch of reality.

How should all this affect our lives and our actions? In many ways, but principally in 2 ways: We should derive from these considerations a deep and effective sense of the worth of our profession, and likewise of the responsibilities we bear as engineers.

## A Current Problem As the Engineer Sees It

It may be worth while to consider one of our current problems in the light of the engineer's knowledge and experience. We believe that the standard of living may be greatly raised for the mass of the population which is able and willing to work. We believe also that the increasing efficiency of machinery, processes, and management will permit the world's work to be done in shorter hours with more leisure for rational enjoyment. In a word we are sympathetic with and committed to the objectives of the present active labor movement in its endeavor to attain shorter hours and higher wages.

But the higher wages must be real wages, that is to say, they must be able to purchase more goods and services for the wage earner and his family. A mere increase in dollar wages will not do if there are no more goods and services to be bought and if prices advance as fast as or faster than wages do. When we see output restricted by shorter hours and the slowing up of the introduction of improved machinery, while wages are being raised, we are justified as engineers in applying elementary analysis to the problem. We must conclude on such analysis that it is hopeless to expect more goods for higher wages if less goods per worker are made. The hope for a better living under those circumstances is illusory and cruelly deceptive.

However, there is hope for a better living, and that better living can come only from better production as a preliminary to better distribution. For that better production—and particularly for better production in shorter hours—the world is now, and in the future will be, dependent on the engineer, as it has been in the past. If our hopes for better material conditions are to be realized, there will be work for the research engineer, for the process engineer, for the designing engineer, for the management engineer. And the sooner this is realized by the pro-

tagonists in our present social strife the better it will be for all concerned.

## A Major Threat to Social Progress

It is in our experience and our present method of meeting these current problems that we find the engineer's responsibilities of today. By the pressure of attractive but impossible doctrine, his usefulness to society is threatened; and with the limiting of his usefulness, there is arising a major threat to the social progress we have been making hitherto. We cannot ignore this situation. We must exercise our responsibility more for the sake of society as a whole than for the sake of ourselves as individual engineers or for the private interests of the businesses with which we may be connected.

There is indeed danger in the fact that the material progress with which we are concerned is so closely associated with business interests that they may seem to be one and the same thing. They are not completely so. There is a large area of business as it has been pursued in years past that has not been socially constructive, but socially dangerous instead. Perhaps the largest single area of this harmful business activity has been found in the realm of security speculation and its allied enterprises. Unfortunately for one area of our responsibility, this speculative activity has been so closely associated with the operation of utilities that it is difficult for the general public to distinguish between the useful and socially necessary on the one hand, and the destructive and damnable on the other. A part of our problem lies in making this distinction clear within our own minds and then in presenting the distinction so clearly that we can take the lead as individual engineers in directing public policy on this utilities question into channels more nearly serving the public interest than does the direction now being pursued.

Another danger that we must carefully avoid is that of running wild on the social and economic aspects of our profession and neglecting the technical foundation on which is built everything else that we say and do. The other serious danger, that we may be rash enough to carry our whole engineering point of view over into social planning, has already been discussed.

Whether or not as individuals or as a profession we attain to high reputation or only to humble usefulness, we know that our civilization depends on us. In the words of Spengler, though with more hopeful emphasis:

> The center of this artificial and complicated realm of the machine is the organizer and manager. The mind, not the hand, holds it together. But, for that very reason, to preserve the ever-endangered structure, one figure is even more important than all the energy of enterprising master-men that make cities to grow out of the ground and alter the picture of the landscape; it is a figure that is apt to be forgotten in this conflict of politics—the engineer, the priest of the machine, the man who knows it. Not merely the importance, but the very existence of the industry depends upon the existence of the hundred thousand talented, rigorously schooled brains that command the technique and develop it onward and onward. The quiet engineer it is who is the machine's master and destiny. His thought is as possibility what the machine is as actuality.

Those words are true! As individuals we may struggle, and succeed or fail; we may be rewarded beyond our deserts or miss a recognition that was richly our due. Whatever may happen, this at least we may hold to: that we lived in a glorious age, full of human possibilities; and that our daily work lay at the heart and center of that age.

As to our responsibilities, they are great. Perhaps the greatest of them lies in the understanding of the nature of the mechanisms and of the organizations on which depend the material interests of our generation. It is hard to say whether the greatest danger to them lies in their being perverted and frustrated by powerful selfish interests, or in being overthrown by the recklessness and ignorance of our fellow citizens—even by those moved by the best of intentions. Our material blessings do not come naturally, as fruit grows on a tree. They come because thousands of individuals, having engineering and organizing skill, devote themselves in large and small capacities to keeping the machinery of civilization in running order. It is an inescapable duty that we each make of ourselves centers of education and influence, to the end that our useful offices may continue, and our civilization fulfill its destiny of an ever-growing service to the needs of mankind.

## The Engineer's Responsibilities to the Public

Doctor Vannevar Bush has analyzed the social responsibility of the organized engineering profession with particular reference to its relations with government (see article elsewhere in this issue). I am going to suggest the nature of our responsibilities to the general public. We are now engaged in a strenuous race, a race between education and the breakdown of democratic government. As one of its major resulting catastrophies the breakdown of democratic government would destroy the engineer's usefulness to society and put an end to all reasonable hope for a continuation of our old progress toward a higher standard of living for the mass of our fellow citizens. To forestall this disaster, widespread education of the voting public is necessary. The first step in this process is our own self-education. Perhaps we never have stopped to think that we may be in need of that, that some of the ideas we have held since our youth may need revision.

We should examine our beliefs with all the critical capacity at our command. We should study and ponder with open minds proposals to which we have an instinctive aversion. Thomas Nixon Carver once wrote that the trouble with radicals is that they read only radical literature, and the trouble with conservatives is that they read nothing at all. We must erase this stigma from our record and approach these new problems from all directions, furnishing ourselves thereby with opinions perhaps somewhat changed but more solidly founded than before, for we do have new problems and they may require from us new attitudes. It is doubtless true that economic law does not change; neither does physical law. But we discover new physical laws and perhaps we may discover new economic ones. At any rate, we have behind us a marvelous record of new invention and enterprise operat-

ing under the ancient and immutable physical laws. Is it not possible that we may discover workable and useful social novelties operable under the ancient and immutable social laws?

As engineers, it is incumbent upon us to distinguish between the device that flies in the face of nature and the device that makes a new application of natural law. With our own beliefs fresh and clear and in order, we face the task of making them broadly useful. I wish to stress our responsibility as an educational force counteracting the forces of social dissolution. In our national meetings, in the meetings of our local sections, in our personal appearances before other bodies and groups, in our private conversations, in human contacts which we must learn to multiply and elaborate, in every way ingenuity can provide, with all the patience and wisdom at our command, we must speak and work for the continuance of an ordered society that moves forward to higher material possessions, more fruitful leisure, and deeper spiritual achievement.

Perhaps you will forgive me if I close with words that originally were addressed to a graduating class at commencement, for, in a sense, we too are facing a commencement.

In the Declaration of Independence our forefathers demanded for the individual the right to "life, liberty, and the pursuit of happiness." When those words were written it was a new idea in the world that happiness might be attained. The ancients and those of medieval times had other aspirations. They sought honor, liberty, and salvation, and were not sure that happiness was consistent with these or even possible on any terms. May I suggest that there is a deeper, richer word than "happiness," and that is the word, "satisfaction."

It is not too much to hope that we may attain satisfaction in the practice of our profession. In part it will come from the very fortunate fact that many of us as engineers see the idea in the mind finally embodied in the material machine, process, or structure, and actively serving the needs of mankind. But an even more powerful satisfaction will come to us if we see our profession in the aspects of history and of the evolving human drama. For those who see, and who act on the vision, the fullness of life is reserved. May that gift be ours!

# The Engineer of Tomorrow

## He should be guided, but not limited, by the record of the past

By A. M. MacCUTCHEON
PRESIDENT AIEE 1936-37

DURING this past year I have talked with and consulted many engineers. I have learned of their ideas and their ideals. They are men of purpose and conviction. The engineering record of the last 50 years is astounding; but these men are not satisfied. The typical engineer is more interested in the problems of the future than in the accomplishments of the past. The engineering profession demands that the engineer of tomorrow shall be broader and greater than the engineer of today or yesterday.

How can this be accomplished? None can deny that we are living in a changing world. History is the great teacher. We should be guided, but not limited, by the record of the past. The last hundred years has been a period of engineering invention and development, and invention will never cease. We should endeavor to decide whether the next 25 years is not to be more largely a period of adjustment—of consolidating, co-ordinating, perfecting, and best utilizing the inventions and developments of the past.

Much has been said of the "engineering method" of approach to, and solution of, a problem. Just what is this "engineering method," and has the engineering profession invariably used it in the consideration of its own problems? In an article published in the February 1937 issue of ELECTRICAL ENGINEERING (pages 206–07), Morris Leeds, a Fellow of the AIEE, defines the essentials as follows:

> A clear conception and precise statement of the objective to be achieved; a consideration, as thorough as practicable, of all the factors—be they physical, social, or psychological—which will influence or may be employed in getting the desired results; and, on the basis of this knowledge, the formulation of the most effective plan for achieving results that can be developed in the allowable time.

To this I suggest that the following be added:

1. An investigation to develop all facts pertinent to the problem.
2. Recognition of additional information which is necessary, and which may be secured by research and experimentation.
3. Correlation and evaluation of the information gathered. Conflicting evidence often develops, and each item should be weighted in reaching the final decision.
4. The decision shall be uninfluenced by ulterior considerations.

I have believed that engineering is an art almost as

The president's message presented at the opening session of the AIEE summer convention, Milwaukee, Wis., June 21, 1937.

much as it is a science. As an illustration, consider the design of a new electric motor. Assumptions are made as to the conditions to be met when the motor is applied, but exact information as to the operating conditions is seldom available. While the motor is designed for a specific horsepower, practically never is this the exact horsepower demanded of it in service. The proper weighting to be given to efficiency, cost, heating, and dimensions must be decided by the designer. A penalty in one direction is often an advantage in another. Materials are selected with a view to taking advantage of technical progress. Often these materials are yet unproved for the specific purpose. Innumerable decisions must be made, based upon past experience and probability. To be an engineering achievement, the finished motor must be as much a work of art as a painting by a master, and it cannot alone depend on the accurate solving of a number of formulas. The successful designer is guided by a trained instinct as much as by acquired knowledge. Of a hundred possible designs, he selects one in much the same way that the musician develops his creative theme. If this is a correct theory, its recognition is important. The future practice of engineering, the future training of engineers, the future relation of engineers to the rest of industry and society, should be influenced by this theory.

Many problems are referred to the engineer. Though the trained engineer is best qualified to make the decision, his recommendation often is questioned. He is expected, being an engineer, to demonstrate quickly and convincingly that no other solution was possible. Seldom is this true. While no engineer can always be right, this is the limit toward which he strives. The critics of engineers are asked to view the remarkable engineering progress of the last 50 years, and to value engineering opinion accordingly; but the engineers themselves should concentrate on what they have failed to accomplish, and by the application of the "engineering method" improve their engineering.

Applying self-analysis, what may be our faults of the past? Have we ourselves viewed engineering too much as a science and not enough as an art? Have we thought that engineering dealt only with inanimate things and natural forces, and failed to recognize that human reactions and the interests of humanity are essential factors to be considered and properly weighted in any engineering recommendation? Have we been too dictatorial and assumed that others should accept our decisions simply because we are engineers? Have we been too intolerant of criticism and failed to profit thereby? Have we had too great a tendency to refuse to recognize things as they are, and insist on how we think they should be? Have we given full value to the viewpoints of others? Have we always realized that while an exchange of views is desirable, a prolonged argument is seldom convincing? Have we been good students of human psychology and fully developed our ability to win confidence and influence others? Have we always recognized that the best speech is of no value unless it is heard; the best book of no value unless it is read; the best engineering plan of no value unless it is so convincingly presented that it is endorsed and adopted by others? Has the engineering profession always charted its course over a period of years, or has it planned from day to day and month to month?

In a recent talk, I presented this definition of an engineer: "one who through training, study, and practice adapts and controls the materials and forces of nature to the benefit of himself, his fellow engineers, and the rest of the human family." This definition implies the adapting and controlling of men, for they certainly can be classed as among the materials and forces of nature. I believe that society's past conception of engineering has been limited to invention, research, design, and education.

The following I list as the desirable qualities to be possessed by every engineer: integrity, dependability, enthusiasm, vision, determination, resourcefulness, forcefulness, adaptability, co-operation, diplomacy, friendliness, broadmindedness, training, experience, and engineering knowledge. Has every engineer of the past, and does every engineer of the present, meet this or a better definition, and possess all of these qualifications to a high degree? If not, is this possible for the engineer of tomorrow? Should the engineer of tomorrow be controlled by 4 fundamental ideals—co-operation, consideration of others, service, and accomplishment?

For more than 50 years, the American Institute of Electrical Engineers has represented professionally the electrical engineers of America, led by such distinguished engineers as Doctor Elihu Thomson, Doctor Edward Weston, and Doctor E. B. Meyer, all of whom have been lost to us during the past year. Their enthusiasm, their cheerful optimism, their breadth of vision, their indomitable spirit, their engineering ability, form a pattern which the engineer of tomorrow well may emulate. As the engineer of tomorrow learns from, and endeavors to improve upon, the engineer of yesterday, so should the Institute profit by the past and fully meet its opportunity and responsibility in representing the electrical profession in the future. To me it seems that our organization should not be static. As the profession grows and changes, it should grow and change, ever keeping in mind its fundamental purpose. Fine as the record has been in presenting, discussing, and recording technical progress; in developing standardization; in fostering and sponsoring engineering education in co-operation with all other agencies; in working with other engineering societies to develop professional ethics and a sense of professional responsibility; in encouraging acquaintance, and providing opportunity for developing the social instinct, is not still greater achievement possible?

Among the national societies and between the national and local societies, a still closer co-operation is needed. Many of their problems and interests are diverse. Many are closely allied. Their most fundamental purpose—service to the profession and to humanity—is identical. Their work should be further co-ordinated; duplication and conflict should be eliminated, each supplementing the others.

Is it not possible to make the Institute more representative of the whole profession? Cannot the organization develop a still finer program, interesting many who are

not now interested? For example, should there not be more papers and articles recording experience, which would appeal particularly to the many electrical engineers who use electric power and electrical equipment but are not connected with the manufacture of either—papers that would relate to electrical applications in the textile, the automobile, the oil, the chemical, the mining, and other industries? Might there not be an increased consideration of the problems of the profession, such as registration, and an endeavor even more actively to study and assist in their solution? Can there be a movement toward providing meetings and presenting information to those associated with the electrical industry but not eligible for membership in the Institute? Is all possible being done to encourage and develop the young men in the technical schools?

I suggest one additional committee, a committee to investigate, review, and plan for "the future of the AIEE." Their deliberations should consider the next 5, 10, and even 25 years. Would we, today, be satisfied with the Institute as it was in 1912? Will the members in 1962 be content with the 1937 model? Is it not in accordance with the "engineering method" not to accept things as they are if improvement is possible, but to make no change unless improvement is probable? I further suggest that this proposed committee particularly plan for activity in those fields where there is the greatest need, even though not the greatest interest.

# The Engineer's Responsibility to Society

## A student speaks his mind on a subject of importance to engineers

By CHAS. W. BLAKER
ENROLLED STUDENT AIEE

OF ALL the definitions of engineering that have been propounded, the one that seems to express most clearly and accurately the true function of the engineer is found in the preamble to the constitution of American Engineering Council. In that document engineering is defined as the "science of controlling the forces and utilizing the materials of nature for the benefit of man, and the art of organizing and directing human activities in connection therewith."

Engineering is, indeed, a science. Without the least fear of successful contradiction, engineering might be called the oldest of the sciences. Far back in the gray dawn of civilization were heard the first awakenings of the engineering consciousness. The savage who first learned to utilize the energy of a distorted elastic system in the contrivance of the bow and arrow was an engineer. The primordial man who recognized the power of fire as a protective agent against the prowling terrors of the night was an engineer as truly as any graduate of our foremost technical institutions of today. In the field of science, then, is to be found the generally accepted work of the engineer. Yet, in accord with the definition quoted, scientific application of the laws of nature covers only part of the field of engineering. Associated with the profession there is also the *art* of organizing and directing human activities. Any ordinary layman, if asked to give his interpretation of the term engineering, would no more think of social organization than he would of music. Many engineers even have no awareness of the art involved in their profession. Yet that engineering does involve, inherently, the art of directing human activities in connection with the scientific utilization of natural resources, is a fact that upon a little consideration must be accepted by even the most ardently technical man. That the duty of the engineer to society extends specifically into this field of organization must be apparent to all. The engineer can no more expect the products of his work to be used intelligently by uninitiated society than could a child be expected to use matches and debris for anything other than a harmful conflagration. Yet engineers, as a profession, have been consistently neglecting this most important side of their work, thus making possible the international conflagration of the years 1914 to 1918. This is discussed more in detail later in this article.

If the engineer is to concern himself with society, what is he to understand in the term? It has had many interpretations in the past, but the one that seems to explain it most clearly is the simple term humanity, or human activity, as mentioned in the AEC definition of engineering quoted previously. The engineer's responsibility to society is a humanistic one, involving the understanding of humanity and its individual personal problems as well as an understanding of the scientific problem and its stereotyped solution. It is necessary for the professional man to remember that, before any contemplation of engineering as a profession occupied his mind, he was an individual in a society of individuals; and that, as a matter of course, his duty is first to humanity and next to his

A paper presented at a conference of the AIEE Branches at the University of Pittsburgh, Carnegie Institute of Technology, and University of West Virginia, held at Pittsburgh, Pa., January 12, 1937.

CHAS. W. BLAKER is a student in electrical engineering at the University of Pittsburgh, Pittsburgh, Pa.

profession. One might say of engineering, as Lincoln said of government, that in order to survive it must be a profession for, by, and of the people; otherwise it must pass in the manner of governments and institutions from the beginning of time that have violated that simple code.

In a broad sense, the responsibility of the engineer to society may be divided into 3 major branches: (1) conservation, (2) production, and (3) distribution. In the last few years, there has been much publicity concerning the conservation problem. The public has been dosed quite efficiently with conservation propaganda; to such an extent has this been carried out that public sentiment has turned conservation conscious, with the result that much work that is good has been accomplished. Yet much of this fervor is but a transient emotion, engendered by a mild hysteria. Hence, it can but pass, leaving a most incomplete work in its wake, for pure sentiment, though a most potent force in mob psychology, is not sufficiently stable to form a basis upon which may be built the superstructure of any enduring principle. If conservation is a necessity, and in our present condition of envisaged power shortage it certainly is, the engineer should carry out a program of public education that will acquaint the public, in general, with the tremendous scope and importance of the problem.

In contrast to the problem of conservation, that formed by production is of a secondary type, being a problem not in the actual processes of production, but in the complications created by our system of mass production and intense specialization. The production lines in our large automobile factories are typical of the type of production wherein the individual consciousness is submerged in that of the entire group. The conditions of our mines and factories are all pregnant with social problems—with living-together implications, as one writer has called them. It is to the engineer that the people must look for the continuation of their individuality in the maze of industrial unification and the amalgamation of humanity.

Of the 3 problems, conservation, production, and distribution, the last is perhaps the most widely publicized, not only in the United States, but throughout the world. It has become an international problem, the solution of which will involve an eruption and disturbance of all existing principles. This disturbance will involve not a change or revolution in that sense, but an upheaval and purging of existing principles—this rather than radical change because there appears to be no other working economic system wherein the individual is permitted to retain his individuality and is as well rewarded, materially, for individual achievement as in the system under which we in the United States of America live. Every economic system has its faults; but the faults inherent in capitalism, in comparison with those of other working systems are small indeed from a humanistic viewpoint. By that I have no intention of implying that capitalism is nearly fault-free; it is far from that. However, in relation to other economic systems its defects are minor. In the purging mentioned, probably the evils that will be given the most careful attention are those accompanying idle and unmerited wealth. With the disappearance of that type of wealth-holder, and the removal of profit from war, the government will have made a definite advance toward the era of social readjustment and capitalism will be enabled to assume the position it merits. As a clear and analytic thinker is needed, who can be better qualified than the engineer to handle the remedial measures; who more naturally should handle them than the one whose works have created situations necessitating those remedies?

All the foregoing discussion might be condensed into a series of 4 "shifts in the social consciousness" for which the engineer might be proved responsible:

1. Shift from individualism to interdependence.
2. Shift from competition to co-operation.
3. Shift from scarcity to plenty with the accompanying living-together implications of industrialized society.
4. Shift from stressing rights to stressing duties.

A sincere consideration of these shifts will clarify the responsible position of the engineer in connection with the problems he has created.

Last of all to be discussed is that scourge of mankind—War. Not long ago a well-known speaker in Pittsburgh placed the responsibility for the Great War at the feet of the engineer. That is a most startling and grave accusation, the most appalling thing about it being its partial truth. None can deny that war would be impossible were all engineers to decree that it should be made so, for with the engineer lies the power to halt the advancing tide of destruction that threatens to tear apart the familiar structures of civilization. The insupportable horrors of warfare as it is made possible by engineering developments form one of the few immanent causes for the failure of engineering as mentioned earlier in this article. True, he who wages a battle against the protagonists of war fights no puny skirmish, for against his calculation and powers for analytic thinking lies the weight of money, that magic talisman used to open the doors to the material forces of the world. It will be a battle requiring men.

In closing, a few commonplace remedial measures are outlined, in a study of which the engineer might well profit:

1. Legislation for remedy of existing ills.
2. Thoughtful study of governmental alteration without disturbing the fundamentally sound principles of good government.
3. Profit removal from war.
4. Sensible and equitable distribution of national wealth.

Let engineers interest themselves in something outside their narrow technical field for a time—something outside the bounds of science—and become human and humanitarian, for it is only in such an interest that they can possibly find the solution to the myriad problems of adjustment and reparation awaiting them. In the words of Doctor W. F. Durand, president of the Third World Power Conference, held in Washington, D. C., last year: "What we are urging is a quickened sense, on the part of the engineer, of his responsibilities, not alone in a purely professional sense, but as a citizen of his community . . . of the world."

# An Experiment in the Recognition of Engineers

By ROGER I. WILKINSON
ASSOCIATE AIEE

**Recognition of outstanding young American electrical engineers by Eta Kappa Nu, honorary electrical engineering society, began with the presentation of awards for 1936. The society expects its plan of annual awards to incite a fuller and broader professional development of young electrical engineers. Statistics for the men nominated for the 1936 awards are presented and discussed in this article.**

IMPLICIT in American democracy is the idea that those who accept and discharge the greatest responsibilities, and those who contribute the most exceptional discoveries and inventions, shall be accorded the highest positions in the respect of their fellow citizens. Practically the only restriction placed on a man's activities is that his endeavors should be oriented in accord with mankind's persistent struggles to attain certain inalienable rights. The greatest of these is that he should one way or another forward the general opportunity for the pursuit of happiness. His own reward is presumed to follow axiomatically.

As with all pure theories, because of certain causes not being comprehended exactly, and of fortuitous circumstances, the practical application rarely works out precisely as predicted. Thus it was that the honorary electrical engineering society, Eta Kappa Nu, proposed to lend whatever weight it might to a more perfect operation of the American "democratic theory," at least as far as electrical engineers were concerned. In its establishment in 1936 of the Eta Kappa Nu Recognition of Outstanding Young Electrical Engineers, then, it is not surprising that the preamble to the conditions of award should state that, "As evidenced by their past records and future promise, this recognition shall be given annually to young electrical engineering graduates, for *meritorious service in the interests of their fellow men.*" In addition to more nearly assuring that due and appropriate recognitions accrue to outstanding young engineers, the award plan hoped to attain 2 other ends, scarcely less important: (1) to give to the engineering profession concrete examples of what young men under 35 years of age and not more than 10 years out of college can be expected to achieve, and (2) to inspire by these young men's careers, and to furnish guides for, undergraduates and new engineering graduates to take up their own professional development as soon as possible.

Very naturally, a broad range of accomplishments from scientific research to civic and political activity and artistic creation is recognized, so as to encourage young engineers to obtain a truly liberal and humanistic perspective at an early point in their careers. Figure 1 shows the contents of the questionnaire which each outstanding young electrical engineer nominated was asked to return. It will give an idea of the breadth of interests which Eta Kappa Nu feels that an engineer who takes full advantage of his academic and postacademic training might well acquire.

Nominations for the 1936 recognition to the number of 47 were received from all of the groups of persons eligible to propose candidates. The distribution of nominators is shown in table I. It is interesting to note that nominations came from 21 different states of the union, being as widely distributed as Vermont and New Hampshire, Florida, Texas, California, and Oregon, about half lying west of the Mississippi. Because of the preponderant number of nominations by heads of electrical engineering departments, there is a close correlation between the schools attended by the nominees and the states from which the nominations came. The present locations of these 47 accomplished young engineers are, of course, less widely distributed due to the concentration of electrical engineers in the areas of denser population. Quite naturally New Jersey, Pennsylvania, and New York each have over twice as many as any of the other 13 states of business, claiming 6, 9, and 10, respectively. The general types of work and industries in which they are engaged are shown in table II.

Table III gives the distribution of years by which the nominees received their baccalaureate degrees in electrical engineering, and their ages on April 1, 1936. Due to a possible misinterpretation of the wording of the 1936 regulations, the one case of a candidate being 35 years old, that is *over* 35, was not thrown out. In the future, however, only those *less* than 35 years of age will be considered to be eligible. The expected tendency for substantial achievement to be attained as an engineer grows more experienced is well borne out by the heavier concentration of nominees in the 1926 and 1927 graduation years and in the 30 to 34 age classifications.

Written especially for ELECTRICAL ENGINEERING.

ROGER I. WILKINSON is a member of the technical staff of Bell Telephone Laboratories, Inc., New York, N. Y., and is chairman of the award organization committee of Eta Kappa Nu Association.

## Record of Achievement

Date.....

To the Secretary, Jury of Award
Dear Sir:

The answers to the questions below give, to the best of my knowledge, a factual record of my work and activities since graduation from college.

### I. General Information

*a.* Name.....

*b.* Date of birth.....*c.* Place of birth.....

*d.* Home address.....

*e.* Business address.....

*f.* College granting your baccalaureate degree.....

*g.* Particular years attended and year graduated.....

*h.* Average grade attained in undergraduate work.....%.....

*i.* Social fraternity and honor societies of which you are a member.....

*j.* Married?.....Date.....Children and ages.....

*k.* Do you rent or own your own home?.....

*l.* Attach in the space below a small photograph or snapshot of yourself.

### II. "On the Job" Record

*a.* By what companies or institutions have you been employed and in what capacities since graduation? Salaries at start and finish of each?

*b.* What papers have you published as a result of your everyday work, or allied work? (Attach copies if possible.)

*c.* What new and important facts have you discovered?

*d.* What new machines, methods, theories have you devised? Patents?

*e.* What application of engineering principles have you made to industrial and business planning or organization?

*f.* What application of engineering principles have you made to civic problems?

*g.* What have you done in the instructional field?

*h.* Have you taken any advanced scientific or professional engineering degrees?

*i.* What other accomplishments in your job?

### III. Record of Activities in Behalf of the Community, State, and Nation

*a.* What philanthropic work have you actively engaged in?

*b.* What have you done for the church?

*c.* Have you led or assisted in boy scout, Y.M.C.A., or other young peoples' organizations?

*d.* What municipal, state, or other political or social volunteer boards have you served upon?

*e.* How have you helped further adult education in the community?

*f.* What have you done to make the depression less heavy for others?

*g.* Have you actively supported any candidates in political campaigns?

*h.* Have you ever run for political office yourself?

*i.* In what way do you think your work under II has added, or will add, to the comfort or happiness of mankind?

### IV. Cultural and Aesthetic Development

*a.* What general (nonengineering) articles or reviews have you written?

*b.* Since graduation have you attended courses in history, sociology, economics, psychology, to increase your understanding of the social order, and what can be done about it? Additional degrees received?

*c.* Have you studied one of the fine arts, or attended courses in art appreciation? Degrees or honors received?

*b.* Have you participated in literary, dramatic, musical, painting, or other fine arts creation? What evidences?

*e.* Have you made outstanding architectural contributions, or achieved noteworthy results in industrial design or decoration?

*f.* Have you assisted and encouraged others in developing their cultural potentialities?

*g.* What books have you read in the last 5 years?

### V. Other Accomplishments

*a.* Have you a hobby? What have you done with it?

*b.* Do you have any athletic distinctions?

*c.* What other advanced study have you taken up? Physics? Chemistry? Law? Philosophy? Astronomy? Religion?

*d.* What engineering societies do you belong to? Offices held?

*e.* What other organizations do you belong to? Offices held?

*f.* What else do you do in your spare time?

*g.* Describe any other accomplishments or honors received.

* * * * *

In addition I refer the jury of selection to the following persons (not less than 3 nor more than 5) who are intimately acquainted with my work and activities. (Please note affiliation, if any, with each person.)

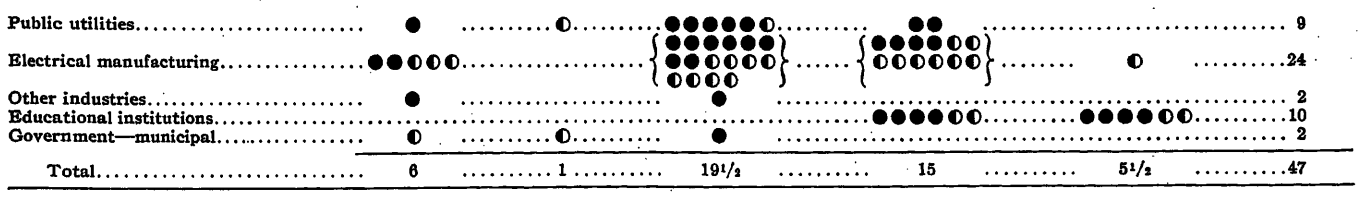
Signed.....

**Figure 1. Questionnaire sent to nominees**

At the award dinner given in New York during the winter convention of the AIEE in January 1937, remark was made that the names of the men receiving the award and the 4 honorable mentions hardly sounded like the "Smiths and the Joneses" commonly associated with American progress. The future only can tell whether the ratio will be maintained which resulted in 1936, when of 4 foreign-born nominees 2 were chosen for honors, while only 3 were similarly selected from 43 American-born candidates! It should be stated here, perhaps, that of the remaining men (whose names have not been published) there was a quite sufficient number of "common" names to gratify even the most nationally minded critic.

Further consideration of vital statistics reveals that 70 per cent of the nominees were married, and of these 2 men out of 3 already have one or more children. Relatively few, however, have attained that state of financial security where they own their own home.

The salaries of these men have apparently been very markedly influenced by the depression. The median annual salary by number of years after graduation is shown in table IV. In figure 2 these salaries have been superposed on the curves determined in 4 salary surveys of electrical engineers made in the period from 1923 to 1930. Two were studies by Eta Kappa Nu on its own alumni,[1] the third by the Society for the Promotion of Engineering Education in 1924 on all electrical engineering graduates,[2] and the fourth from a survey in 1928 of graduates of land-grant colleges made by the United States Office of Education.[3]



Other things being equal, one would feel justified in expecting that these exceptional young engineers would equal if not exceed the median salaries of the corresponding Eta Kappa Nu alumni. The recent financial unpleasant-

1. Results of the 1923 study appear in *The Bridge of Eta Kappa Nu* for November 1923, and January and May 1924. Note that averages, *not* medians, were used here. The 1930 study is summarized in "Comparison of Engineers' Salaries in 5 Major Industries," by M. S. Mason and J. A. Umhoefer, *The Bridge*, February 1931; a similar summary by the same authors appears in the *Proceedings* of SPEE, volume 39, 1931, pages 723–39.

2. The SPEE study on electrical engineers was published as Bulletin No. 8 of the Investigation of Engineering Education, volume I, pages 368–87. Also, in *The Bridge* for May 1926, H. P. Hammond compares the SPEE and the HKN 1923 salary results in "The Contributions of Eta Kappa Nu to the Investigation of Engineering Education."

3. "Engineering Graduates of Land Grant Colleges and Universities," by D. S. Bridgman, SPEE *Proceedings*, volume 39, 1931, pages 861–8, sets forth the data collected by the United States Office of Education in 1928 on electrical engineering graduates from 4 typical land-grant institutions.

## Table II. Distribution by Types of Work and Industries

| Type of Industry | Type of Work: Administration | Operating | Engineering Development | Research | Instructing | Total |
|---|---|---|---|---|---|---|
| Public utilities | ● | ◐ | ●●●●◐ | ●● | | 9 |
| Electrical manufacturing | ●●◐◐ | | ●●●●●●●●●●◐◐◐◐ | ●●●●◐◐◐◐◐◐ | ◐ | 24 |
| Other industries | ● | | ● | | | 2 |
| Educational institutions | | | | ●●●●◐◐ | ●●●●◐◐ | 10 |
| Government—municipal | ◐ | ◐ | ● | | | 2 |
| Total | 6 | 1 | 19½ | 15 | 5½ | 47 |

● Full time ◐ Part time (assumed half time)

ness, however, has seemingly delayed progress of these engineers, taken as a group, from 2 to 3 years. Somewhat more difficult to explain is the fact that the median of 32 of their starting salaries (nearly all prior to 1929) is only $1,287, lower indeed than those of any of the other studies on figure 2. A partial explanation may be found in the fact that such a preponderant number of the nominees went initially with large electrical manufacturing concerns (see table II). The 1930 Eta Kappa Nu salary study showed this group as receiving the lowest starting salaries, although 10 years later they had caught up with the general average, and thereafter exceeded it.

The problem of evaluating the achievements of so many engineers with such varied interests and activities caused the award organization committee much thought and reflection. The solution seemed to lie somewhere between a consideration of what engineers had probably done and what more they might be doing. After about a year was spent in discussing this basis with numerous leading educators and engineering executives who expressed a considerable interest in the idea, it was finally decided to inaugurate the plan giving a certain weight to nearly every activity a man might have engaged in under the following headings:

(*a*) His achievements of note in his chosen work.
(*b*) What he has done for his community, state or nation.
(*c*) How he has shown his cultural or aesthetic development.
(*d*) His activities in technical societies, and miscellaneous accomplishments, such as athletics, special honors, etc.

The exact weights which were placed on these categories were not decided upon until after reviewing a considerable number of nominees' records, because it was difficult to predict to what extent a group of young engineers might have participated in these various directions. The final weighting suggested by the award organization committee* and accepted for use by the final jury of award was

(*a*)—5 (*b*)—2 (*c*)—1 (*d*)—2

A very careful summary of each man's accomplishment was first made by 2 Eta Kappa Nu committees, and the engineers placed in 3 groups, called *A*, *B*, and *C*, in order to lighten the labor of the jury of award.** Each member of the jury reviewed carefully every one of the 25 nominees who had been placed in the *A* division, while at least one member reported on each of the nominees in the *B* and *C* divisions. Then a comparison of scores rather quickly brought the list down to a relatively small number of eligibles for the recognition honor. After considerable discussion and comparison, the jury selected Frank M. Starr (A'30, University of Colorado, '28) of the General Electric Company at Schenectady, N. Y., to be the first recipient of the Eta Kappa Nu Recognition for Outstanding Young Electrical Engineers. Awards of honorable mention also were given to P. L. Bellaschi (A'29, M'34), E. W. Boehne (A'29), A. C. Seletzky (A'29, M'35), and C. G. Veinott (A'28, M'34).†

Since not all nominees were rated by all members of the jury, it is not practicable to summarize statistically their conclusions—even were it desirable to do so. However, prior to the final jury selections, a fairly detailed analysis of all candidates was made by a committee of Eta Kappa Nu engineers actively interested in the recognition plan, the results of which later tallied very closely with the selections made by the jury of award. A portion of this study covering the 43 of the 47 who returned questionnaires and on whom sufficient information was known for forming relatively reliable ratings is shown in table V. These results, although perhaps not bearing too close analysis quantitatively, are nevertheless thought to be sufficiently revealing qualitatively to indicate quite clearly

## Table III. Age and Year of Graduation

| Age | Year of Graduation (Bachelor of Science Degree): 1926 | 1927 | 1928 | 1929 | 1930 | 1931 | 1934 | Total |
|---|---|---|---|---|---|---|---|---|
| 26 | | | | | 1 | | 1 | 2 |
| 27 | | | | | | 1 | | 1 |
| 28 | | | 1 | 1 | | | | 2 |
| 29 | 1* | | 3 | | 2 | | | 6 |
| 30 | 2 | 4 | 1 | 1 | | | | 8 |
| 31 | 4 | 1 | 1 | | | | | 6 |
| 32 | 4 | 2 | 1 | | 1 | | | 8 |
| 33 | 4 | 3 | | 1 | | | | 8 |
| 34 | 3 | 1 | | | | | | 4 |
| 35 | | 1 | | | | | | 1 |
| Unknown | | | | 1 | | | | 1 |
| Total | 18 | 12 | 7 | 4 | 4 | 1 | 1 | 47 |

* Class of 1926; did not graduate.

* The president of Eta Kappa Nu in the fall of 1935 appointed an award organization committee of R. I. Wilkinson (A'35), *chairman*, O. W. Eshbach (A'17, M'30), E. S. Lee (A'20, F'30, director), H. H. Henline (A'19, M'26, national secretary), and C. A. Faust (A'35) to put the recognition plan into effect.

** The jury of award is appointed annually by the president of Eta Kappa Nu and consists of 2 present or past national officers of Eta Kappa Nu, and 3 or more prominent American educators or industrialists. For 1936 L. W. W. Morrow (A'18, F'25, director), C. A. Butcher (M'22), the late General R. I. Rees, and the late E. B. Meyer (A'05, F'27, past-president) were appointed to serve on the jury; E. S. Lee and R. I. Wilkinson filled the 2 appointments from Eta Kappa Nu ranks.

† Of these 5 men, only one attended a college with a chapter of Eta Kappa Nu; later one other became an associate member of the society.

## Table IV. Annual Salaries

| Number of Years After Graduation | Number of Cases | Annual Salaries in 1936 | | |
|---|---|---|---|---|
| | | Median | Lowest | Highest |
| 0* | 32* | 1,287* | 938* | 2,600* |
| 5 | 1 | 2,400 | | |
| 6 | 2 | 2,704 | | |
| 7 | 2 | 2,880 | | |
| 8 | 7 | 3,300 | 1,900 | 4,800 |
| 9 | 10 | 3,210 | 2,400 | 8,200 |
| 10 | 15 | 3,450 | 2,250 | 5,600 |

* These are starting salaries at whatever year of graduation.

certain characteristics of the most exceptional young American electrical engineers who could be discovered in 1936. It is believed that this is the first of this type of comprehensive study of engineers attempted in this country.

In the first place, it is clear from table V that the nominators selected their candidates mainly by their technical accomplishments. Since this category is given the weight of "5," such a basis of selection would seem to have considerable justification. In several instances, however, those with records of the very highest quality of research work or other scientific contributions ranked near the bottom of one or more of the other classifications, thus drastically bringing down their over-all ratings. The fact that only 11 tallies out of 129 under headings *b*, *c*, and *d* exceeded a "50" rating might mean that either the method of appraisal was too severe, or that the engineers had not entered to any extended degree on pursuits outside of their chosen lifetime occupations. Even in the former event, the wide dispersion of the rankings would indicate that many of these technically proficient engineers had not paid very particular attention to their full professional development.

Correlation studies on the association between the various groups of activities showed positive results in every instance.* Only really significant, however, were the *ac*, *bc*, *bd*, and *cd* coefficients of correlation, ranging from $r = 0.34$ to 0.49. That is to say, although those engineers who participated most extensively in civic and social affairs were but little more distinguished technically than those who did not, their concurrent cultural and miscellaneous outside activities were very much greater. It is a little surprising that degree of technical accomplishment and cultural development (*ac*) should be found so strongly associated while no similar connection was noted between, for instance, technical accomplishment and civic and social work or miscellaneous activities. A most tentative hypothesis which might be advanced to comprehend these observed relationships is that a considerable block of the men with the highest technical achievement had concentrated on their personal advancement and development to the neglect of assuming group responsibilities.

Some have argued that in the early years of his professional career an engineer is, and ought to be, too busy on his technical development to devote much of his energ to other activities. The present study of exception young engineers disputes such a view, indicating instea a slight superiority of technical achievement by those wit considerable extracurricular activity. Partial-correlatic studies also show for those engineers in the upper half ( the rankings for social and civic activity, a marked ass( ciation between technical achievement and cultural de velopment. Thus, as far as these facts go, they woul seem to suggest that exceptional performance in scientifi pursuits need not at all preclude a paralleling develop ment along social and cultural lines.

Just such beliefs that an engineer's "service to mankin( is manifested not only by achievements in purely tech nical pursuits but in a variety of other ways," and tha "an education based upon the acquisition of technica knowledge and the development of logical methods o thinking should fit the engineer to achieve substantia success in many lines of endeavor," prompted Eta Kappa Nu to establish the recognition plan.

When it is considered, that, in the main, electrical engineers are working in large business organizations where their technical opportunities are largely prescribed by their immediate or distant superiors, the remaining activities in which a man engages, most of them voluntarily, are likely to be a considerably more accurate clue than his technical proficiency to his value as a citizen. Table V would seem to bolster the claim often heard these days that engineers have not yet gone very far as a professional group in engaging in more than their narrow technical pursuits.

For the purposes of the Eta Kappa Nu recognition, the rating plan was so devised that an engineer cannot be entirely one-sided and reach the top, nor hardly can he be a "jack of all trades and master of none." A study of the careers of the 5 men selected for honors in the first year of the award will quickly confirm the operation of this design. Biographies in some detail of these men appeared in the January 1937 issue of the Eta Kappa Nu *Bridge*, and somewhat briefer summaries covering their technical achievements were reported in the January 1937

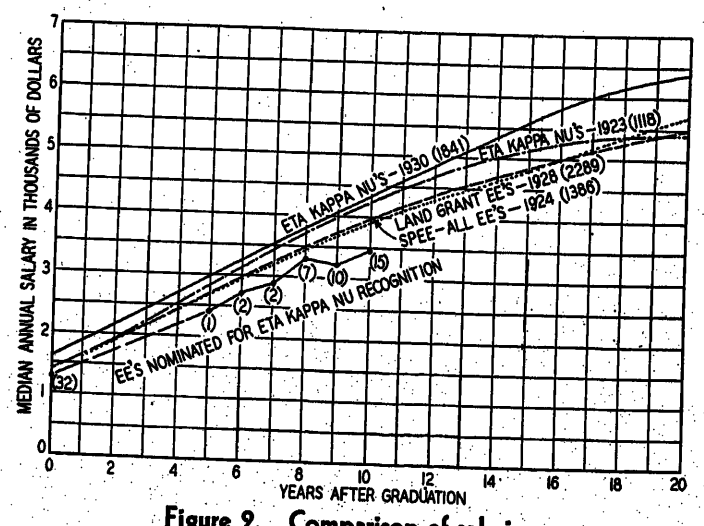


**Figure 2. Comparison of salaries**

Figures in parenthesis show number of returns

* Although the number of "observations" is only 43, still the fact that they are very homogeneous data seems to permit a certain amount of statistical analysis.

issue of ELECTRICAL ENGINEERING. The addresses made by these men at the award dinner, and which in the main gave their views on young engineers, their success and proper attitudes on life, appear in subsequent issues of the *Bridge*. The merest outline of the activities of Frank Starr, the 1936 recognition winner, will indicate the extent to which a young engineer may be expected to enter upon both technical and "extracurricular" work in his first 10 years after graduation:

(*a*) He is the author of 8 technical papers, several presented before AIEE conventions, principally on the theory and practice of electric power distribution. In 1932 he was awarded the Alfred Noble prize of the ASCE for his paper on "Equivalent Circuits." More recently he has been sent by the General Electric Company on a speaking tour of the country, touching practically every city of 100,000 population, discussing design problems with operating and engineering forces of power companies. His papers are used as texts in a number of engineering schools. He holds 2 patents on the control and protection of a-c network distribution systems, with others pending. He has been a lecturer in the advanced course of the General Electric Company for 6 years.

(*b*) He is a member of the Unitarian Church and the Schenectady Y.M.C.A., and has been active in boy-scout work.

(*c*) He has written a number of human interest articles and personal essays; since graduation he has attended classes in economics, psychology, sales analysis, and public speaking; he is an accomplished speaker; he has studied music and harmony, and is accumulating a sizable phonographic library of symphonic and operatic recordings. He is a member of the Schenectady Civic Players Association and has portrayed rôles in several of their amateur productions. He collects rare editions of books, and has read some 230 substantial books in the last 5 years. His main interest is in philosophy, and he follows a systematic reading plan.

(*d*) He is a member of the AIEE and Edison Golf Club, and is listed in "America's Young Men."

The winner of the Eta Kappa Nu recognition receives no monetary prize; presumably he has been successful

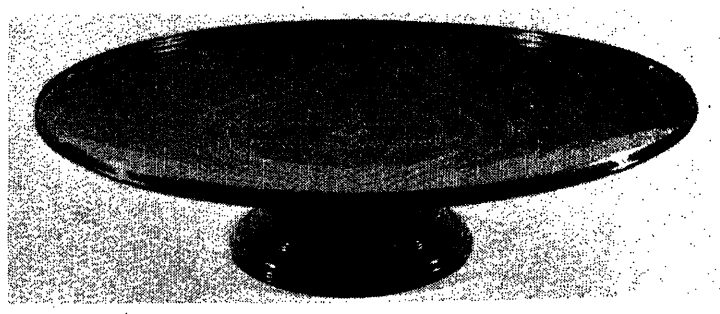

**Figure 3. The bowl for the recognition**

enough that he is hardly in any particular financial need. Rather it was believed that through the careful and scrupulous recognition of a closely limited number of candidates each year, the honor of being selected would be very great, and that as time proceeds its importance will be advanced by the illustrious records of past successful candidates. A large bronze bowl (figure 3) has been subscribed by some 30 Eta Kappa Nu alumni which will remain on permanent display in the AIEE headquarters in the Engineering Societies Building in New York, and each year will have added to its face the name of the recognition winner. The man, or men, so honored will also be presented with a smaller replica of the large bowl. Recipients of honorable mention are presented with a certificate appropriately naming their chief contributions to science and the humanities.

The future success of the Eta Kappa Nu recognition depends in no small measure on the continuing interest of engineering educators in nominating those young electrical engineers whom they believe to be outstanding. The possibility of doing some exceptionally talented young man a good turn, too, may conceivably persuade the faculties of some of our schools to follow more closely the progress of their graduates. It is apparent that in many instances this is being carefully done today; with the growing development of college personnel officers even closer contacts with the alumni may be expected to be maintained.

No less generous has been the response of the hundreds of business and engineering executives who were asked in the capacity of "references" to give their opinions of the qualifications of the nominees in the 4 major categories outlined hereinbefore. In numerous instances presidents and vice-presidents of the companies employing the nominees responded in considerable detail, often adding a personal word of recommendation. Whether or not he receives formal recognition from Eta Kappa Nu, any man nominated can hardly help but benefit from thus being advantageously called to the attention of those higher in his company or organization.

For 1937 the plan has been altered but very slightly. An interesting observation will be whether the scheme has to a detectable degree impelled any of the 1936 nominees who are still eligible for recognition (and are considered to be automatically renominated) to engage more widely in activities suggested by filling out the 1936 questionnaire. Such will be the severest test of the recognition plan.

# Industrial Unit Heaters Cool Transformers

By F. L. MOSER
MEMBER AIEE

H. B. WOLF
ASSOCIATE AIEE

**Unit heaters of the industrial type have been applied for external cooling of transformers and found to be especially useful as a substitute for the original water cooling system or as a supplement to the regular cooling system. Portable substations of smaller size and reduced weight were made possible by the use of these units.**

CHOICE of type of transformers, either self-cooled or water-cooled, in the design of a station is usually a matter of economics. In general, where transformers are small or where cooling water is not available, self-cooled transformers are used; where large transformers are required and water is available, water-cooled transformers are selected. Sometimes, however, conditions change through the years and it becomes desirable or necessary to change a water-cooled transformer to a self- or aircooled type.

Having in mind several stations on the Duke power system where cooling systems would soon require extensive replacement, company engineers made an effort in 1930 to apply external coolers to a transformer. A 1,000-kva 44-kv unit was selected and 2 automobile radiators were connected so that the oil would circulate through them from the top to the bottom of the transformer. Large fans forced air through the radiator fins. The results of this test were not encouraging; and from subsequent tests it was evident that the radiators were too small and that natural convection would not give rapid enough circulation through the radiators and piping.

In the latter part of 1933, the cooling coil in a 1,200-kw transformer at Gaston Shoals plant failed inside the tank. Ordinarily the repair or replacement of such a coil would be a minor job, but not so in this instance. This plant was erected about 1906, and was acquired by the Duke company in recent years. There were 9 1,200-kw transformers installed in a small room having thick stone walls and concrete roof. During the early existence of this plant, apprehension was felt that the transformers might be flooded during periods of high water, and therefore they were jacked up 8 feet and a concrete pier erected under each bank. This brought the tops of the transformers close to the 12-inch concrete roof. In these transformers the core and coil assembly and the cooling coils are suspended from the transformer covers. Therefore, to get at this particular cooling coil would require jacking 2 transformers off their piers and removing a portion of the station wall. It was decided to make an attempt to cool this transformer externally, this time using 2 industrial unit heaters as radiators. The particular units chosen were made of cast aluminum and had a fan mounted directly behind the radiating fins. The oil passed straight through the unit through rather large passages. A small pump circulated the oil from the top of the transformer through the coolers and into the bottom of the transformer tank, as shown in figure 1. Although these 2 units did not provide sufficient cooling to keep the temperature of the top oil within desired limits, the results were quite encouraging, so 2 additional unit heaters were obtained and installed, giving the desired results. This installation is shown in figure 2.

It was observed that with these 4 units in operation the fins of the radiators were cold; in other words, heat was not being transferred as rapidly from the oil to the metal of the radiator as from radiator to air. A study was then made of various types of available unit heaters, and one was found which had small copper tubes having a reverse bend. The intimate contact between oil and the walls of the small tubes, together with the comparatively long path obtained by means of the reverse bend, was believed to make a more efficient cooling unit for this application. One such unit was purchased and installed alongside the 4 cast-aluminum heaters, and on test it dissipated heat at approximately the same rate as the 4 cast-aluminum heaters combined. This test gave a

fairly accurate idea of the rate of heat dissipation for this unit. All 5 units have been in service since installation.

The next application of these external coolers was at the Greenville substation. Here, as the result of the combination of loss of efficiency of the cooling coils and severe operating conditions, 2 3,500-kva 100-kv transformers operated at unduly high temperatures. To supplement the existing cooling system, 2 coolers were installed on each transformer, together with a small oil-circulating pump for each pair of coolers. This installation gave entirely satisfactory results. A drop of approximately 15 degrees centigrade in the temperature of the top oil was obtained. On this installation a rate of oil circulation giving a drop of 5 degrees centigrade through the cooler with the top oil at 65 degrees and an ambient temperature of 30 degrees was determined upon. This gave good results and has been used on all subsequent installations.

At the Lakewood station, 12 4,000-kva 100-kv transformers are in service. These transformers, manufactured at the end of the World War when there was a shortage of copper, were equipped with iron cooling coils. That the cooling coils as well as other portions of the cooling system would soon have to be replaced was realized several years ago, and one suggestion was that the transformers be made self-cooled by the application of standard transformer radiators. However, when the manufacturers submitted a price of approximately $50,000, plus an estimated cost of $10,000 for installation expense, this idea was abandoned. In 1935, a test installation of unit coolers was made on 2 transformers, and complete and accurate data were obtained on cooling them without water in the cooling coils. These tests indicated that, with normal load, as shown by figure 6, 4 coolers per transformer would properly cool them; and it was further observed that spraying sufficient water on the radiator fins to keep them wet increased the rate of heat dissipation to such an extent that only 3 coolers per transformer would be required.

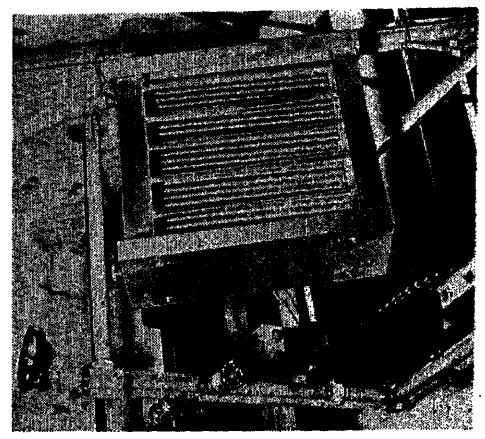

**Figure 5. Copper-tube cooler installed at Gaston Shoals for comparative test with cast - aluminum coolers**

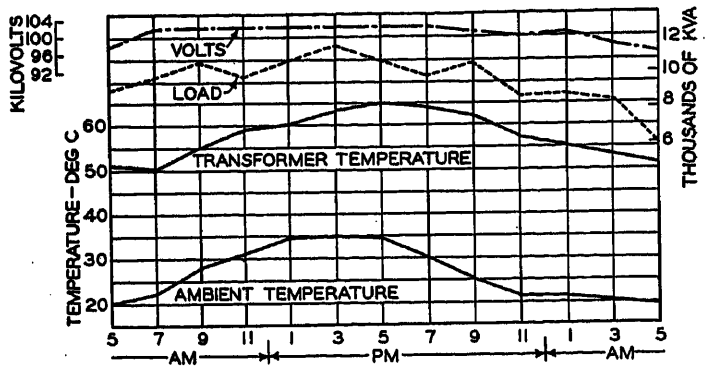

**Figure 6. Chart showing 24-hour test on 4,000-kva transformer, using 3 coolers and water spray**

Kilovolt-amperes in terms of load on bank of 3 transformers

Early in 1936, the cooling reservoir at this station was lost when the dam was washed away. The decision was then made that installing unit coolers on the transformers would cost less than rebuilding the dam. Three coolers per transformer were installed with provision for future installation of a fourth unit should it be found desirable. Two oil circulating pumps per transformer were used.

After the coolers were installed in 1936, various methods of spraying the cooling fins were tried and finally a hollow hub was installed on the fan shaft, which would throw the water radially between the fan and the radiator, and this was found to wet the radiator uniformly with a minimum wastage of water. These hubs were installed on all of the units and properly piped to the city water supply. This spray system gives a reserve to the cooling system which can be used in extremely hot weather or during periods of abnormal load on the transformers. The total cost of labor and material on this installation was under $10,000.

Recently, 3 transformers were moved from Lakewood and installed at China Grove. A fourth cooler was added on each transformer because no water is available at this station for spraying the fins.

Since the Lakewood installation was made, installations have been made on a 1,000-kva transformer to replace old radiators, on 3 1,000-kva transformers to replace

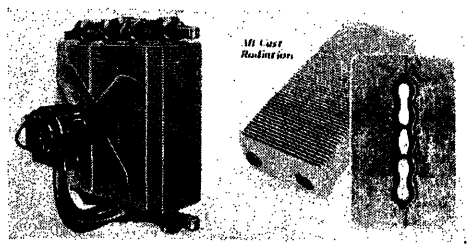

**Figure 3. Details of cast-aluminum coolers**

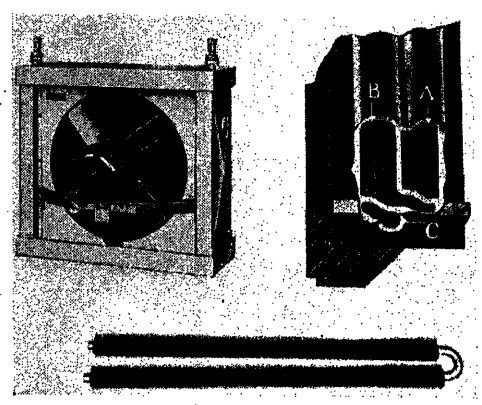

**Figure 4. Details of coolers having copper tubes with a reverse bend**

Figure 7. (left) Coolers at Lakewood station

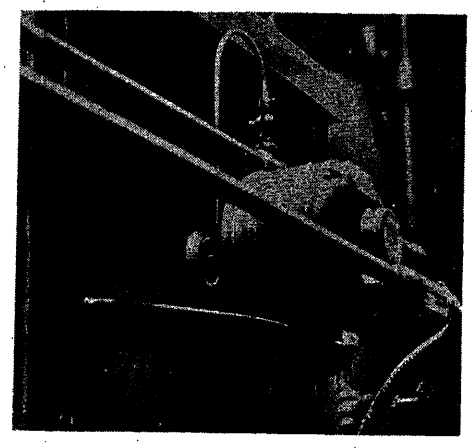

Figure 8. (right) Cooling unit equipped with spray hub

an old water cooling system, and on 3 more 3,500-kva transformers at Greenville to supplement the water cooling system.

A very interesting application is the recent furnishing of 2 1,320-kva portable substations, each equipped with 2 of these coolers by the transformer manufacturer. Not only are these transformer units more compact than those previously furnished, but they also weigh 2,000 pounds less, which is of considerable importance. The importance of keeping the weight of these portable transformers to a minimum can be appreciated when it is realized that these units, 6 in number, are used for backing over 380 banks of transformers having primary voltages of 44, 33, 22, or 13 kv, and secondary voltages of 13.2 kv, 6.6 kv, 2,400 volts, or 600 volts. Many of these are installed in substations located on very poor roads. It is interesting to note that a bank of 3 single-phase self-cooled 55-degree-centigrade transformers to give a capacity of 1,320 kva would weigh approximately 25,500 pounds. By the use of external fans, this weight might be reduced to approximately 21,100 pounds. A standard 3-phase transformer, complete with external fans, would weigh approximately 16,000 pounds. A special portable transformer with tubular radiators, built some time ago, weighs 15,000 pounds plus 6,400 pounds for the trailer, giving a total weight of 21,400 pounds.

The new portable transformer, shown in figure 10, equipped with unit coolers, weighs 13,000 pounds plus 3,000 pounds for the semitrailer, making a total weight of 16,000 pounds. This can be handled readily over almost any road.

The use of external coolers on transformers is not new, but the application of comparatively inexpensive commercial heating units as coolers seems to be an innovation. The principal use would appear to be the substitution in certain instances of this type of cooling for existing water cooling. It also provides a simple and inexpensive method of supplementing existing cooling systems. However, it would probably be wise to consult the transformer manufacturer before making a major change such as replacing an existing cooling system. On new transformers, the most obvious application is on those having space and weight limitations, and on those installed at points where water is not available.

The energy loss of this system is comparable to that of a water cooling system. It is evident that in many instances the first cost and maintenance will be less than with a water cooling system, particularly where reservoirs, cooling towers, or extensive piping systems would be required.

The authors have been informed that the manufacturer of this type of unit cooler, in co-operation with a large electrical manufacturer, has redesigned the unit, using nonrusting parts and improved joints, for this particular application.

# Heat Transfer Efficiency of Range Units

By W. JAMES WALSH
ENROLLED STUDENT AIEE

**Surface units of electric ranges have various efficiencies of heat transfer according to the design of the unit. Results of a study made with bright- and black-bottomed utensils are reported in this prize-winning student paper.**

THE SUPERIORITY of electric cookery from the standpoint of cleanliness, convenience, and safety has been generally well established. However, the economy of using electricity for cooking depends usually upon 2 factors: (1) the cost of electrical energy, and (2) the efficiency of the equipment employed in utilizing the electrical energy. The results of efficiency tests performed on the surface units of several late-model electric ranges reported in this paper clearly show that there is need for material improvement in the heat transfer efficiency of these units. Since electrical energy can be converted to heat energy with an efficiency of 100 per cent, it is obvious that efficiencies ranging between 50 and 68 per cent, the values found for modern units, are far too low.

The methods employed in determining the heat transfer efficiency of the several units, the results obtained, and several suggestions for possible improvement are presented in this paper.

## Selection of Units for Test

Since it was desired to conduct the proposed tests on the selected surface units with the units mounted in the ranges for which they had been designed and as they would be used in actual practice, it was decided to obtain 3 complete, late-model, electric ranges for which the popular demand had been greatest. When the selected ranges were delivered, it was found that but 4 of the 12 surface units furnished with the ranges were of the same wattage. Fortunately, however, 4 different types of surface units were exemplified by the 4 units having the same rating of 1,200 watts. It was therefore decided to perform the proposed tests on these 4 units. The units selected for test are shown in figure 1. For purposes of identification, the units have been labeled, as indicated in figure 1, *A*, *B*, *C*, and *D*, and will be referred to by these symbols.

## Measurement of Energy Input to Test Units

In any efficiency test, it is necessary to determine the energy input to the energy-converting device, and the corresponding energy output. In this case, determination of the energy input to the surface units under test, because of the ease and accuracy with which electrical energy may be measured, presented little difficulty, it being merely necessary to select a suitable type of watt-hour meter. The meter selected for use in these tests was a standard instrument of the rotating type commonly used in the calibration of ordinary watt-hour meters. Prior to its use in the tests, the rotating standard was checked for accuracy against a laboratory standard watt-meter and stop watch.

The heat energy equivalent of the electrical input to the units, in calories, is, of course, simply the number of revolutions completed by the disk of the rotating standard multiplied by a suitable constant. However, the standard watt-hour meter was so connected that it not only measured the energy input to the unit under test, but also measured the energy consumed in its own potential circuit and that consumed in the voltmeter employed in measuring the constant alternating voltage applied to the terminals

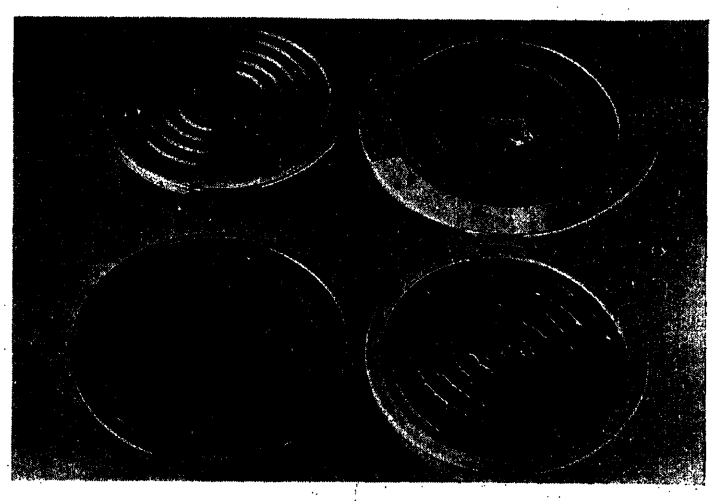

**Figure 1. Four types of 1,200-watt units tested**

Upper left—Unit *A* Upper right—Unit *B* Lower left—Unit *C* Lower right—Unit *D*

of the unit. The energy consumed in the potential circuit of the watt-hour meter was found to be negligible, but that consumed by the voltmeter was appreciable, so that a correction for it was deemed necessary. It may also be noted that the voltage applied to the units under test

A paper presented at a joint meeting of the Portland Section and the Oregon State College Branch, Corvallis, Ore., May 16, 1936, and subsequently awarded the Institute's 1936 Branch paper prize; recommended for publication by the AIEE committee on award of Institute prizes. Manuscript submitted February 15, 1937; released for publication June 10, 1937.

The author is indebted to the General Electric Company, the Westinghouse Electric & Manufacturing Company, and the Malleable Iron Range Company for the use of the electric ranges and elements studied in this investigation. Lee Bennett of the Mountain States Power Company was actively interested in the project and assisted in securing the equipment for test. The utensils used were furnished by the Aluminum Company of America. Much valuable assistance in conducting the tests was rendered by W. Arno Gish and Charles H. Butler. The author would also like to express his appreciation to Professor F. O. McMillan of the electrical engineering department of Oregon State College who suggested the subject and offered many valuable and helpful suggestions throughout the investigation.

was measured at the terminals of the units, so that no correction for losses occurring in the range wiring needed to be applied to the watt-hour meter reading.

The energy input to the unit under test at time $t$ seconds from the start of the test may then, taking into account the energy consumed by the voltmeter, be expressed as follows:

$$W_t = 860.4\left(K_h R - \frac{E^2 t}{3{,}600 r}\right) \qquad (1)$$

in which $W_t$ is the energy input to the unit in calories, $K_h$ is the disk constant of the watt-hour meter in watt-hours per revolution, $R$ is the number of revolutions completed by the disk of the watt-hour meter in the $t$ seconds which have elapsed since the start of the test, $E$ is the effective value of the alternating voltage maintained constantly at the terminals of the unit, $r$ is the resistance of the voltmeter in ohms, and $t$, as previously indicated, is the time in seconds which have elapsed since the test was started.

## Determination of Energy Transferred by Surface Units

While the determination of the energy input to the surface units was found to be a very simple matter, the measurement of the corresponding useful energy transferred by the unit was, in comparison at least, a much more difficult problem. Several methods of determining this essential quantity were considered. One of these entailed the use of a mass of some metal such as copper or iron with the use of thermocouples as the temperature-measuring device. It was decided, however, that the tests would be much more representative if a water-filled utensil of a type ordinarily used on the units in practice was employed. This further had the added value of presenting temperature differences between the unit and the substance being heated more commonly encountered in actual practice.

The suitability of several liquids other than water as the liquid to be heated was also investigated. The few

**Figure 2. Aluminum pans used in the tests**

liquids having suitable characteristics, however, either proved too costly, were not readily available, or information concerning the behavior of their specific heats over the temperature range to be covered was either very uncertain or apparently nonexistent.

Having decided that an ordinary kitchen utensil filled with water would be used as the receiver of the useful energy transferred by the units under test, there remained other items to be considered, such as the type of utensil to be used, and the means to be employed in measuring the temperature of the water. Since aluminum utensils have been widely used in recent years, 2 2-quart vessels of that material were selected. The 2 utensils selected were identical in size and shape, but the bottom of one had the usual bright finish, while that of the other was blackened with a lacquer-like material. The 2 pans are shown in figure 2 with handles removed as they were used in the tests. Another view of the same utensils showing the character of their bottoms is shown in figure 3.

Several factors other than their popularity were also instrumental in the selection of the aluminum utensils. In the first place, aluminum is a material of low specific heat and high heat conductivity, which means, as will develop later, a minimum of error in the computation of the energy transfer of the test units. In the second place, since the sides of the utensils are highly polished, radiation losses from the utensil will be a minimum, which also aids in reducing the error in the computation of the heat energy transferred by the units. Lastly, the aluminum utensils used were designed especially for electric range surface use.

One of the most important items in the determination of the heat transferred by the units is the method of measuring the temperature of the water contained in the aluminum vessels. Previous investigators have employed ordinary mercury-in-glass thermometers or thermocouples. Both of the latter methods give temperature indications at one or more points in the liquid dependent upon the number of

**Figure 3. Bottoms of pans, showing bright and black surfaces**

such instruments used. The temperature of the water in the vessel cannot be the same throughout its volume, because of the convection currents which are readily discernible in it. Therefore, a device capable of indicating an average of the temperatures existing throughout the volume of the water gives much more representative temperature values. It was therefore decided to construct a resistance thermometer with the resistance element spread out over a considerable cross section of the water volume. The resistance thermometer constructed is shown in figure 4. The light framework is of bakelite, and the resistance element is a number 40 American wire gauge nickel-alloy wire expressly made for the purpose. The fineness of the wire and its high resistance per unit length (16 ohms per foot) make it very sensitive to changes in temperature. Another desirable feature of the resistance thermometer is its extremely short time lag in comparison with the long time lag of a mercury-in-glass thermometer.

The resistance thermometer was calibrated with a mercury-in-glass thermometer by immersing both in a constantly stirred transil-oil bath, the temperature of which

was changed very slowly. Several points on the calibration curve obtained were checked by immersing the resistance thermometer in liquids, the boiling points of which were accurately known. It was found that the resistance of the thermometer was not a linear function of temperature, but followed a law of the form

$$\log r = a + bT$$

where $r$ is the resistance in ohms at the temperature $T$ degrees centigrade, and $a$ and $b$ are constants. In this case, $a$ had the value 2.162, and $b$ the value $9.92 \times 10^{-4}$.

By means of the resistance thermometer, it is possible to determine the temperature of the water at any time $t$ seconds from the start of the test, and, from the temperature measurements, the heat transferred from the unit to the utensil and water may be calculated by employing the following equation:

$$W_o = (w + c_{Al}w_{Al})(T_t - T_o) \qquad (2)$$

in which $W_o$ is the heat energy in calories transferred by the unit, $w$ is the weight of the water used in grams, $c_{Al}$ is the mean specific heat of aluminum in calories per gram per degree centigrade ($c_{Al} = 0.217$), $w_{Al}$ is the weight in grams of the aluminum pan used, $T_t$ is the temperature of the water in degrees centigrade at time $t$ seconds from the start of the test, and $T_o$ is the temperature of the water at the start of the test in degrees centigrade.

The specific heat of water departs so slightly from unity over the range from 20 to 100 degrees centigrade, the temperatures encountered in the tests, that it is impractical, in view of other limits of measurement, to consider it other than unity. The same statement may be applied to the specific heat of aluminum. It will further be noted from equation 2 that it is assumed that the aluminum pan experiences the same temperature change as the water. This, of course, is not strictly true, especially as regards the bottom of the pan. However, since the specific heat and weight of the aluminum pan are small compared to the corresponding values of the water used, and since the heat conductivity of aluminum is so very high, the error resulting from this assumption is negligibly small.

It will be noted further that equation 2 does not account for any heat transfer between unit and utensil represented by possible evaporation of water. This is permissible because special precautions were taken to greatly minimize evaporation. Normally, of course, the evaporation of water below the boiling point represents a heat transfer which is not negligible. The amount of heat transfer represented by evaporation at any particular temperature, however, is very difficult to determine because of the variation in the rate of evaporation and the heat of evaporation with temperature. It is, therefore, imperative that evaporation be reduced to a negligible quantity.

It was found possible to do this by forming a thin film of a low-vapor-pressure oil over the surface of the water just prior to starting the tests, and by halting the tests at temperatures slightly below the point at which violent ebullition of the water began to take place. The success of this method is attested by the fact that the upper portions of the temperature-time curves remained straight after its adoption, where previously they had tended to curve to the right due to the evaporation loss. The loss of water by evaporation was reduced from approximately 7 per cent to 0.5 per cent, which made the evaporation heat loss negligible up to the boiling point.

## Calculation of Efficiencies of Heat Transfer

The efficiency of any piece of apparatus is defined as the amount of energy delivered by the apparatus expressed as a percentage of the energy delivered to it. Since the necessary values of energy input to, and heat transfer from, the surface units tested have been determined, it is now possible to calculate an efficiency of heat transfer for the units. This value may quite obviously be obtained by dividing equation 1 into equation 2, and may be expressed as follows:

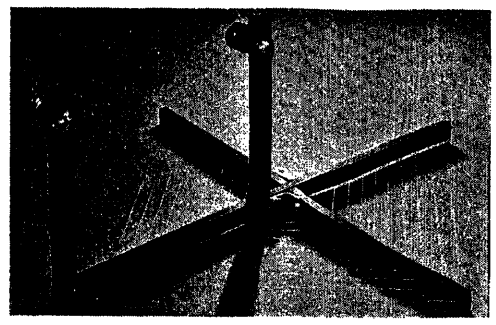

**Figure 4. Frame and wire for resistance thermometer**

$$\eta = 100\left(\frac{W_o}{W_t}\right) \qquad (3)$$

in which $\eta$ is the efficiency of heat transfer of the unit in per cent, $W_o$ is the heat energy transferred by the unit in calories up to, and including, the time $t$ seconds which have elapsed since the start of the test, and $W_t$ is the energy input to the unit in calories during the same time interval.

While the efficiency defined in equation 3 is important, because it is a direct measure of the amount of useful energy transferred by a given unit, it is taken over time intervals measured successively from the origin, and hence gives no clue as to the efficiency with which the unit is transferring heat energy to the utensil and water at any particular instant. The instantaneous efficiency of heat transfer may, however, be obtained by plotting energy output $W_o$ values against energy input $W_t$ values, and determining the slope at various points along the resulting curve. The values of elapsed time corresponding to the several slope values may be easily obtained by reference to a curve of elapsed time values plotted against corresponding energy input $W_t$ values. Mathematically, of course, the instantaneous efficiency may be indicated simply as follows:

$$\eta_t = 100\,\frac{dW_o}{dW_t} \qquad (4)$$

in which $\eta_t$ is the instantaneous efficiency of heat transfer in per cent.

Fundamentally, the instantaneous efficiency, $\eta_i$, is the quotient of 2 time rates, that is,

$$\eta_i = 100 \frac{\frac{dW_o}{dt}}{\frac{dW_i}{dt}} \qquad (5)$$

and when expressed as such is, perhaps, more capable of complete understanding. When expressed as indicated in equation 5, the instantaneous efficiency simply expresses the fact that the instantaneous rate at which useful energy is being transferred by a given surface unit is a certain percentage of the rate at which energy is being supplied to the unit.

The meaning of the 2 efficiencies defined by equations 3 and 4 may, perhaps, be made clearer by comparing them with the 2 efficiencies of, say, a power transformer. The efficiency defined by equation 3 is comparable with the over-all or all-day efficiency of the transformer, while that defined by equation 4 is comparable with the efficiency of the transformer at any particular load or instant during the day. Because of the similarity of the efficiency defined by equation 3 to the over-all or all-day efficiency of the transformer, it has been termed the over-all efficiency of the surface units, and will be referred to as such to distinguish it from the instantaneous efficiency.

## Experimental Procedure

The surface unit to be tested was in each case placed in the range for which it had been designed, connected as it would be in actual use, and the range then connected to a 3-wire a-c system, the voltage of which could be readily controlled. The instrument leads from the voltmeter and the potential circuit of the watt-hour meter were connected directly across the terminals of the test unit, so that the watt-hour meter readings would not include the losses occurring in the range wiring or the current circuit of the watt-hour meter.

In each case, rated voltage, that is, the value of rated voltage required to give rated wattage, was maintained constant at the terminals of the test unit. In order that the voltage at the terminals of the unit should be very close to its rated value at the instant the test unit circuit was closed, the voltage of the supply source was adjusted to a value slightly higher than the rated value previous to starting the test. The requisite supply voltage value was determined by previous experiment.

The following procedure was employed in determining the efficiency values for the 4 1,200-watt surface units tested. The identical procedure was used for all units with both bright- and black-bottomed aluminum pans.

The resistance thermometer was placed in the particular pan to be employed, and the utensil then placed upon one pan of a beam balance, and the combined weight noted. The usual amount of water, 1,250 grams, was then admitted to the utensil, care being taken to see that no drops of water were splashed on the exterior of the pan or the balance. Then, with the pan still upon the balance, a thin oil film was formed over the water surface by dropping a slight amount of apiezon oil on it from a dropper. The weight of the oil thus added was found to be insignificant. The utensil was then removed from the balance, and carefully centered over the particular unit to be tested. Connection of the resistance thermometer to a precision bridge was then made, after which the thermometer was carefully centered in the pan, and the bridge balanced. No lid was employed in any of the tests.

Then, with the bridge balanced, the supply circuit was closed on the test unit, not by means of the unit switch on the range, which was in all cases left on "high" during the tests, but by means of a knife switch in the supply lines. A stop watch was started at the instant the switch was

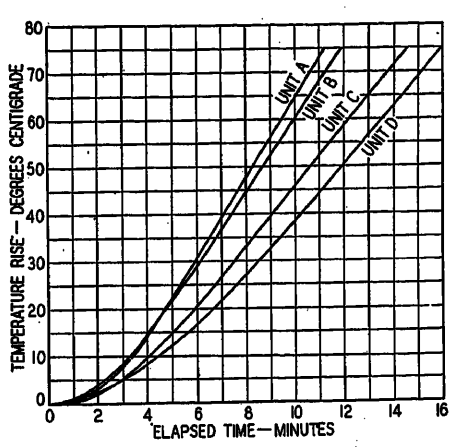

**Figure 5. Temperature rise of water in bright-bottomed aluminum pan placed upon several types of 1,200-watt electric-range surface units**

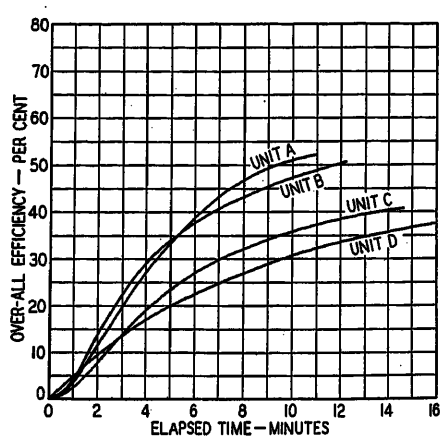

**Figure 6. Over-all efficiency of several types of 1,200-watt electric-range surface units when used with a bright-bottomed aluminum pan**

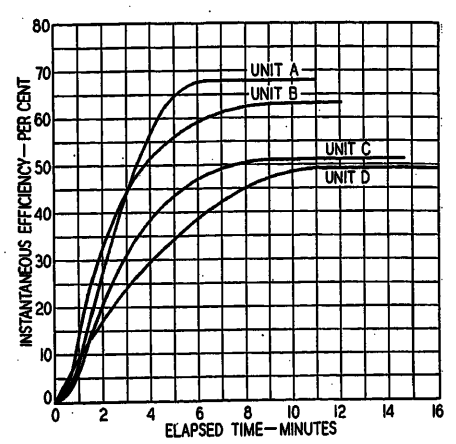

**Figure 7. Instantaneous efficiency of several types of 1,200-watt electric-range surface units when used with bright-bottomed aluminum pan**

Units at room temperature at start of test. Weight of water used, 1,250 grams (2.76 pounds); weight of pan, 418.8 grams (0.92 pound)

closed. Thereafter, at a signal from the observer operating the bridge, indicating that the bridge was in balance, simultaneous readings of elapsed time, revolutions of the watt-hour meter, and resistance of the resistance thermometer were noted and recorded.

Each test run was halted at a point slightly below the boiling point corresponding to barometric conditions prevailing at the time of the test. When the selected final temperature was reached, the test unit circuit was opened, the stop watch stopped, and the utensil removed from the unit. As soon as possible after removing the utensil from the unit, a well-fitting lid was placed on the utensil, and the utensil and contents weighed to determine what loss in weight, if any, had taken place. If an unusually large difference existed between the original and final weight values, the test was in all cases repeated until the difference was brought to within 0.5 per cent.

## Results

The results obtained from the data secured in the tests are presented in curve form in figures 5, 6, 7, 8, 9, and 10. Figures 5, 6, and 7, as indicated, are from data obtained on the test units using the bright-bottomed aluminum pan, while figures 8, 9, and 10 give corresponding values for the same units using the black-bottomed aluminum pan.

## Discussion of Results

An examination of figures 5 and 8 shows that the temperature rise of the water becomes a linear function of the elapsed time after a certain time interval. It follows, therefore, that the heat energy transferred by each unit also becomes a linear function of the elapsed time, and hence a linear function of the energy input to the heating unit, since the energy input is directly proportional to the elapsed time. Over the linear range, the heat energy, $W_o$, transferred by the unit may be expressed as follows:

$$W_o = cW_i - d \tag{6}$$

in which $c$ and $d$ are constants. If now both sides of equation 6 are divided by $W_i$, the following result is obtained:

$$W_o/W_i = c - d/W_i \tag{7}$$

The left-hand side of equation 7 will be immediately recognized as the over-all efficiency of the unit, $\eta$. Hence, equation 7 may be written,

$$\eta = c - d/W_i \tag{8}$$

Now, as time, and consequently $W_i$, increases, it is seen that the over-all efficiency approaches, as a limiting value, the constant $c$ in equation 8. Examination of figures 6 and 9 demonstrates that the over-all efficiency does tend to approach certain limiting values in both cases.

Now differentiate equation 6, obtaining the result,

$$dW_o/dW_i = c \tag{9}$$

The left-hand side of equation 9 is, of course, the instantaneous efficiency of the unit, $\eta_i$. Hence, over the linear portion of the curve,

$$\eta_i = c \tag{10}$$

and the instantaneous efficiency curves should become straight lines parallel to the time axis. Examination of figures 7 and 10 shows that such is the case.

The following deduction may now be drawn from a consideration of the preceding discussion and a critical examination of equations 8 and 10. When any of the surface units tested is used as previously indicated in this paper, the over-all efficiency of the unit approaches a limiting value which is identical with the maximum value attained by the instantaneous efficiency of the unit. The importance of the above statement may be made clearer by considering the fact that, under the condition stated, units

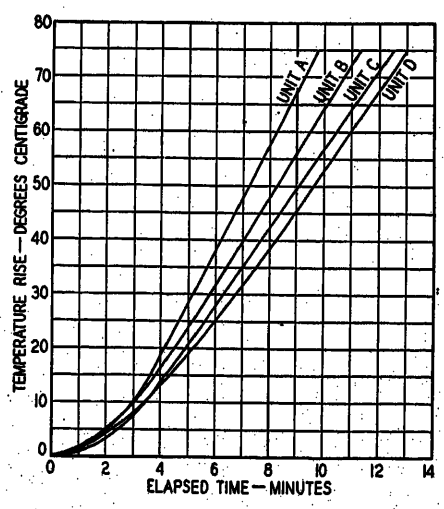

**Figure 8. Temperature rise of water in black-bottomed aluminum pan placed upon several types of 1,200-watt electric-range surface units**

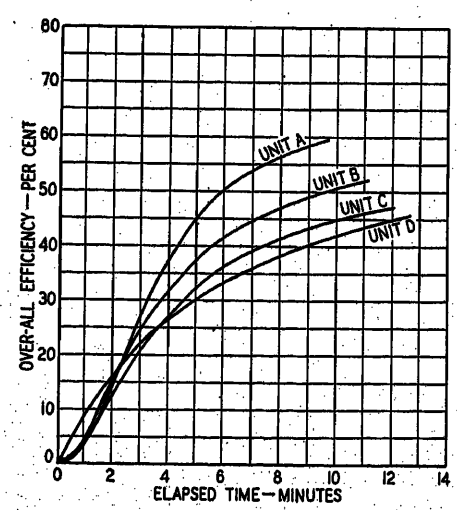

**Figure 9. Over-all efficiency of several types of 1,200-watt electric-range surface units when used with a black-bottomed aluminum pan**

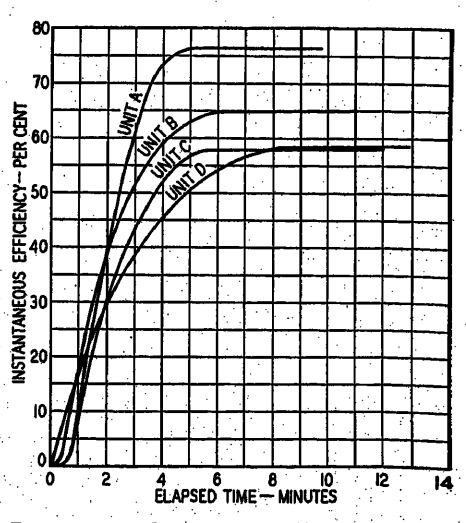

**Figure 10. Instantaneous efficiency of several types of 1,200-watt electric-range surface units when used with black-bottomed aluminum pan**

Units at room temperature at start of test. Weight of water used, 1,250 grams (2.76 pounds); weight of pan, 430.5 grams (0.95 pound)

such as $A$ and $B$ can never transfer more than approximately 65 per cent of the energy they consume, and units such as $C$ and $D$ can transfer only about 50 per cent of their energy input when, as is usually the case, bright-bottomed pans are used.

It may be seen from figure 10 that if a black-bottomed pan is used, approximately 76 per cent of the energy consumed by unit $A$ may possibly be realized. It may further be noted that but a small increase in the percentage of energy realizable is obtained by using the black-bottomed pan with such a unit as $B$. For units such as $C$ and $D$, it is seen, the percentage of consumed energy which may possibly be realized if the black-bottomed pan is used is approximately 58 per cent, which may be compared with the value of 50 per cent possible with the same units using the bright-bottomed pan. The magnitude of the increase in efficiency to be obtained by the use of a black-bottomed utensil is shown in table I.

As is to be expected, the open-coil type unit $D$ has the largest percentage increase in instantaneous efficiency. This is because this unit transfers heat chiefly by radiation, and the efficacy of the black-bottomed pan lies in the fact that a black surface is a more efficient absorber of radiant energy than other types of surfaces.

## Suggestions for Possible Improvement

*Unit A.* The already relatively high efficiency of this unit is due to the small amount of mass in the regions of high temperature, the use of a surface beneath the unit for reflecting the radiant energy directed downward by the unit, and the opportunity provided for air convection currents to pass easily from the lower surfaces of the heating elements to the bottom surface of the utensil. However, since this unit is constructed by spiraling lengths of circular tubing containing the heat-developing resistance, there is at best a series of line contacts between the heating element and the utensil. Irregularities in the units introduced by warping reduces the line contacts between unit and utensil to a series of point contacts, which permits but a very small amount of heat transfer by conduction to take place from the unit. The efficiency of this unit would undoubtedly be much improved if the upper surfaces of the heating element tubes were flattened, and if the tubes were so mounted that the flat surfaces would remain in the same plane. Some improvement in efficiency would also be expected if the reflector plate placed beneath the heating element was treated with a reflecting surface which would not be destroyed by the heat of the unit.

*Unit B.* This unit ranks second in efficiency, and is quite well designed for transferring heat to a utensil by thermal conduction. The surfaces of the heating elements are flat, and are rigidly supported to prevent warping. The mass of this unit could probably be reduced to some extent by a reduction in the size of the cast iron supporting structure, and the heat transfer efficiency of the unit improved by operating it at a higher temperature in order to obtain more heat transfer by radiation. The relatively small amount of heat transferred through the medium of radiation by this unit is shown by the fact that its instantaneous efficiency was increased but 2.8 per cent by using the black-bottomed utensil.

**Table I. Influence of Utensil Bottom Finish on Efficiency**

| Unit | Maximum Instantaneous Efficiency (Per Cent) | | Increase (Per Cent) |
|---|---|---|---|
| | Bright Bottom | Black Bottom | |
| *A* | 68.1 | 76.4 | 12.2 |
| *B* | 63.3 | 65.1 | 2.8 |
| *C* | 51.3 | 57.8 | 12.7 |
| *D* | 49.2 | 58.5 | 18.9 |

*Unit C.* The efficiency of this unit would undoubtedly be greatly improved if the surface it provides for the utensil to rest upon was flattened to increase the amount of heat transferred by conduction. As the unit is constructed at present, heat transfer from it to the utensil takes place largely through radiation as is shown by the 12.7 per cent increase in instantaneous efficiency secured by the use of the black-bottomed utensil. A reduction of the mass of material subjected to high temperatures would, no doubt, also improve the efficiency of the unit.

*Unit D.* The transfer of heat from this open-coil type of unit takes place almost exclusively through the medium of radiation. The character of the utensil bottom, therefore, has a marked influence on the efficiency of heat transfer of the unit. This is clearly shown by the 18.9 per cent increase in instantaneous efficiency secured through the use of the black-bottomed utensil. Not a great deal can be done to increase the efficiency of this type of unit through changes in construction, except, perhaps, changes in the form of the ceramic used to support the heating coils made possible by future research in the ceramics field.

## Conclusions

1. There is very definite need for marked improvement in the heat-transfer efficiency of electric range surface units.

2. When used under the conditions outlined in this paper, the efficiency of heat transfer of each unit approaches a limiting value which it cannot exceed.

3. A very definite increase in the limiting value of the heat-transfer efficiency of a given unit, used with a bright-bottomed pan, may be obtained by using a black-bottomed pan.

4. The percentage increase in efficiency obtained by employing a black-bottomed utensil is greatest for those units depending principally upon radiation as the medium of heat transfer.

5. The enclosed type of surface unit, in general, is superior to the open-coil type of unit.

# Present-Day and Probable Future Electrical Applications in Aircraft

By W. V. BOUGHTON

THE ELECTRICAL system plays a very important part in present-day airplanes. In addition to lighting the plane and starting the engines, it is required to furnish power for radio, instruments, landing gear, flaps, and remote operations. The fact that electrical operation leads to more convenient and often lighter installations makes it desirable to use it whenever applicable.

A description of the electrical installation in the Douglas sleeper transports appears to present the best way of explaining present-day electrical applications in aircraft.

The airplane is wired in 2 main feeder circuits with the intermittent and continuous loads so divided that the total drain on each circuit is approximately equal for a given period. This is approximately as follows:

CIRCUIT NUMBER 1

| | |
|---|---|
| Interior lights | 408 watts |
| Navigation and passing light | 48 watts |
| Deicers | 48 watts |
| Argon lights | 36 watts |
| Maximum continuous load | 540 watts |
| One landing light | 444 watts |
| Cigarette lighter | 60 watts |
| Seat belt signs | 25 watts |
| Maximum intermittant load | 529 watts |

CIRCUIT NUMBER 2

| | |
|---|---|
| Cockpit and instrument lights | 32 watts |
| Electrical instruments | 16 watts |
| Airspeed head heater | 75 watts |
| Landing gear signal lights | 13 watts |
| Radio receivers | 120 watts |
| Maximum continuous load | 256 watts |
| Landing gear warning horn | 60 watts |
| Fuel and oil-pressure warning lights | 13 watts |
| One landing light | 444 watts |
| Radio transmitter | 890 watts |
| Maximum intermittent load | 1,407 watts |

The initial load on starting is about 2,520 watts for each engine dropping almost immediately to about 1,935 watts. This is usually carried by the battery cart at the airport. Each circuit is supplied from a 12-volt 85-ampere-hour storage battery and a 50-ampere 14.5-volt constant-potential generator, driven by the airplane engines. In case of mechanical or electrical failure of one source of supply, either or both circuits can be switched to either battery and generator. A remote-controlled master switch enables the pilot to open the battery circuits instantly in an emergency and also to connect the airplane circuits to a receptacle in the side of the fuselage for plugging in a battery cart while at the air terminal. This permits the use of the electrical equipment in the plane before taking off, without running down the batteries. The entire system is single wire with the metal airplane structure as the return.

The batteries are located in the fuselage in tight compartments, the bottoms of which are platforms mounted on telescoping tubes. When these platforms are lowered the batteries can be placed on them from the outside of the airplane, and, when raised into place the batteries are automatically connected into the circuits by means of plug- and jack-type connectors. As it is possible to change them by this method in less than 3 minutes, no delay in the departure of the plane would be occasioned because of the necessity of installing a fully charged battery.

The main electrical distribution box is located adjacent to the batteries and contains the master switch, circuit-selector switches, generator-control boxes, starter relays, landing-light relays, meter shunts and resistors, and individual circuit fuses. These are readily accessible in the air or on the ground.

Located above the windshield in the pilot's cockpit are the various switches for lights, ignition, starting, airspeed head heater, seat belt warning signs, and the meters in the generator circuits. Below the windshield is the instrument panel with the navigation and engine instruments. On this panel are located the landing gear warning lights, the door-open warning light, the airspeed head heater warning light, the fuel- and oil-pressure warning lights, the co-pilot-to-stewardess call light and button, and a number of electrically operated instruments.

In large airplanes, the use of mechanical tachometers, capillary tube thermometers, and mechanical fuel-quantity gages is impractical. These instruments are electrically operated in the Douglas sleeper transports. The tachometers consist of small magneto generators mounted on and driven by the airplane engines. The voltage output varies directly with the speed and the indicators in the cockpit are calibrated to read directly in revolutions per minute. The electric thermometers which are used to measure the temperature of the incoming carburetor air and the incoming oil are of the resistance bridge type. The fuel-quantity gauges consist of potentiometers with the moving arms actuated by the tank floats and voltmeters calibrated in gallons to measure the voltage drop through the resistances.

The cockpit is lighted by small automotive-type instrument lamps and 2 small spot lights with universal mountings. In addition 2 argon lamps are located so as

A paper recommended for publication by the AIEE committee on transportation. Manuscript submitted February 24, 1936; released for publication June 25, 1937.

W. V. BOUGHTON is chief electrical engineer with the Douglas Aircraft Company, Inc., Santa Monica, Calif.

**Figure 1**

to provide ultraviolet fluorescent illumination of the instrument dials for night flying when general illumination in the cockpit would be undesirable. These argon lights are supplied by a small rotary converter delivering 110 volts. The degree of illumination from all cockpit lamps is controlled by rheostats.

The front passage to the cabin, the cabin itself, the dressing rooms, lavatories, and rear compartments are lighted by ceiling lights. In addition, there is a reading light by each seat, a reading light for each upper berth and provision for plugging in a table light in each section. Located near the aisle floor are small night lights for use after the passengers retire.

Each seat and each berth has a push button to call the stewardess. Each station has a small light and colored jewel, visible from either end of the aisle to indicate the origin of the call. When the button is pushed, a buzzer sounds at the stewardess' station and the light at the calling station comes on and locks on electrically through a relay. The light is reset with a switch at the stewardess' station. An electric sign for use during landing and taking off is located at each section. It is controlled by the pilot and bears the wording "No Smoking. Please Fasten Seat Belts."

The airplane is equipped with a radio receiver and transmitter for 2-way communication with the ground, a radio beacon receiver for use with the beam transmitted by the Department of Commerce stations located along the airways and an auxiliary stand-by receiver. The transmitter is rated at 50 watts output and both it and the 2-way receiver are designed for continuous wave, interrupted continuous wave, and phone. The filaments of all the radios are supplied directly from the 12-volt system and the plate circuit is supplied from dynamotors operating from the 12-volt supply. Small batteries are carried for the emergency operation of the stand-by receiver. Two jacks, located in the side of the fuselage at the battery cart receptacle, provide means for plugging in a telephone set to communicate from the field to the pilot's cockpit before taking off. An interphone system between the cockpit and the cabin permits the stewardess to communicate with the pilot and co-pilot. Radio wiring and equipment weights are about as follows:

| | |
|---|---|
| Transmitter and receiver for 2-way communication | 71 pounds |
| Beacon receiver | 23 pounds |
| Auxiliary stand-by receiver | 18 pounds |
| Transmitting dynamotor / Receiving dynamotor | 47 pounds |
| Emergency batteries | 12 pounds |
| Conduit | 15 pounds |
| Junction boxes, brackets, and supports | 36 pounds |
| Wiring | 14 pounds |
| Total | 236 pounds |

For night flying, navigation lights are located on the wing tips and the rear of the fuselage. A landing light is located in the leading edge of each wing outboard of each engine nacelle and a red passing light is incorporated in the left-hand landing light. These landing lights are equipped with 12-volt 35-ampere bulbs which, because of their rather high design factor of 25 lumens per watt, have a life of only 100 hours.

In each engine nacelle, or on each engine, are mounted the carburetor air-temperature resistance bulb, oil temperature-resistance bulb, engine-temperature thermocouple, tachometer generator, 12-volt generator, starter, magnetos and booster coil, and exhaust-gas analyzer cell. The engine section wiring is connected into plugs at the firewall to permit rapid disconnection for engine change This helps to reduce maintenance delays in schedules.

Other electrical applications encountered in aircraft are electromechanical or electrohydraulic operation of landing gear and flaps. Deicing of wings and tail surfaces is accomplished by inflating and deflating rubber strips along the leading edge. The valve which controls this is electrically driven as is the pump which delivers alcohol to the propellers and carburetors for ice removal.

The wire used in these airplanes is in accordance with the United States Army Air Corps specifications. It consists of a multistrand flexible conductor, insulated with 2 layers of varnished cambric and a lacquered, woven cotton braid. This type of wire weighs less than rubber insulated wire and has a smaller outside diameter, permitting the use of smaller conduits

Because of the necessity for reliable radio operation, it is essential that all radio interference arising from the operation of the airplane be kept to the absolute minimum. The proximity of the antenna to the possible sources of interference makes it necessary to completely enclose every portion of the electrical system in a tight electrostatic shield, thoroughly bonded at frequent intervals to the airplane structure. This is accomplished by using a metal conduit and junction-box system and enclosing all equipment which is not inherently shielded by its construction, in shielding boxes. Aluminum and aluminum alloys are used for this purpose. The radio wiring is isolated from the main wiring by installing it in a separate conduit sys-

tem. The question of adequately shielding electrical equipment is one which the entire electrical industry may have to face in the near future, especially when television comes into general use.

Bonding consists of connecting electrically all metal parts of an airplane. Its purpose is: To increase the capacitance between the airplane and the radio antenna; to prevent absorption of the radiated energy of the radio transmitter by electrically isolated metal parts; to eliminate the danger of sparks occurring between metal members between which there exists a difference in potential caused by the collection of static charges; to eliminate noises produced in the radio receiver which are caused by the varying resistances between rubbing or vibrating metal parts; to lower the resistance of the metal shielding. The all-metal structure of the transports is inherently bonded and such parts as conduit, fuel and oil lines, etc., are bonded by their attaching parts. These attaching parts (clamps, brackets, etc.) are usually located at intervals of 18 to 20 inches. In places where this interval is greater, bonding strips of tinned copper braid are used to connect to the structure. This bonding interval of about 18 inches is necessary to prevent the secondary radiation of energy when standing waves are generated on long, ungrounded parts, and to provide sufficient low resistance paths to the structure to insure the effectiveness of the shielding. Fuel and oil tanks are bonded at diagonally opposite corners. All bonding connections should have a resistance of not more than 0.002 ohm.

The problem of weight is one with which the airplane designer is constantly confronted and the electrical installation in a plane the size of the Douglas sleeper transport requires serious consideration in this respect. It is estimated the completed installation will weigh about 772 pounds divided as follows:

| | |
|---|---|
| Wire | 135 |
| Conduit | 85 |
| Junction and shielding boxes | 136 |
| Equipment | 416 |

The equipment weights are divided as follows:

| | | |
|---|---|---|
| 2 | 85-ampere-hour 12-volt batteries | 155 pounds |
| 2 | Generators and regulators | 62 pounds |
| 2 | Battery compartments | 34 pounds |
| 2 | Starters | 66 pounds |
| | Lights | 57 pounds |
| | Switches, relays, etc. | 42 pounds |
| | Total | 416 pounds |

When designing electrical equipment for aircraft, this question of weight must be kept in mind as it is possible to effect considerable saving by the use of proper materials. As an example of what can be done, we have recently had designed and built a 3-position single-pole double-throw 200-ampere switch which weighed 2.2

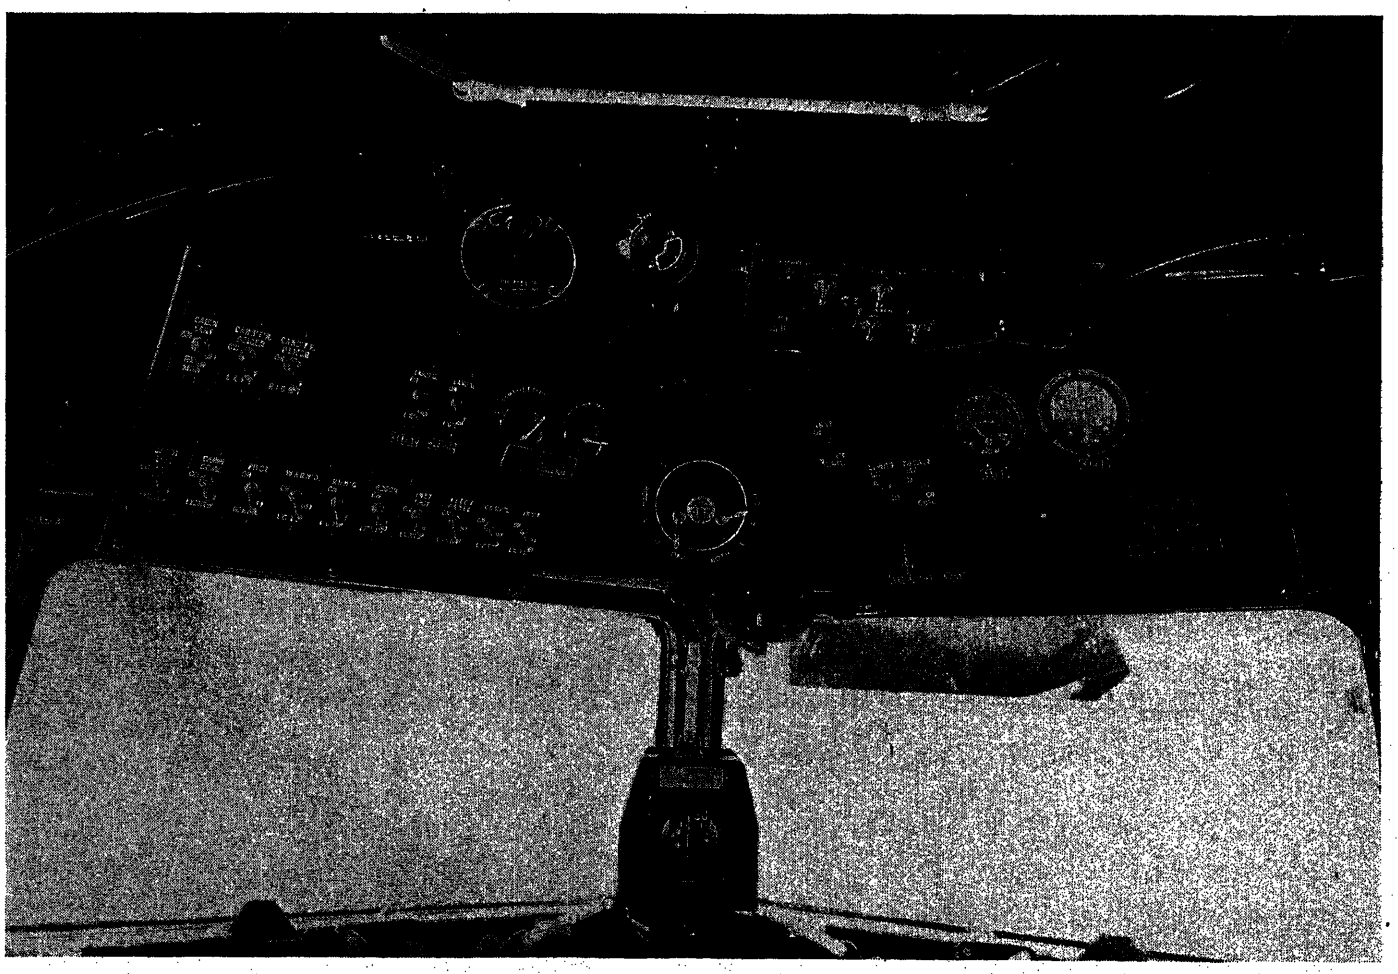

**Figure 2. Electrical panel above windshield. Radio controls above and below ignition switch**

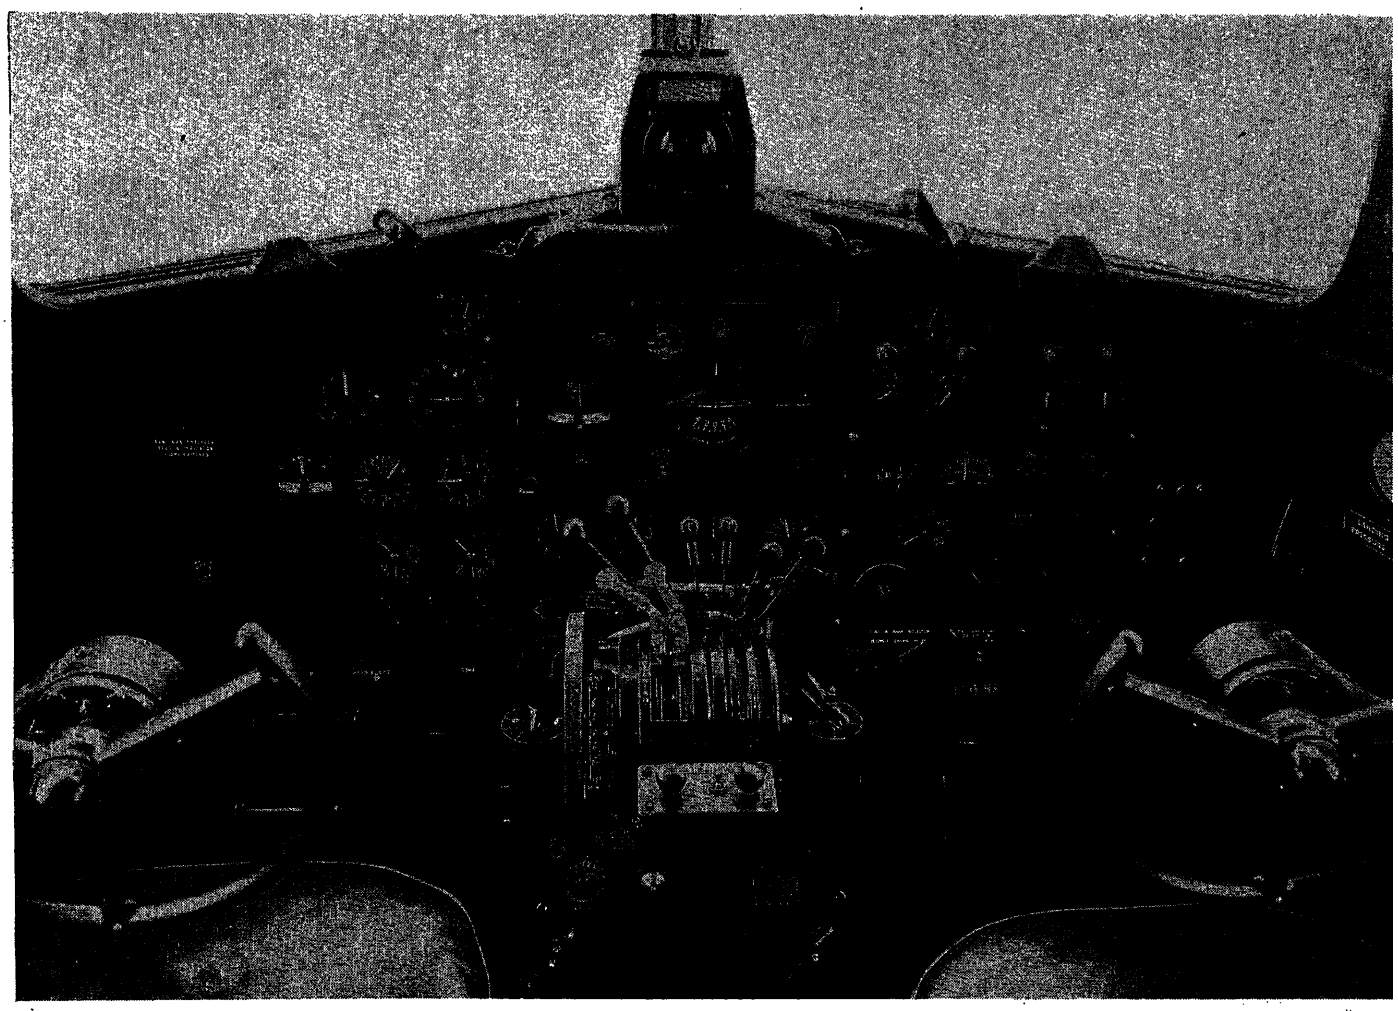

Figure 3

pounds. However, weight should never be saved at the expense of reliability.

Another factor which enters the design problem is the matter of operating temperatures. Equipment for use on aircraft must be capable of operating through a range of from −30 degrees Fahrenheit to +130 degrees Fahrenheit without change in lubricant or any other adjustment that is not wholly automatic. These extremes may be encountered within a period of 30 minutes.

Operating noise must be kept to the absolute minimum. Considerable weight, expense and time are spent in soundproofing the interiors and any equipment which introduces more noise is undesirable. The sound level in the present transports is such that the operation of the small toggle switches for the lights can be distinctly heard.

It becomes evident on studying today's large airplanes and tomorrow's larger ones, that an increase in the supply voltage would help considerably to keep the weight down. This would seem to be rather easily accomplished by placing the 2 12-volt batteries in series and using 24-volt generators. However, weight is not the only problem.

The amount of electrical equipment used is such that the present power supply is hardly adequate and with the increasing amount of equipment on larger planes, it is imperative that a larger source be made available. The larger airplanes require from 10,000 to 20,000 watts available continuously and this supply should be independent of the airplane engines. There are units being designed and built to meet these requirements. They consist of small 4-cycle gas engines driving generators and possibly some of the other accessories now driven by the airplane engines such as vacuum pumps, oil pumps, etc. To guard against failure, 2 such complete units will be carried.

A great deal of thought has been given to supply characteristics and it has been agreed that alternating current at 115 volts is the logical choice. This voltage makes available many commercial developments and the inherent flexibility of alternating current makes it very desirable.

A study of 60-cycle equipment shows that a large system such as has been outlined would involve considerable weight. Quite a saving could be made by using some frequency higher than 60 and a study has been made of frequencies as high as 800 cycles.

It is believed that the amount of power involved and the length of the transmission lines are such that no serious reactance trouble will be encountered. However, there is considerable doubt that satisfactory motor characteristics are possible at 800 cycles.

Development work on equipment for this frequency has been under way for some time and this problem may be solved shortly.

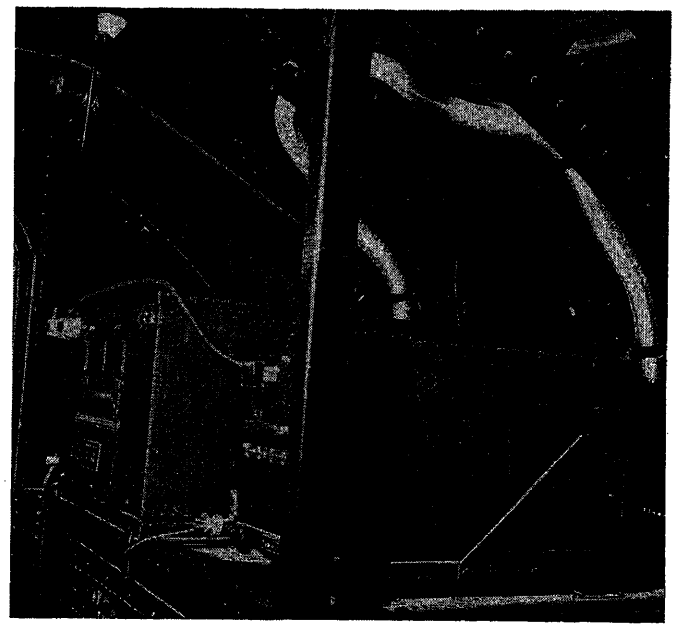

Figure 4. Transmitter and receiver for 2-way communication

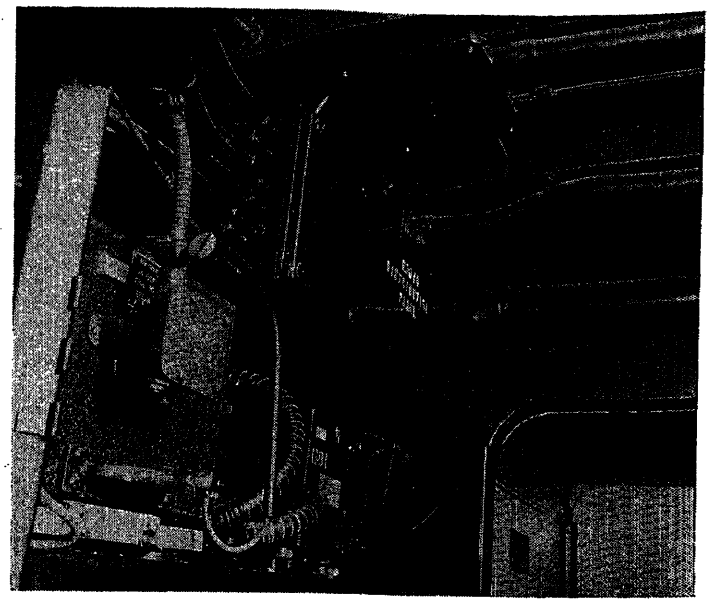

Figure 5. Radio beacon receiver, dynamotor, and stand-by receiver

It is known that satisfactory 360-cycle motors can be obtained and that radio filament supply at this frequency is feasible. A large percentage of the possible weight saving at 800 cycles is possible at 360 cycles. This or some other frequency lower than 800, may prove to be the best compromise. There is also the possibility that the various loads may become great enough to warrant the use of a double-frequency generator, supplying high frequency for radio plate supply, lighting and heating, and some lower frequency for motors and radio filaments.

Both single- and 3-phase supply have been considered and the advantages and disadvantages of each are about balanced. Of course, polyphase motors have an advantage over single-phase where power is required.

With airplanes steadily increasing in size and with a sufficiently large electrical supply, there is almost no limit to the possible applications in the future. All engine instruments will be electrical, possibly of the selsyn type. Various remote indicators for flaps, landing gear, fuel and oil quantity are already being used. Heater units to prevent carburetors and windshields from icing up and to provide hot water in the lavatories may be installed.

Lighting problems will be greatly simplified with a larger supply available. It will be possible to furnish adequate light for reading and general illumination comparable to that found in a modern home. Landing lights of much greater intensity have been developed. Development work on lamps has progressed to the point where satisfactory 115-volt lamps for aircraft are available in 6-, 15-, 20-, 25-, and 50-watt sizes. These are obtainable with the standard automotive bayonet base up to and including the 25-watt size. The 25- and 50-watt sizes are obtainable with the medium bayonet base. Landing-light lamps have been made in the 500-, 750-, 1,000- and 1,500-watt sizes with reasonably concentrated filaments. Tests indicate that all of these lamps are sufficiently rugged to have a reasonable life.

One of the problems of air transportation is that of serving satisfactory meals aloft. These large planes of tomorrow will have an electrically equipped galley where appetizing meals can be prepared. Light-weight hot plates, thermally insulated to prevent heat loss by radiation, electric mixers, and special cooking utensils will be needed. Making coffee at from 16,000 to 20,000 feet may require some experimenting, when the lower atmospheric pressure is considered. Electric refrigeration will be included.

Electric razors, now used by many airlines, curling irons and other modern conveniences will be available on overnight planes. Passenger comfort will be stressed and any electrical appliances contributing thereto will receive consideration.

Radio equipment of greater power for 2-way communication, radio direction finding and blind-landing equipment will be standard on all planes. With alternating current available, the high-voltage plate supply will be furnished by step-up transformers, rectifiers, and filters instead of by dynamotors. When transmitters with ratings of 1,000 to 2,000 watts output are considered, the size and weight of the power supply becomes very serious. It is here that great savings in copper and iron weight can be made by using a supply frequency well above 60 cycles. Transmitters of this power are not unreasonable when transoceanic flying, with the attendant need for absolutely reliable communication, is considered. Broadcast reception and television may be furnished for the passengers' amusement.

In planes designed for high-altitude flying, various indicators and controls, electrically operated will doubtless be used. Air conditioning will be necessary

The aviation industry is dependent upon the electrical engineers for these and other developments and it is hoped that this article has been able to present a general picture of the probable future needs.

# Proposals for the Administration of Federal Power in the Pacific Northwest

By H. V. CARPENTER
FELLOW AIEE

## Synopsis

This paper undertakes to state briefly the plans of organization of the Ontario Hydro-Electric Commission, the British Grid, the Tennessee Valley Authority, and then the proposals made by the planning bodies and in bills submitted to Congress for the public administration of power from Bonneville and Grand Coulee.

(I have not received Senate Bill No. 2092, and H.R. 6151, a bill prepared by the Senators of Oregon and Washington, which is more similar, I suspect, to their bill described herein which died with the 74th Congress. I would have been glad to add a summary of this bill if time had permitted.)

SINCE the depression has led the Federal Government into a number of great public-service construction projects, the method of administering the power to be produced has become of increased interest. Sale of power from Muscle Shoals has been a troublesome problem in the Congress at frequent intervals ever since the service became available. Now merged with the Tennessee Valley Authority the sale of the same power continues to find its way into the courts or to be the subject of legislation. This is not strange since the federal administration of such a utility is a new thing in the United States, and its promise of permanency gives the subject major importance.

Oldest of the government works for handling power on a large scale in North America is the Hydro-Electric Power Commission of Ontario. Under the wise and able administration of Sir Adam Beck, this organization has made a most valuable contribution to our fund of experience in governmental administration of a vast public utility. The Commission consists of 3 persons appointed by the Lieutenant Governor in Council, one of whom must be a member of the Executive Council of the Province. One member is named chairman and is the only one that is drawing a salary. The Commission chooses its staff, the staff members choose their own assistants, and the administration within the organization has been much the same as that of a private corporation, including a system of retirement funds and insurance for employees and the usual wide latitude granted to department heads in carrying out individual administrative duties. The Enabling Act refers to the Commission as a body corporate without capital. Its precise legal status has been determined gradually through later acts which have amended the original status, and through the results of legal procedure.

A unique feature of the legislation is that no action at law may be brought against the Commission or against its agents without the special consent of the Attorney General of Ontario. The Commission is given unusual power of eminent domain, permitting it to enter upon the property of anyone without any preliminary proceeding, or authorization whatever, adjustments to be made later by an evaluator appointed by the Lieutenant Governor. The relations of the Commission with municipalities purchasing power for local distribution is somewhat involved since it gives considerable authority to the Commission over the activities of a local group. Hydro is the third largest public utility in Canada, having a capital of about $285,000,000, exceeded only by the Canadian Pacific and the Canadian National Railways. All accounts are audited by independent auditors appointed by the provincial government. All revenues to support the undertaking must come from the sale of power and rates are set on the principle that service is furnished at "cost" where cost includes a sinking fund to liquidate the capital, a renewal reserve to replace the system in 25 years, and all expenses of operation and maintenance. Similar careful financing in the local municipalities has led to a rather stable financial status. An elaborate bookkeeping system assesses against each municipality served the proportional amount of cost, including the cost of transmission. Funds for construction work are provided by sale of bonds or through funds borrowed through or from the Provincial Treasury.

The Commission has been able to maintain a staff of technicians and an extensive laboratory, and a certain amount of research work is usually under way. Thorough analyses are made of all constructions, designs, and materials so that their work has been well protected from technical mistakes. On the business side, the Commission has not been quite so fortunate. Following the death of Sir Adam Beck in 1925, certain contracts were made for the purchase of power from private companies in larger quantities than could be used, payments for which threatened the Commission with disaster and required cancellation of these contracts by the legislative assembly in order to avoid bankruptcy. This illustrates one weakness of public organizations of this type in which administrative authority is placed in persons whose own capital and interests may really be elsewhere.

The possibility of satisfactory administration of transmission networks as a federal function has been encouraged also in this country by the success of the British experience

A paper recommended for publication by the AIEE technical program committee. Manuscript submitted April 28, 1937; released for publication June 21, 1937.

H. V. CARPENTER is dean of the college of mechanic arts and engineering, State College of Washington, Pullman.

with what is commonly called the "British Grid" administered by the Central Electricity Board, known as the C.E.B. Beginning 20 years ago, our British friends spent nearly 10 years considering the problem of reducing coal consumption by substituting high-grade modern steam plants for some 500 old and small industrial and public generating stations. These had grown up supplying individual industries or very small districts with a multitude of frequencies and voltages and the condition was rapidly becoming worse with continuing high coal consumption and legal limitations against the combination of small districts into larger ones.

Finally, in 1926, the C.E.B. was established with considerable arbitrary power to build transmission systems, purchase the entire output of modern generating plants, and sell power to industries and communities at rates which have brought about the closing down of a few hundred old-fashioned stations. The organization and administration of the British Grid is involved in such a greatly different legal setup from ours as to make it impossible in this summary to give a worth-while comparison with the conditions in the United States. The Grid has met with considerable success and has over 3,000 miles of 132-kv lines covering most of the island. With sound management, they can hardly fail to be a success due to the great difference in economy between the old-style small steam plant and modern practice. There are problems still existing but they are being worked out and the C.E.B., which resembles in most ways an American corporation, seems likely to be of vast usefulness to the English communities and industrialists.

The most ambitious undertaking by the United States of the type under consideration is the Tennessee Valley Authority, familiarly known as the T.V.A. The T.V.A. Act established a corporation with the purpose of maintaining and operating United States property, to aid agriculture and industries, and to control floods and contribute to the national defense in the valley of the Tennessee River. The authority is vested in a board of 3 directors appointed by the president and subject to recall only by joint action of House and Senate. This board hires all employees without civil service limitations, is to pay prevailing wages, and has the usual corporate power to sue and be sued, make contracts, etc., is given the power of eminent domain to be exercised in the name of the United States, and is authorized to construct dams and reservoirs needed to complete and maintain a 9-foot channel to Knoxville with appertinent power plants and transmission system. It may produce, distribute, and sell electric power and go into the phosphate- and nitrogen-fertilizer business. Power is to be furnished for navigation locks free, and the surplus sold with preference for public groups of users. They may limit the rate schedules of any privately owned distributors to whom power is supplied, or cancel their privilege to buy. Earnings go to the United States Treasury, except for maintaining a continuing fund of one million dollars for operating capital. Any works on the river proposed by other parties are subject to approval by the T.V.A. Board.

The approaching completion of the construction work at Bonneville and the rapid progress at Grand Coulee, both on the Columbia River, add to the interest in a suitable plan for federal administration. Each new plant and each new region entered brings up new conditions and indicates an added need for flexibility in any scheme under which these utilities are to be operated. Every effort is being made to ensure that the benefits accruing from them shall be widely distributed.

Under authorization of the National Resources Committee, a thorough study of the Pacific Northwest and its resources was made during 1935 by the Pacific Northwest Regional Planning Commission made up of the heads of the planning boards of the 4 Northwest states, under the chairmanship of Marshall N. Dana, of Portland, Ore. This Commission, with the co-operation of a consulting staff of some 25 members, presented among other things recommendations for the administration of federal power in the Columbia Basin. These recommendations are based on the results of many hearings and consultations held throughout the region and represents closely the consensus of the Pacific Northwest opinion. These recommendations include: first, that federal construction work, including Bonneville and Grand Coulee, should be continued under the present departments, Bonneville being under construction by the engineers of the United States War Department and Grand Coulee by the United States Bureau of Reclamation. Much praise for the work of these 2 departments has been expressed by those familiar with their work on these projects. So since the operation of Bonneville will be associated with the operation of the lock in the Columbia and since a substantial portion of the power at Grand Coulee is to be used for irrigation pumping at Grand Coulee Dam, it is also recommended that the operation of these 2 plants be left permanently with the departments constructing them.

Second, the disposal of commercial power from Bonneville and Grand Coulee should be considered as a separate undertaking and placed in the hands of a new and separate agency. This power agency should have the form of a public corporation with the financing and other power usually accorded to such bodies. Its board of directors should be made up of 3 or 5 members to be appointed by the president with the approval of the Senate. One of these directors should be qualified for administration and management of the power system, another with special qualifications for planning, development, and promotion, and the third to have special qualifications in public relations and in the fields of social and economic development. If 5 are named, one might be at the suggestion of the Secretary of Interior and one by the Secretary of War, these probably to serve as part-time advisory directors. The following functions and powers should be entrusted to this power agency:

1. Major transmission lines, planning, designing, construction, maintenance, and operation.
2. Interconnection plans.
3. Interchange and dispatch of energy and its measurement.
4. Design of power facilities (including the review of any such designs carried out by other federal constructing agencies).

5. Development of power markets.

6. Specific planning for the further extension and development of its power system.

7. Sale of power at wholesale from points on its transmission system with contractual requirements that will insure that rates to the consumer pass on the economies in generation and transmission. With due respect to the interests of other agencies, the power agency should be given power to specify the maximum resale rates of any distributor which buys all or a major portion of its electric energy from the power agency.

8. Co-ordination and control of power production at federal power plants.

9. Regulation of release of water from federal storage reservoirs subject to state rights and irrigation needs.

10. The power agency should be authorized to interchange power with other agencies.

The power agency should be endowed with the accessory and usual powers, rights, and obligations of a corporation necessary to the exercise of the functions named. Initial federal financing should be provided and the obligation to contribute to state tax funds in proportion to the levies which are made upon similar private enterprises should be recognized. Public and nonprofit agencies should be given priority in the purchase of power and the power agency should be given the right of eminent domain as to purchase and lease of property useful in its operations. It should have the right to make contracts, to sue and be sued, and to conduct itself otherwise as a corporate autonomy. The agency should also be authorized to carry on research and experimentation to widen power utilization and markets and should be responsible for all recommendations as to future federal multiple purpose projects within the Basin.

The first official attempt to crystallize Northwest opinion into law was introduced May 12, 1936 as Senate Bill No. 4695, by the 4 Senators of Oregon and Washington and was analyzed and reported on by the committee on commerce, Report No. 2280. As finally presented it places the Bonneville plant construction, maintenance, and operation, and later installation of remaining machines, under the Secretary of War, through the chief of engineers. They also control the sale of power subject to approval by the Federal Power Commission. The War Department also is authorized to construct, operate, maintain, and improve transmission lines and related facilities. Navigation has first claim on the power; district and municipal organizations organized to serve rather than for profit come next. Within limitations surplus power may be sold to commercial operating companies. Contracts may be made for not to exceed 10 years but may give preference for an additional 10 years.

The War Department may purchase or condemn any or all real and personal property (including any existing electrical facilities) necessary to carry out the act. All receipts go to the United States Treasury. The Federal Power Commission may fix and revise rates without regard to existing statutes, rates to be based on costs.

The president may designate a federal agency to handle everything here assigned to the United States Engineers. This bill was brought up for consideration but failed in passage before the adjournment of the 74th Congress.

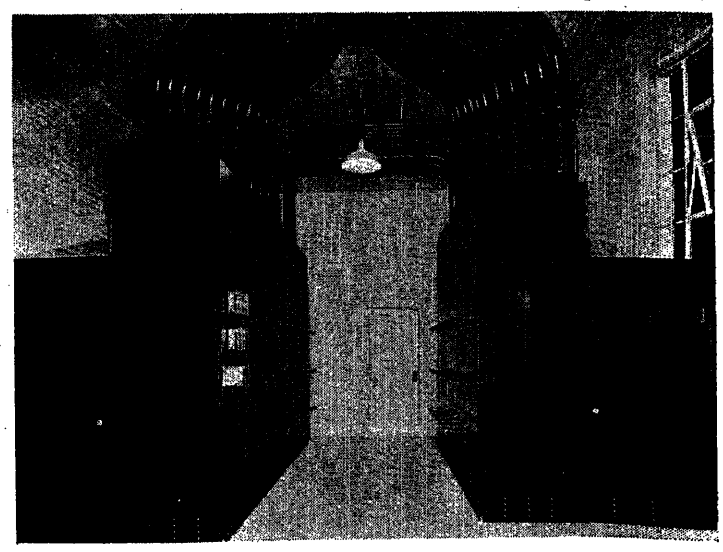
The first bill of the 75th Congress, dealing with power on the Columbia, was introduced by Representative Smith of Washington on January 5, H.R. 92. This bill placed the development of the plant at Bonneville and the building of transmission lines in the charge of the Secretary of War. The sale of power, also, was to be handled by the engineers of the War Department, but with almost every detail of power policy and, to some extent, contracts subject to the approval of the Federal Power Commission. The bill did not find satisfactory support and aroused considerable objection since it implied a control of rates at Boulder Dam. Largely, I believe, on this account this bill has been superseded by Mr. Smith's bill of February 19, 1937, when he offered House Bill No. 4948 incorporating what he stated were the desires of the President for control of power in the Northwest. The bill is to authorize maintenance and operation of the Bonneville project for navigation, flood control, and other purposes. The bill would leave completion of construction of Bonneville to the Secretary of War and also reserves to the Army Engineers, the operation of the lock which is to permit ocean boats to proceed upstream about 45 miles to The Dalles. Otherwise, the administration of operation, maintenance, sale of power, and promotion is to be by a Columbia River Administrator appointed by and responsible to the Secretary of the Interior. The Administrator is to act in consultation with an advisory board composed of 3 representatives, one to be designated by the Secretary of War, one by the Secretary of Interior, and one by the Federal Power Commission. This form of administration for Bonneville is stated to be intended as provisional until the establishment of permanent administration of Bonneville and other federal projects in the Columbia River Basin. The Administrator is authorized to operate, maintain, and improve Bonneville and related facilities, and is directed to carry on primarily for the purpose of promoting navigation and controlling floods, which, by the way, are 2 matters practically beyond his power. So far as consistent with these and to prevent waste, he shall add and improve machines and facilities for generation and transmission of such power as may be saleable. He shall encourage use of energy, construct, operate, maintain, and improve transmission lines and appurtinences to bring Bonneville's power to markets, existing and potential, and is authorized to interconnect with other federal projects and private or other public systems for exchange and emergency service. Public and co-operative agencies are to be given preference in purchase of power and half of the firm power available is to be held for them until January 1, 1939. Rates are to be approved by the Federal Power Commission. Contracts are to be made on a wholesale basis, except that sale may be made direct to large consumers. No contracts for more than 20 years may be made and these are to be subject to rate readjustment at ntervals of not over 5 years. Sales to privately owned agencies may be cancelled on 5 years notice if the power is needed for public agencies. Contracts with private companies for resale may contain stipulations concerning resale rates in order that the consumer may be protected. Rates are to be fixed with a view to

encouraging use but are to consider costs of generation, transmission, and amortization of capital investment over a reasonable number of years, the power to bear its fair share of the total cost of Bonneville. Except in emergencies, bids are to be called for on all items amounting to more than $500, but the Administrator may use usual business discretion in awarding contracts to responsible parties and in judging the materials offered.

The Administrator is to report to Congress each year. He appoints his own lawyers, engineers, and other experts and fixes their salaries, and appoints others under civil service rules.

All receipts are to go to the United States Treasury, except an operating fund of $500,000. Authorization of appropriations necessary to carry on is included. The Administrator, in the name of the United States, may bring suits and, by implication, may be sued.

On April 14, 1937, Representative Walter M. Pierce of La Grande, Oregon, introduced still another bill for establishing a suitable administration for Bonneville. He would place an administrator in full charge of both generation and distribution and make him responsible solely to the Secretary of the Interior, except that rate schedules and revisions become effective after approval by the Federal Power Commission. This places the responsibility for operation of the Bonneville plant for power production in the hands of the Administrator subject to completion of construction of the plant, including locks, fishways, power, and appurtinences and the continued operation of locks and fishways only by the United States Engineers under the Secretary of War. This administration is to be provisional, pending the establishment of permanent administration for Bonneville and other projects in the Columbia River Basin. The authority carries with it the right to condemn property, franchises, etc., needed for carrying out the purpose of the act and the preferential rights of public nonprofit bodies domestic and rural consumers, is carefully guarded through reservation of 50 per cent or more of the energy until January 1, 1941, for such nonprofit bodies, provided, however, that such energy reserved but not actually purchased by nonprofit groups prior to January 1, 1941, may be disposed of temporarily to any purchaser. The Administrator is further authorized to contract for interchange of power with any other system as mutual emergency protection of service. The Administrator is also instructed to consult and co-operate with nonprofit groups within economic transmission distance of Bonneville in order to assist them in securing their privileges. In other ways the bill closely resembles other earlier measures.



This bill by Representative Pierce is based to some extent upon the recommendation of President Roosevelt, dated February 24, in which he approves the progress report of the President's Committee on National Power Policy. The recommendations of this committee are quite closely followed by Representative Pierce, except that the Committee advises that the Administrator should act in consultation with an advisory board composed of representatives designated by the Secretary of War, Secretary of the Interior, and the Federal Power Commission. Included in the Committee's statement is:

> "In computing the cost of electric energy developed from water power created as an incident to the construction of Bonneville project for other purposes, there may be allocated to the cost of electric facilities not simply the cost of such facilities, but also such a share of the cost of facilities having joint value for the production of electric energy and other purposes as the power development may fairly bear as compared with such other purposes. The rate schedules may provide for uniform rates or rates uniform throughout prescribed transmission areas with a view to distributing the benefits of an integrated transmission system and encouraging the equitable distribution of the electric energy developed."

Since power will be available at Bonneville before the end of 1937 early action is important. This is true not only to conserve a national asset but to enable the public utilities of the Northwest to determine their program for ensuring a sufficient power supply. They have operated all available steam plants most of the time in recent months and must build or buy power to prevent a serious shortage within the next few months.

## Compact Distribution Center

Westinghouse Photo

FIFTY-TWO distribution circuits are concentrated in this switchboard recently installed in a Philadelphia, Pa., industrial plant. Dead-front air-break circuit breakers are used throughout. On the left is a 440-volt 3-phase 60-cycle power-distribution switchboard supplied from 3 500-kva stepdown transformers, which has 30 400-ampere distribution-feeder breakers with 7 submetering current transformers and watt-hour meters. The switchboard on the right is for lighting distribution, and has 22 300-ampere circuit breakers for the 3-phase 4-wire grounded-neutral system, which is supplied with 120 and 208 volts from 3 333-kva transformers. Each circuit breaker controls a main feeder circuit to a definite plant section.

# The Ultrahigh-Speed Reclosing Expulsion Oil Circuit Breaker

By A. C. SCHWAGER
MEMBER AIEE

DURING the last few years, the problem of increasing the continuity of service of electric transmission systems has been given considerable study. Of all the proposals by which it is intended to bring about a reduction in outages, the practice of ultrahigh-speed reclosing of oil circuit breakers gives promise of the most effective and most economical solution.

The advantages of automatic-reclosing circuit breakers have been known for a long time and records are available showing that approximately 90 per cent of all outages can be eliminated during the first opening followed by reclosure. This value was first determined for a reclosing interval of 15 seconds but later confirmed for immediate reclosure.[1]

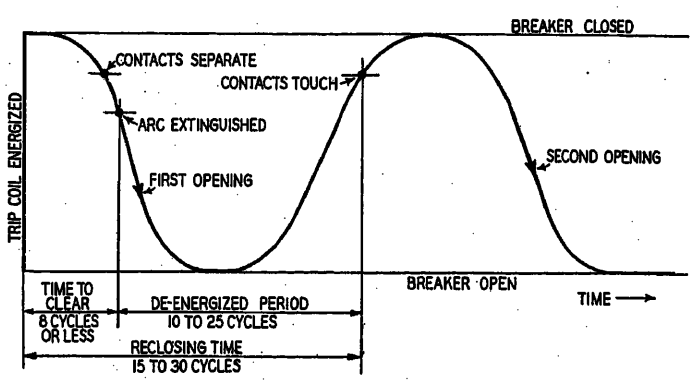


**Figure 1. Travel-time chart of ultrahigh-speed reclosing breaker**

"Immediate reclosure" in the above sentence defines operations in which the interval from trip coil energized to circuit reclosed amounts to from 30 to 80 cycles, the lower value applying to lower, the upper limit to higher voltages.

It is obvious that additional advantages could be obtained by reducing the reclosing interval still further. A reduction to from 15 to 30 cycles would in many instances prevent the loss of synchronous equipment load and would in general eliminate the remaining disadvantages of outages of too long a duration.

Figure 1 shows a travel-time chart of the reclosing cycle taking place within the above-mentioned periods. The term ultrahigh-speed reclosing has been previously applied to this type of operation and will be used in the following.[2] The de-energized period according to figure 1 amounts to from 10 to 25 cycles. This is sufficient time to allow the dielectric strength of the fault path to recover to such a degree as to withstand reapplication of line voltage, provided that the short circuit is due to the most common causes such as insulator flashover or line swinging.

In designing an oil circuit breaker which will meet the specifications outlined in figure 1, the manufacturer is confronted with the following 2 major problems:

1. Develop an operating mechanism which will meet the specifications as to mechanical performance, when applied to present designs of breakers.

2. Assure the behavior of the rupturing devices under immediate reclosing conditions. Although a great deal of interrupting capacity test data on modern breakers is available, information on 2 successive interruptions within an interval of a few cycles is lacking. If possible, tests should be carried on with time intervals smaller than those employed in service.

## Problem 1—Operating Mechanisms

For a considerable period of time, the solenoid control represented the standard design of operating mechanism. With the demands for shorter opening and closing times, spring-actuated motor-wound mechanisms were developed and during the past 10 years have found a great field of application. In addition to increased operating speeds, they had the advantage of requiring small operating currents, in many instances eliminating the necessity for expensive batteries. These controls provide stored energy for one closing and one opening operation of the breaker. Rewinding of the springs occurs immediately after the opening stroke and in general requires several seconds. It is obvious that in spite of the above-mentioned advantages this latter type of control is not suitable for immediate reclosing.

The conventional solenoid control was, therefore, re-

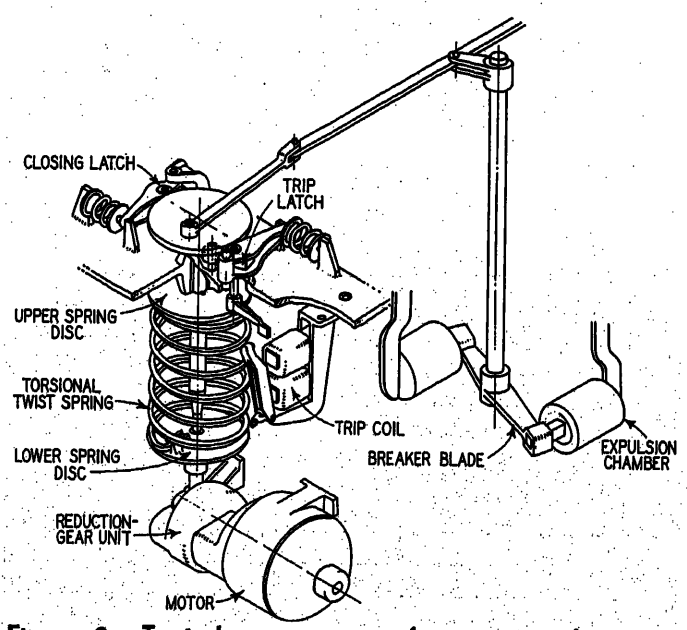

**Figure 2. Typical arrangement of motor-wound spring-actuated reclosing mechanism**

A paper recommended for publication by the AIEE committee on protective devices. Manuscript submitted March 29, 1937; released for publication June 4, 1937.

A. C. SCHWAGER is vice-president in charge of engineering for the Pacific Electric Mfg. Corporation, San Francisco, Calif.

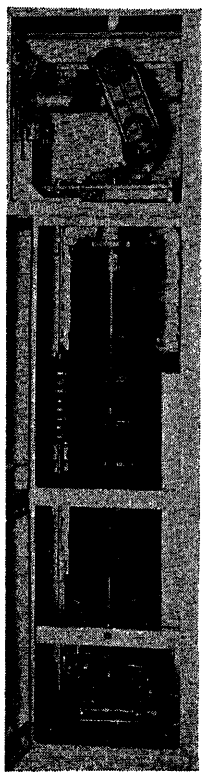

**Figure 3. Fast-reclosing operating mechanism for 69-kv breaker**

considered with a view to improving its performance to comply with the specifications contained in figure 1. No difficulty was encountered in meeting high speeds in opening, which is generally accomplished by springs. In closing, however, the upper limit of the specifications was not even approached. This is due mainly to the fact that an excess of time is lost in accelerating the heavy plunger. A combination of 2 prewound motor controls would, of course, solve the problem in an academic way, but it does not seem feasible economically and introduces complications due to the presence of double closing and trip coils. The problem was, therefore, attacked on a more fundamental basis along the following lines of thought.

Some type of motor-wound spring-actuated mechanism, designed to produce the required operating cycle with the least number of parts and in a thoroughly reliable manner seemed preferable. The mechanical design should be such as to produce the greatest possible speed and shortest operating time. The simplest mechanism is one which incorporates only one spring to perform the entire cycle of opening, closing, and opening.

A control of the type shown in figure 2 seems to meet the above specifications in the most direct manner. It is shown applied to a conventional rotary-type oil circuit breaker, although it is equally suitable for the drop bar type and has been developed for breakers from 7.5 to 138 kv. A reduction-geared motor winds up a torsional twist spring. Suitable closing and tripping latches retain and release the upper spring disk. A motor limit switch is provided which rewinds the spring automatically to a predetermined torque whenever an operation of the breaker has released part of the spring energy. Although the length of the spring is chosen to give one immediate reclosing cycle it is possible to meet possible future requirements for more than one immediate reclosure by lengthening of the spring. The motor is of such size that the spring is wound for additional time-delayed reclosure in an interval smaller than that available in the conventional automatic reclosing timers. Figure 3 shows a control of this type as applied to a 69-kv breaker. The simplicity of the design is apparent, the essential parts such as motor and spring constituting the major portion of the mechanism. In the particular case shown the unidirectional rotary motion of the upper spring disk is transformed into a reciprocal radial motion of the horizontal breaker operating shaft by means of a bevel link.

**Table I**

| Test Number | Amperes (Root-Mean-Square) | Voltage Across Breaker (Root-Mean-Square Kilovolts) | Time to Clear. Trip Coil Energized to Arc Interruption (Cycles) | Reclosing Time (Cycles) | De-energized Period (Cycles) |
|---|---|---|---|---|---|
| 1 | 400 | 12.3 | 5.3 | 11.3 | 6.0 |
| 2 | 920 | 12.3 | 5.3 | 11.3 | 6.0 |
| 3 | 1,800 | 12.3 | 5.1 | 10.8 | 5.7 |
| 4 | 2,600 | 12.3 | 5.0 | 11.5 | 6.5 |
| 5 | 3,760 | 12.3 | 5.5 | 10.2 | 4.7 |

## Problem 2—Interrupting-Capacity Tests

In order to satisfy the questions brought up under the heading of the second problem, the need for an analysis of the arc-interruption phenomena within expulsion chambers during quickly repeated interruptions was indicated.

The expulsion-chamber arc-rupturing device consists essentially of an explosion chamber which is vented in a direction opposite to the direction of opening the blade. The gases produced during interruption, therefore, escape into

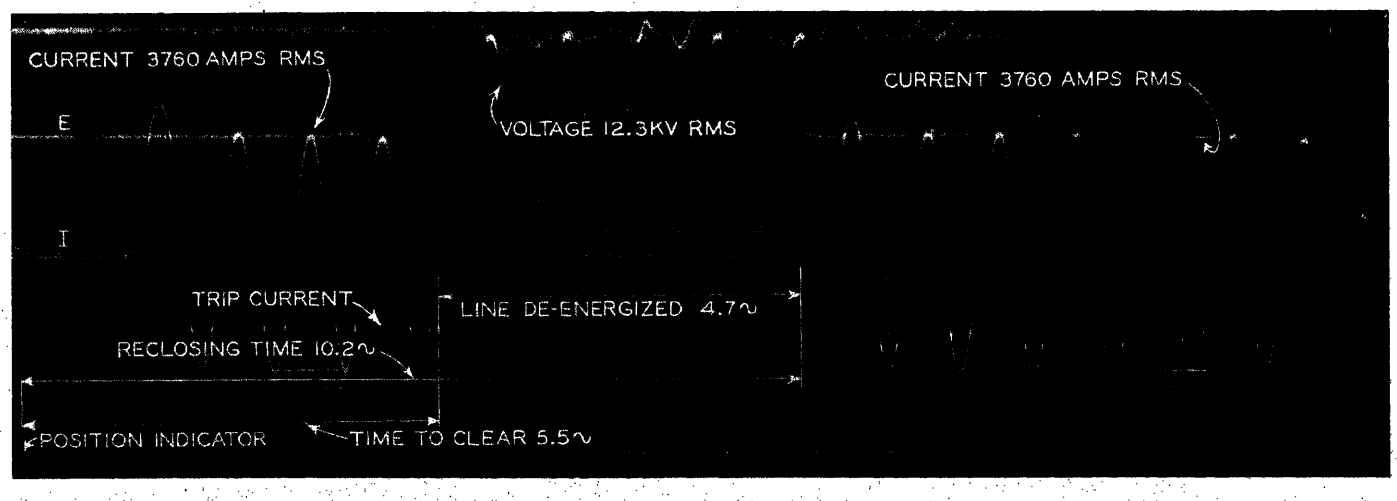

**Figure 4. Oscillogram of interrupting-capacity test on 15-kv expulsion breaker and fast reclosing control**

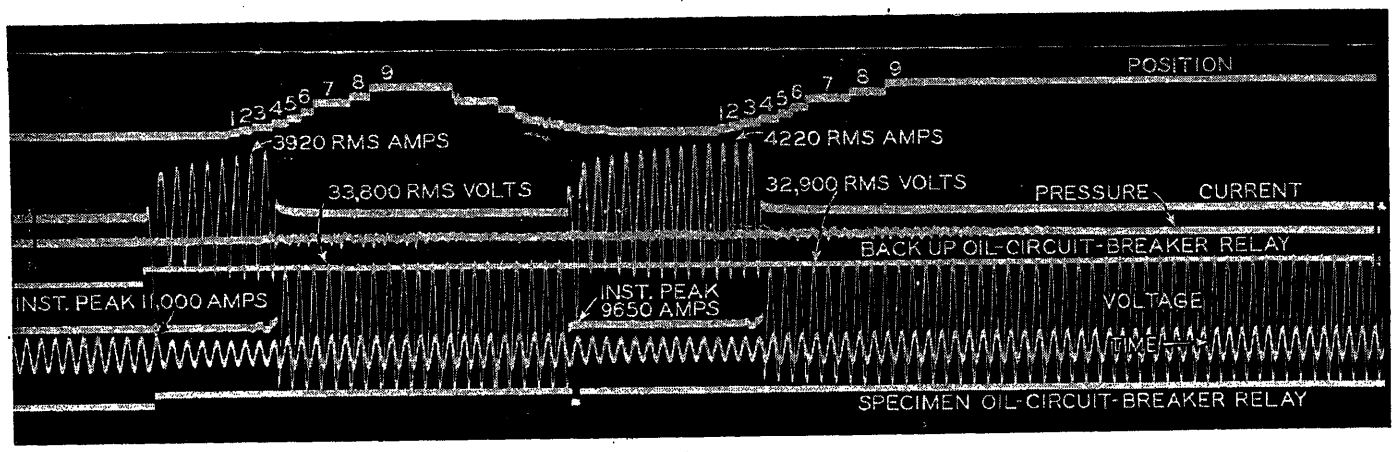

**Figure 5. Oscillogram of 69-kv field interrupting-capacity test on expulsion breaker operated by means of ultrahigh-speed control**

a space remote from that in which the blade opens. Contrary to many other modern arc-rupturing devices, no contamination of the major break path takes place, a fact which allows the accomplishment of a large number of successive rapid interruptions without any loss in effectiveness of the expulsion chamber.

For the purpose of interrupting capacity tests the control shown in figure 2 was connected to a single phase of a 15-kv expulsion circuit breaker. In this manner the smallest time interval between 2 successive interruptions was obtained. The results are shown in table I.

**Table II**

| Cause of Interruption | Fault Cleared After Immediate Reclosure | Fault Not Cleared After Immediate Reclosure |
|---|---|---|
| Lightning | 27 | 2 |
| Birds | 4 | |
| Insulation | 1 | 1 |
| Unknown | 1 | |

Interruption occurred in all cases without disturbance, without oil throw and without noticeable tank pressure. The arcing times for the first and second opening were substantially the same. The suitability of the expulsion chamber for ultrahigh-speed reclosing operation is, therefore, established for intervals in the order of 10 cycles. Figure 4 shows an oscillogram of the interruption corresponding to test 5, table I.

## Field Tests

A 69-kv expulsion oil circuit breaker equipped with the ultrahigh-speed reclosing control shown in figure 3 was given a field test to determine operation under immediate reclosing duty. Generating capacity of 75,000 kw was available at the test location, and an additional 90,000 kw capacity was feeding from remote sources into the short circuit. As shown on oscillogram figure 5, the equivalent 3-phase short circuit amounted to 400,000 kva during the first opening and to 420,000 kva during the second opening, the reclosing and de-energized period being 28½ cycles (including relay time) and 19½ cycles, respectively.

## Field Experience

The 69-kv breaker reported on under field tests has been in continuous operation since February 29, 1936; it protects a single-circuit 60-kv line, 113 miles long which is subject to severe lightning conditions. Up to December 31, 1936 the breaker was called to clear 36 short circuits, in 33 cases the fault was eliminated by means of the immediate reclosure and only in 3 cases did the breaker trip out a second time. Table II shows the causes of the short circuits.

It is hoped that additional field experience will soon be available on a reclosing breaker recently installed on a 115-kv tie line.

## Conclusion

An extremely simple motor-operated spring-actuated operating mechanism, suitable for ultrahigh-speed reclosing has been developed. In conjunction with expulsion oil circuit breakers it has been shown to provide an ideal means for immediate re-energizing of transmission systems. A 90-per-cent reduction in outages, previously reported by others is confirmed on an additional system. From limited experience the exact field of application cannot be completely defined, but indications are that ultrahigh-speed reclosing circuit breakers of this type will become more and more common. The simplicity of design of the mechanism gives promise of its use as a standard operating means, and if at a later date ultrahigh-speed reclosing is desired, but a slight change in wiring and instruments is required.

# Radiotelephone Noise Reduction by Voice Control at Receiver

By C. C. TAYLOR
MEMBER AIEE

## Introduction

IN TRANSMITTING speech over radiotelephone circuits there are a number of conventional methods of increasing the signal with respect to the noise. Examples of such methods are the use of higher power, directive antennas, diversity reception, and filters to narrow the received frequency band. In addition, there are other methods of a special character which reduce the effect of the noise interference with the speech transmission. One example of such a device limits the noise interference by eliminating the high peaks of noise of very short duration and depending upon the persistence of sensation of speech in the ear to bridge the gaps. Another method diminishes the noise in intervals of no speech. This is the method which will be discussed here.

## Speech and Noise Considerations

Speech signals may be represented by a group or band of frequencies occupying a certain interval of time. In using the conventional method of narrowing the received frequency band, filters eliminate all noise outside the band actually required. In fact we sometimes go beyond this and remove some of the outer frequency components of speech which are weak and submerged in the noise and therefore contribute little or nothing to the intelligibility. Experiments have shown the effect on voice transmission of removing portions of the frequency range.[1] Articulation tests were used to afford a quantitative measure of the recognizability of received speech sounds. These show that the upper frequencies may be cut off down to about 3,000 cycles without serious reduction in articulation. After such treatment, as the noise level increases, the weaker and less articulate sounds become more and more submerged in the noise and additional reduction in the detrimental effect of the noise is required.

In addition to the speech waves covering a frequency band they occupy intervals of time. The unoccupied intervals between the speech sounds contain noise. Reduction of the noise reaching the ear in these intervals has been found to result, under certain conditions, in an improvement in speech reception. This may possibly be explained by considering the characteristics of the ear.[1] It has been shown that noise present at the ear has the effect of shifting the threshold for hearing other sounds or has a deafening effect. That is, there is a reduction of the capacity of the ear to sense sounds in the presence of noise. For example, if a person has been listening to a noise for a certain period, his ear is made insensitive so that speech signals following are not so easily distinguished. The ear has a sensory build-up time, that is, a time needed for the noise to build up to a steady loudness. By reducing the noise in the intervals of no speech the average threshold shift seems to be diminished. Aside from this the presence of the noise tends to distract the attention from the perception of the speech. Removal of noise during the intervals of no speech tends to reduce this effect.

## Requirements

In considering the elimination of the noise during these intervals it is necessary to bear in mind certain characteristics of speech.[2] Speech waves may be regarded as nonperiodic in that they start at some time, take on some finite values and then approximate zero again. In connected speech it is usually possible to approximately distinguish between sounds and to ascribe to each an initial period of growth, an intermediate period which in some cases approximates a steady state and then a final period of decay. The duration intervals of various syllabic sounds vary from about 0.03 to as much as 0.3 or 0.35 second. When noise is high the weaker initial and final sounds become obscured so that they contribute little to the intelligibility.

In connected speech, silent intervals occupy about $^1/_5$ to $^1/_3$ of the total time. Also there are frequent intervals when the sounds are rather weak. However, if we attempt to suppress noise during all these intervals, experi-

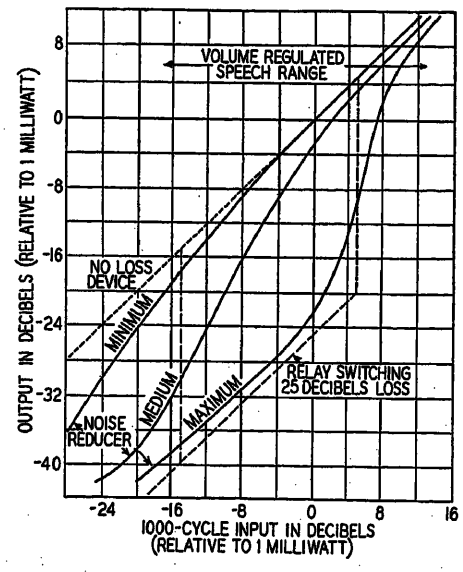

**Figure 1. Input-output comparison of noise reducer and voice-operated relay**

A paper recommended for publication by the AIEE committee on communication. Manuscript submitted June 4, 1937; released for publication June 25, 1937.

C. C. TAYLOR is a member of the technical staff of the Bell Telephone Laboratories, Incorporated, New York, N. Y.

1. For all numbered references, see list at end of paper.

ence shows that the suppression becomes too obvious, and the speech is apt to sound mutilated. For this reason the function of any device to be used for reduction of noise in the intervals between speech is to operate rather quickly to remove suppression and pass the speech and approximately to sustain this condition for sufficient periods to override weaker intervals so that obvious speech distortion does not occur.

To reduce the noise in the intervals between speech it is necessary to depend for control upon either the speech

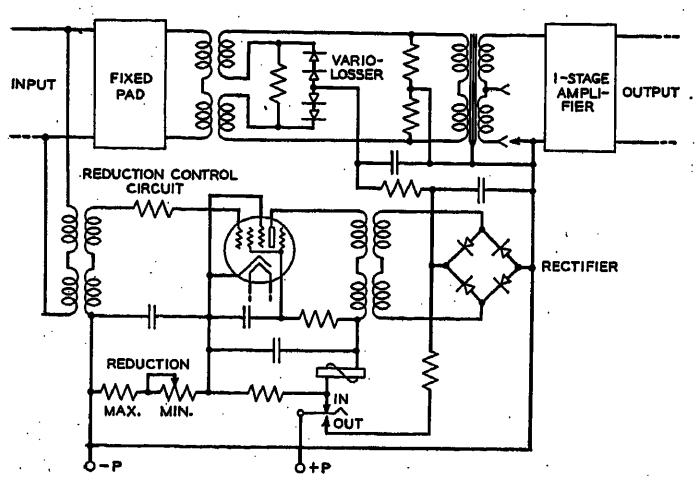

**Figure 2. Simplified schematic of noise reducer**

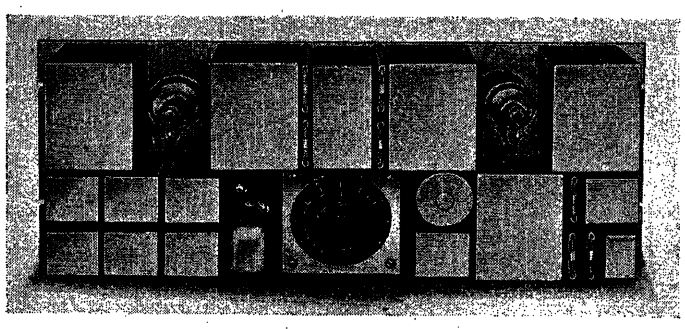

**Figure 3. Noise reducer panel**

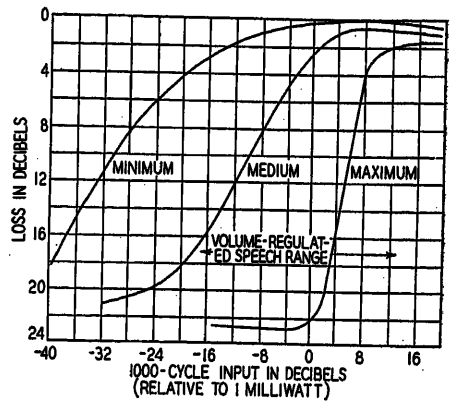
itself or upon some auxiliary signal usually under the control of the speech at some point in the circuit where the signal-to-noise ratio is better. This latter condition is illustrated on a circuit where the carrier is transmitted only during speech intervals. The carrier then acts as an auxiliary signal which operates a device at the receiver to remove loss.[3,4] The device to be discussed below utilizes the speech itself at the receiver to perform this function.

In using the speech in this way it is obvious that control can only be accomplished when the speech energy sufficiently exceeds the noise energy so that the presence of the speech is distinguishable. The device could operate abruptly as, for example, a relay which removes a fixed loss in the operated position and restores it when nonoperated. Experience indicates that the use of such a device makes the suppression too obvious if it is to follow the speech sounds closely. It is desirable, then, to perform this reduction by more or less gradually removing loss as the speech increases to accentuate the difference between levels of speech sounds and levels of noise which occur in the gaps between speech.



## Noise Reducer

This kind of performance has been secured in a device known as a noise reducer. A comparison of the action of the noise reducer and a relay having similar maximum loss is shown in figure 1. This figure shows the input-output characteristics of these devices over the voice amplitude range to which they are subjected on a radio circuit. The noise reducer may be likened to a relay with a variable loss, the loss not varying instantaneously but over a short period of time. The loss, for any short period, may be any value within the loss range and the device has, therefore, been likened to an elastic or shock absorbing relay.

The noise reducer has no loss for strong inputs, considerable loss for weak inputs and changes this loss gradually over a short interval of time. It introduces loss in the absence of speech but reduces this loss in proportion to the amplitude and duration of waves impressed upon it. The time required for the loss change is such that abruptness of noise change is absent and very short impulses of static do not effectively control the loss. This contrasts with a very fast limiter acting on high peak crashes only.

The noise may control the loss if its average amplitude is strong enough. Therefore, the control is made adjustable so that the noise waves are not permitted to control for any noise condition within the range of usefulness of

**Figure 4. Loss versus input for several settings of the reduction control**

this device. Thus the noise in the absence of speech is always reduced and the portions of the initial and decay periods of the speech sounds which are also reduced vary with this adjustment for noise intensity. Of course, if the speech-to-noise ratio becomes too small or if other transmission conditions interfere, an improvement becomes impossible.

## Circuit Arrangement

Figure 2 shows the circuit of the noise reducer in simplified schematic form.[5] Incoming waves pass from left

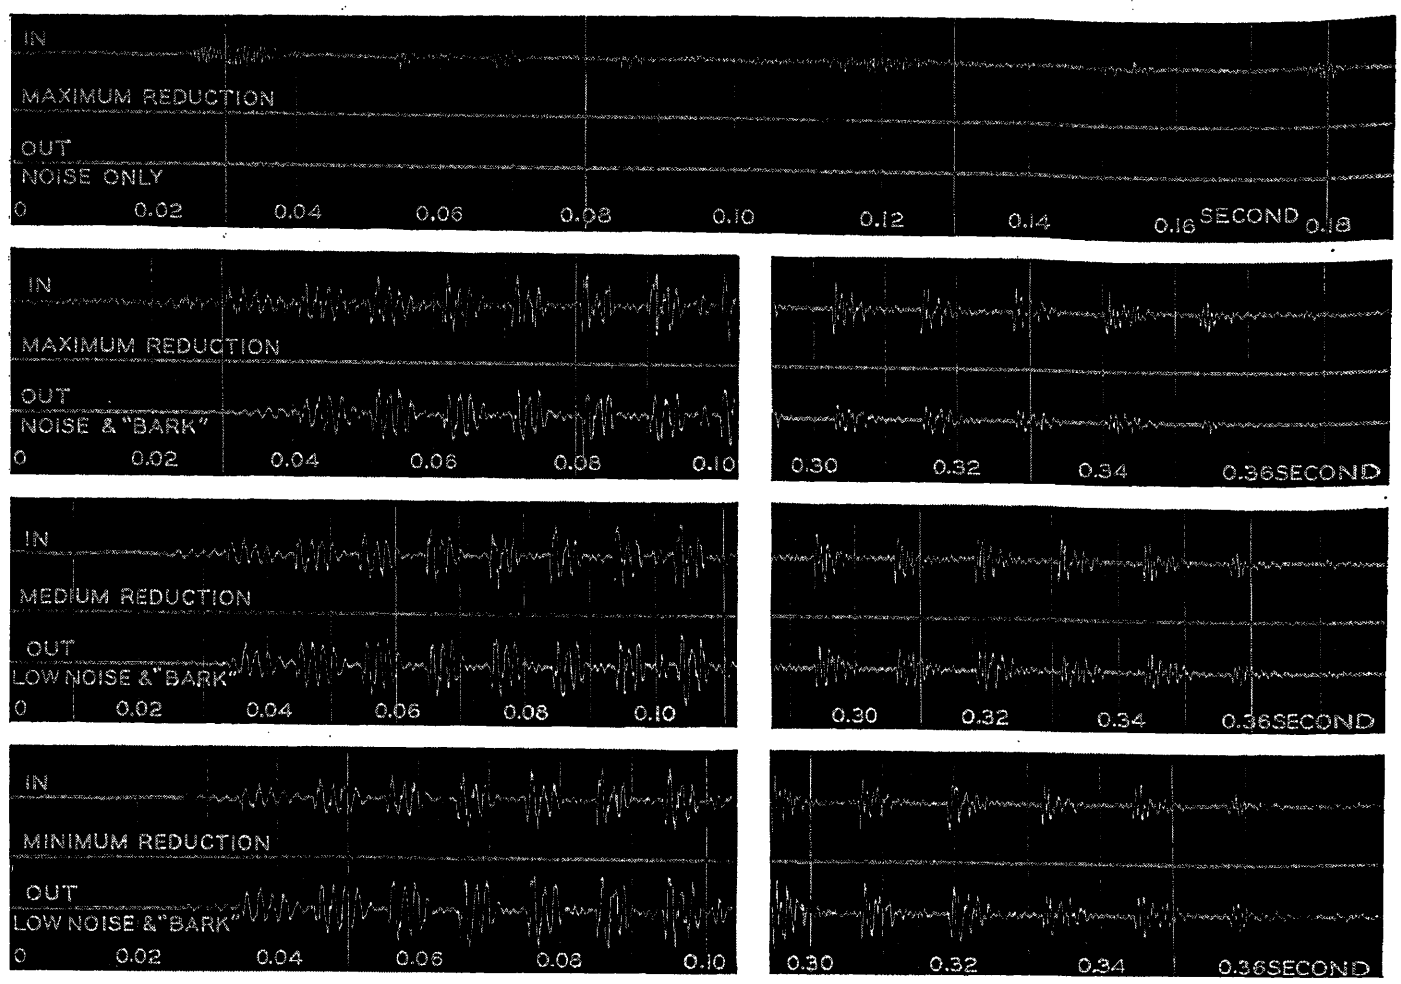


**Figure 5. Input and output for (top to bottom): high noise with maximum reduction; high noise with the beginning and ending of the word "bark"—maximum reduction; low noise, the word "bark"—medium reduction; low noise, the word "bark"—minimum reduction**

to right through the fixed pad, the vario-losser and the amplifier to the output. At the input, part of these waves pass through the reduction control branch circuit which includes a variable resistor, an amplifier, and a rectifier. The direct current produced by the rectifier is applied through the condenser and resistance filter to the copper-oxide losser circuit. For current below a threshold value, no appreciable change occurs in the losser and the loss introduced is about 20 decibels. As input increases, rectified current reaches a value where the loss begins to change rapidly. It becomes zero decibles at an input about 20 decibels above the point at which the loss starts to change. The design is such that the loss remains substantially constant for higher inputs.

The vario-losser makes use of the resistance variation with current of copper-oxide rectifier disks. This variable resistance shunts a fixed resistance in series with the windings of a repeating coil as shown in figure 2. The maximum loss is determined by the fixed resistance when small current is flowing through the disks while the varying loss is determined by the shunting copper-oxide resistance which decreases rapidly with increasing current above a threshold value until a low value is reached. The minimum loss is limited by the output of the control tube approaching a maximum and the shunting resistance becoming so small that additional decrease affects the loss inappreciably.

The variable resistor setting in the reduction control circuit determines the input amplitude at which reduction begins and therefore the point above which the loss remains substantially constant. If there is a difference in amplitude between speech and noise, the reduction control may be so adjusted that the noise on the circuit, when no speech is present, is appreciably reduced. The action then is as follows: In the absence of speech noise is reduced usually the maximum value of 20 decibles, during intervals of lower speech amplitudes the loss decreases in proportion to the increase in amplitude and during speech of high amplitude both noise and speech are transmitted without loss. As the noise encroaches upon the range of speech amplitude, it becomes necessary to reduce greater amplitudes, thereby also further reducing the weaker parts of speech.

The noise reducer is contained on a $7^1/_4$-inch panel for relay rack mounting. Figure 3 gives a front view. The panel contains the reduction control resistor and an "in-out" key which, in the "out" position, gives the device a fixed loss. Both resistor and key may be duplicated external to the panel with the wiring arranged to give remote control.

## Characteristics

Figure 4 gives the 1,000-cycle input-loss characteristic for 3 settings of the reduction control. For any setting, there is an input volume above which the loss remains constant, while for volumes below this the loss increases with decreasing input until the maximum loss is reached. The volume-regulated speech range encountered on radio circuits at some point in the circuit which is 5 decibels above reference volume as measured on a volume indicator is indicated as extending from +13 decibels to −17 decibels referred to one milliwatt for the purpose of showing approximate corresponding speech amplitudes.

Figure 5 shows oscillograms giving the input and output characteristics of noise for maximum reduction and of speech for maximum, medium, and minimum reduction. The upper trace is the input and the lower trace the output. The middle trace is not used. It will be noted by inspecting the "in" and "out" traces at the beginning and ending of the word "bark" that there is some distortion in speech for the maximum reduction condition, but very little distortion for minimum reduction. Maximum reduction would be used only in case of high noise where this distortion is less objectionable than the noise.

## Performance

Laboratory tests have been made in an attempt to evaluate the advantages to be gained by the use of the noise reducer. It was shown that, for the rather limited and controlled conditions which were tested, definite advantage can be observed in judgment tests of the effectiveness of speech transmission through noise with and without the noise reducer. This advantage is of the order of magnitude of 3 to 5 decibels at the border line between commercial and uncommercial conditions on the noisy circuit.

This figure is in approximate agreement with results obtained from records of performance on commercial connections. A curve is available which shows the approximate relation between percentage lost circuit time and transmission improvement for a long-range short-wave radiotelephone circuit.[6] From the records of lost circuit time as affected by the noise reducer use an improvement of 4 decibels is obtained from this curve.

Observations were made and records kept for 12 months of the use of the device at the land terminal of the high seas ship-to-shore circuit and for shorter periods on New York-London circuits. These observations indicate that the noise reducer most satisfactorily reduces objectionable effects where the interference consists of noise of a fairly steady character. As might be expected it is somewhat less effective on crashy static. If the noise is very low there is no improvement; as the noise increases the benefit increases up to a certain point; when the noise amplitudes begin to approach too closely the peak amplitudes of the voice waves it becomes impossible to distinguish between them without producing objectionable speech distortion and there is again no advantage. Where volume fading is present there is a tendency to accentuate the volume changes and it becomes necessary to adjust the reduction control to limit this. Otherwise this effect may offset the possible noise improvement. The operating practice is to adjust the reducer control circuit for each noise or transmission condition so that optimum reception as judged by the technical operator is obtained. The general rule is to use the minimum reduction possible.

## Use of Noise Reducer With Voice-Switched Circuits

On radiotelephone circuits for connection to the land telephone system, control terminal equipment is used at the junction of the land lines and the 2 one-way radio channels (one transmitting, the other receiving) necessary for 2-way communication. In making this connection a widely used method is one in which the 2-wire land circuit is normally connected to the receiving radio channel and is switched to the transmitting channel when the land subscriber talks. This switching is done by voice operated relays.[7,8] The noise reducer in addition to improving the intelligibility of the speech protects these voice-operated relays against false operation by the received noise.

## Introduction

IN THE past several years series capacitors for the compensation of line drop in power circuits have found increasing use,[1-9] because improved and automatic voltage regulation can, in many cases, be obtained more economically by this method than by any other means.

Most of the applications have been entirely successful in improving the system performance. However in a few instances unforseen difficulties of an unusual character have been encountered. These difficulties were the occasion of a systematic and detailed analytical study of series capacitor performance. This study has been paralleled, as far as possible with laboratory tests and correlated with field experience. It is believed that a satisfactory explanation and understanding of the abnormal system behavior have now been obtained and that adequate methods for predetermining the system performance have been developed, although it is recognized that the investigation cannot be regarded as absolutely final and complete.

The objects of this paper are to present a survey of some of the troubles which may be encountered in the application of series capacitors to power circuits, to present criteria for determining the range and probability of abnormal operation, and to describe methods for minimizing the difficulties.

Three types of abnormality have been investigated:

1. Distorted and excessively large transformer exciting currents, due to saturation.
2. Hunting of synchronous machines.
3. Self-excitation of induction motors.

In case 1, the application of voltage to an unloaded or very lightly loaded transformer through a series capacitor may result in abnormally large and distorted exciting currents. These large currents are not simply transients but persist as a steady-state condition. This type of circuit, that is, a saturable inductance in series with a capacitor, has been found to have at least 2, and probably more, different steady states, depending on how the voltage is applied.

Solutions of the equations for this type of circuit have been found by the differential analyzer[10] at the Moore School of Electrical Engineering and are discussed in section I.

In case 2, interconnected synchronous machines will oscillate or "hunt," under certain circuit conditions. The tendency to hunt becomes more pronounced as the effective ratio of line resistance to line reactance increases, and putting in a series capacitor to decrease the reactance obviously increases this ratio. Consequently, if the machines are susceptible to hunting, the condition is further aggravated by the addition of capacitors. The case of hunting of a single synchronous machine operating from an infinite bus was investigated several years ago.[11,12] In section II of the present paper, further analytical methods are developed involving 2 or more machines which enable the size and location of a capacitor to be so chosen as to product the least tendency to hunt consistent with proper voltage regulation.

In case 3, under certain circuit conditions an induction motor operating with series capacitors will be self-excited and will generate other voltages of lower than normal frequency and thus produce objectionable voltage fluctuations. Analytical methods are presented in section III, which make it possible to determine the effectiveness of methods for eliminating this trouble.

It has been found in this investigation that the addition of a resistor in shunt with the series capacitor will eliminate the difficulties of cases 1 and 3, while the synchronous machine hunting of case 2 is minimized or not obtained by proper choice and location of the capacitor. The shunt resistor is of such a high value as not to interfere with the capacitor's effective operation as a line drop compensator and the value of the power loss in the resistor necessary to ensure complete freedom from these circuit troubles will in general be less than 10 per cent of the resistance loss in the line to be compensated. The proper value of resistance to be used in any given case may be determined from the analysis presented here. It is concluded, therefore, that the material offered in this paper, will enable practical and economically sound series capacitor applications to be made with confidence that the operating results will be in accordance with predictions.

## Section I—Distorted and Excessively Large Transformer Exciting Currents

### A. General

In the usual case of application of voltage to an unloaded transformer it is known that if the voltage is applied at or near the zero point of the voltage wave a high inrush current may result. This is because the transformer flux tends to rise, in the first half cycle, to double its normal value, with consequent excessive magnetizing current due to the very high degree of saturation. Stated in another

A paper recommended for publication by the AIEE committee on power transmission and distribution. Manuscript submitted June 1, 1937; released for publication June 28, 1937.

J. W. BUTLER and C. CONCORDIA are in the engineering division, central station department, General Electric Company, Schenectady, N. Y.

1. For all numbered references, see list at end of paper.

way, at high values of flux the effective inductance of the transformer becomes very low. The high inrush current lasts for several cycles and then the transformer draws only its usual low value of exciting current. On the other hand, if the transformer is supplied through a series capacitor an abnormal current may persist in the steady state. That is, the energizing of an unloaded or very lightly loaded transformer through a series capacitor may result in a continuous abnormal flow of exciting current. This current may be equal to or even greater than full load current and is of an apparently very low frequency, resulting in a badly distorted current wave. Under this condition of excitation the secondary voltage is also badly distorted, and it likewise is largely composed of a lower frequency component. Oscillographic records of the magnetizing current, the secondary voltage and the voltage across the capacitor when a circuit is in this state of excitation are shown in figure 1.

These abnormal steady-state currents flow when the voltage is applied at or near the zero point of the wave just as the high transient occurs for this condition in the ordinary case without the series capacitor.

This phenomenon has been reported before[13–16] in the technical press and is sometimes called "ferro-resonance." The peculiar circuit behavior depends essentially on the nonlinear transformer characteristics and not on any secondary features such as hysteresis, eddy currents, etc.

The nonlinear characteristic of the transformer makes the mathematical analysis very difficult and to the authors' knowledge there has been no satisfactory analytical solution made as yet.

The differential analyzer at the Moore School of Electrical Engineering was used, with the able assistance of Irven Travis and C. N. Weygandt, to obtain solutions to the nonlinear differential equations of this circuit. Appendix *A* gives the equations of the circuit and the form into which they were put to adapt them to the analyzer.

The single-phase circuit, as shown by figure 2, was set up and investigated thoroughly before the 3-phase case was studied, as it was believed that the essential features of the phenomenon could be obtained more directly in this manner. A schematic diagram giving the analyzer set-up for equations 2*a* and 3*a* is shown in figure 3.

The 3-phase circuit was set up as a final check and the results obtained indicated that the single-phase results were qualitatively applicable.

Typical curves drawn by the analyzer as solutions to equations 2*a* and 3*a* are shown in figures 4, 5, and 6.

A short simplified explanation of the physics of the phenomenon will be made here, for the sake of completeness.

## B. Qualitative Explanation of Phenomenon

These abnormal currents may be explained as follows: Consider that the voltage is applied to the transformer at the zero point of the wave. During the first part of the cycle the flux in the core builds up just as though the capacitor were not present, since the current drawn is so small that there is no appreciable voltage drop across the capacitor. However, as soon as saturation is reached, the current drawn becomes very large and a voltage soon appears across the capacitor. The voltage absorbed by the capacitor prevents the flux from building up to as high a value as it would have without the capacitor, so the first half cycle inrush current is somewhat less. Moreover, as the flux tends to remain offset it does not reach a high value in the negative direction in the second half cycle. To the contrary, it may hardly dip below zero. Thus the exciting current remains very small (or, the transformer inductance remains very large) for the interval following. The charge is therefore left on the capacitor, which simply acts as an additional voltage source. This additional voltage tends continually to depress the transformer flux, just as in the first half cycle it prevented the flux from reaching double its normal value. Thus in the second cycle the flux may not go high enough to saturate the core so no additional charge is put on the capacitor. On the other hand, as practically no charge has leaked off, the capacitor voltage is still decreasing the flux. The general effect is as shown in figures 4*b* and 4*c* and is that of first

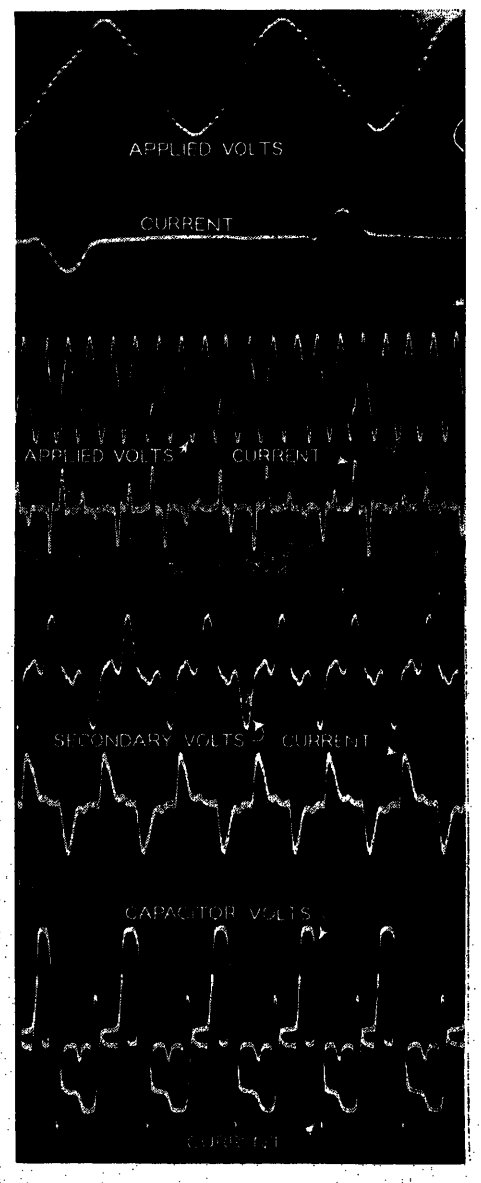

**Figure 1. Oscillograms of abnormal currents and voltages obtained when transformer is excited through series capacitor**

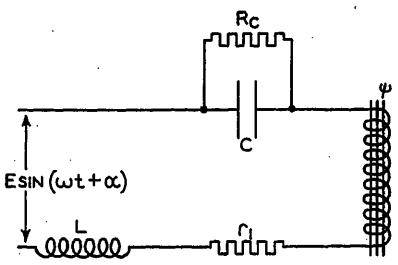

**Figure 2. Circuit diagram of transformer energized through a series capacitor, series impedance, and shunting resistance $R_c$**

tending to reduce the offset and then actually to build up an offset in the negative direction. This process continues, at a rate proportional to the magnitude of the voltage trapped on the capacitor, until saturation is reached in the negative direction. When this occurs a large negative current is drawn, discharging the capacitor. This large negative current may discharge the capacitor partially, completely, or may put on a charge in the reverse direction. It is easily seen that, except for a fortuitous combination of circumstances, the discharge will be either partial or an overshoot. If it is partial the flux will reach a larger negative value at the next cycle, and then the capacitor will receive an opposite charge. This negative charge will, of course, have the effect of reducing the negative offset and then building up a positive offset, so that the cycle of abnormal operation is complete.

Since the rate of decrease of offset is proportional to the voltage on the capacitor, the apparent frequency of occurrence of these large currents (due to saturation being reached) is necessarily dependent on the voltage applied and on the angle at which it is applied. For instance, the larger the initial charge on the capacitor, the sooner it will build the linkages down to the saturable place on the negative side, and give a higher frequency appearance to the exciting current.

In order to demonstrate this property of the circuit, solutions, as given by the analyzer with different values of voltage applied at the zero point of the wave, are shown in figure 4. The periodicity increasing with the applied voltage is clearly seen. If the voltage is increased sufficiently, the circuit can be made to saturate every half cycle and results such as those obtained by Suits[17] are then obtained.

## C. Summary of Results Obtained From the Differential Analyzer

It is felt that the major contribution this investigation made was that of explaining and clarifying to a certain degree the physics of the phenomenon. In order to appreciate the "goings on" in the circuit, fundamental circuit concepts must be kept in mind, as vector diagrams, resonance, sustained harmonic solutions, and other linear circuit concepts fail when nonlinear parameters are employed.

The effect of a damping resistor shunting the capacitor was investigated and the results are summarized in figure 7.

In these figures, the region above each curve represents an unstable or abnormally excited circuit condition; that is, if a given circuit has a value of capacitance and shunting resistance that fall in the area above the corresponding

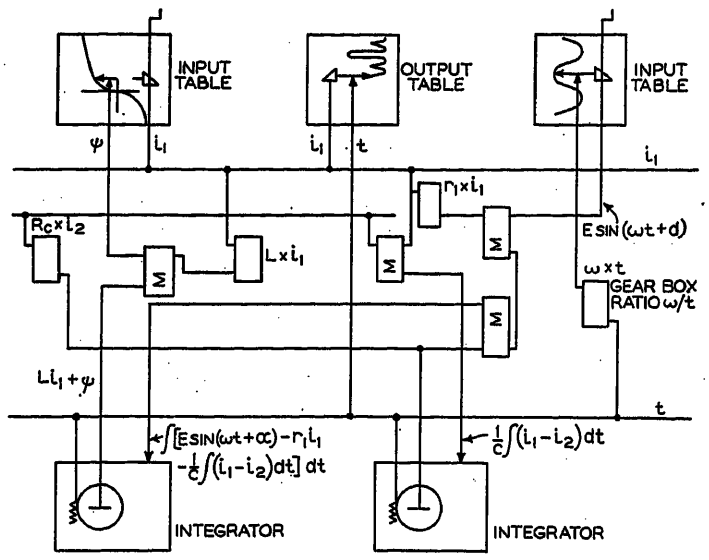

**Figure 3. Schematic diagram of differential analyzer connections for solution of circuit equations**

curve and the voltage is applied at or near the zero point on the wave, the circuit will draw a sustained large distorted magnetizing current. All points below each curve represent a so-called stable area where the circuit will have its normal low value of magnetizing current. The various curves show the effect of changing the line reactance, the line resistance, and the transformer iron characteristic. The 2 iron characteristics are shown in figure 8. Curve 1 represents the magnetization curve of a modern transformer. Curve 2 was taken arbitrarily to have the current scale of curve 1 multiplied by 3 merely to show the effect of a different magnetizing characteristic or of a larger transformer.

In figure 7 the value of capacitance, to which the left side of each curve is asymtotic, represents the value of capacitive reactance that must be used to prevent the circuit from going into a state of overexcitation without a damping resistor. Unfortunately these values are so low, that they can seldom be useful in correcting a bad voltage condition.

These curves were all determined for normal voltage applied at the zero point of the wave. In certain cases, it may be found that a resistance sufficient to insure normal operation under these conditions will not be low enough if the system is operated at a different voltage. For example, figure 5 illustrates a case in which reducing the voltage caused an abnormal state of excitation. Curve 1 shows normal operation at normal voltage, while curve 2 shows the overexcited condition occurring when 0.75 voltage is applied. Both voltages were applied at the zero point of the wave. This indicates also that in some cases the application of voltage at the zero point of the wave may not be the worst condition since in a sense a shift of angle is partially equivalent to a reduction of voltage, at least as far as the initial charge given to the condenser is concerned.

A circuit having a resistance shunting the saturable inductance, simulating a load being taken off the circuit

between the transformer and the capacitor, was also investigated on the differential analyzer. The critical points obtained with this circuit agreed very well with the points for the same resistance when it was shunting the capacitor, indicating that it made little difference where the resistor was located.

From figure 2 it may be seen that the 2 locations of the resistor are equivalent to 2 locations of the applied voltage, the circuit remaining unchanged. Further, in the canonical equations for a general linear circuit, consisting of any number of meshes, the characteristic determinant is independent of the magnitude or location of the applied voltages. It is therefore evident that the *form* of the transient response, or the building up or dying away of a transient current, is also independent of where the voltage is applied.

This reasoning, showing that in a *linear* circuit, the location of the resistor does not affect the periodicity of the circuit, combined with the differential analyzer results for the nonlinear circuit, indicate that this may well be a general conclusion. It has been known in practice that intervening or secondary loads prevent this overexcitation condition, but the effect had not been previously investigated quantitatively.

## D. Conclusions

An unloaded transformer, operating at normal densities, if excited through a series capacitor of reasonable reactance, is susceptible to conditions of large distorted magnetizing currents. These abnormal conditions can be restored to normal by the addition of a suitable shunting resistor to the capacitor, as indicated by figure 7, or by the locating of a certain amount of load on the load side of the capacitor.

The resistor shunting the capacitor, introduces additional losses. However, in general, this loss is less than 10 per cent of the normal line loss and this can usually be justified by the improvement in voltage regulation. Moreover, since the presence of the abnormal condition depends on the initial transient, it may be eliminated by shorting out the capacitor only while the starting switch is being closed, or by having the resistor connected only during the energizing period. The shorting switch or temporary resistor may readily be arranged so as to function automatically whenever the abnormal condition tends to develop.

# Section II—Hunting of Synchronous Machines

## A. General

An electric power system consists in general of a group of interconnected synchronous machines together with impedance and induction motor loads. Any such system is subject at practically every instant of its existence to disturbances caused by changes in load, switching, pulsating loads, pulsating driving torques, changes in excita-

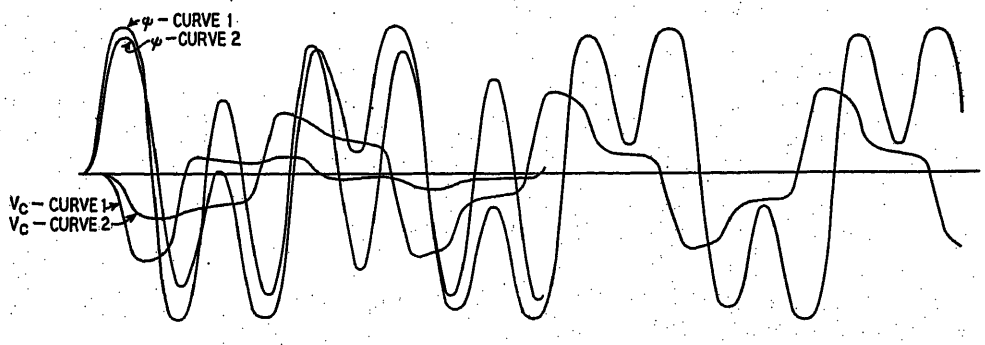

**Figure 5. Effect of voltage on excitation**

Curve 1 $E = 1.0$. Normal excitation, capacitor voltage decreases

$R_e = 6.3$ $r_1 = 0.197$
$\alpha = 0$ Magnetization curve 2

tion, etc. These disturbances tend to set up rotor oscillations of the synchronous machines, with consequent voltage and frequency pulsations. Therefore, for satisfactory operation, the system constants must be such as to cause any such oscillations to disappear rapidly if due to a momentary disturbance, or to remain of small amplitude if due to a continuous pulsating force. A momentary disturbance will, in general, produce oscillations of the synchronous machines at all of the principal natural frequencies of the system, while a sustained pulsating force of any frequency will of course produce machine oscillations of the same frequency.

## B. Effect of Line Resistance and Series Capacitance

The inherent damping of the system is usually sufficient to prevent severe hunting. However, in certain cases the damping may be either too small to be effective or may actually be negative. That is, the rotor oscillations may be amplified rather than damped out. There are present in all systems 2 conflicting effects. Resistances in the rotor circuits, some types of load, and mechanical friction will produce true damping of rotor oscillations, while resistance in the lines or armature circuits tend to produce amplifying rotor oscillations (or negative damping).

In the case of a single synchronous generator connected to an infinite bus, it has previously been shown[11,12] that the ratio of line resistance to line reactance determines whether or not there is negative damping, and that if all rotor circuits except the field winding are neglected, there is a critical operating angle determined by this ratio above which the machine is unstable. The critical angle is always decreased by the presence of rotor windings, so the method provides a conservative criterion.

If a series capacitor is used in the line the ratio of line resistance to line reactance is increased, since the reactance has been reduced. Consequently the tendency toward negative damping is increased.

## C. System of Several Machines

In case of a system consisting of several machines, it is shown in appendix $B$ that there is a corresponding relation among the line resistances and reactances which determines the negative damping and that therefore such damping will be affected by the insertion of series line capacitors. However, it cannot be expected now to be a simple resistance-to-reactance ratio; instead the criterion for stable operation is a ratio of certain combinations of line constants. For example, if the case treated in reference 11 is extended to include shunt loads taken off the line, the criterion becomes the ratio of the resistance to the reactance components of the transfer impedance between the synchronous machine and the infinite bus (see appendix $B$, equation 8$b$).

In appendix $B$ a system consisting of 2 synchronous generators, an infinite bus, and a shunt load (see figure 9) has been analyzed. This is believed to be sufficiently general to form a basis for the study of almost any particular case which may arise. The critical operating angle of either generator in this general case is shown to be dependent not only on the ratio of combinations of the line constants, but also on the operating angle of the second machine and on its relative amplitude and phase of oscillation. The line constants enter the equation as ratios of the resistance to the reactance components of the several transfer and driving point impedances and so are correlated to the criterion developed by Nickle and Pierce.[11]

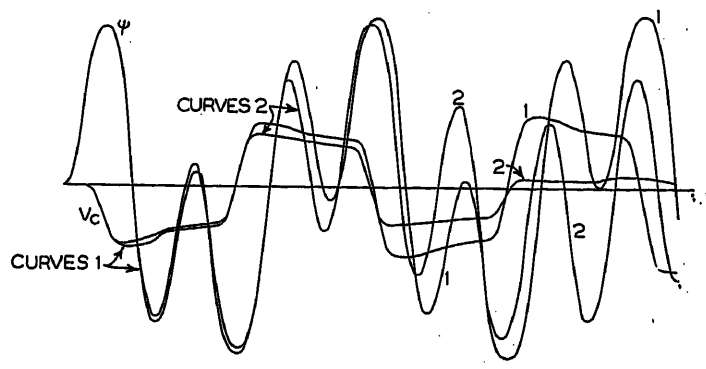

**Figure 6. Linkage and capacitor voltage curves with critical values of $R_c$**

Curve 1— $R_c = 6.7$. Abnormal, capacitor voltage builds up
Curve 2— $R_c = 4.2$. Normal, capacitor voltage decreases
$\alpha = 0$ $r_1 = 0.197$ Magnetization curve 1
$L = 0.394$ $1/C = 0.21$

The equations of appendix $B$ may be used to study any particular proposed series capacitor application to determine whether or not it is in the danger zone and, if it is, to determine the optimum location and maximum permissible reactance of the series capacitor consistent with proper line drop compensation. These equations also enable the effectiveness of putting additional series reactance in certain machine circuits to be evaluated.

## D. Discussion of Results

As an example of the method of analysis, a problem in which the circuit may be represented as in figure 9 has been worked out. In this case the synchronous generators at 1 and 4 ordinarily supply the load, line 3 merely acting as a tie to the large system at 3. However, occasionally power must be supplied to 4 from 3. Under this condition the voltage regulation at 4 is rather poor and it is desired to correct it by the insertion of a series capacitor between points 3 and 4. As considerable line drop occurs in line 3 the logical place to put the capacitor might seem to be in that line so as to give loads at 2 some benefit. Unfortunately, when this is done the hunting of machine 1 is found to be excessive, while if the capacitor is placed in line 4 hunting is no worse than without the capacitor. The desired result of correcting the bad voltage condition at 4 is accomplished by putting the capacitor in line 4. However in this location the additional advantage of correcting the voltage at the junction is not obtained.

Table I shows the results of calculations of the minimum permissible load angle of machine 1 for stability, under the 3 conditions of no capacitor, capacitor in line 4, and capaci-

tor in line 3, and also for different reactances in branch 4 and with and without shunt load. It is evident from this table that the capacitor in 4 causes a much smaller difference from the original condition than it does when in branch 3.

Although a picture can thus be obtained of the relative tendencies toward hunting of several proposed arrangements, it has not been absolutely determined by calculation that one arrangement will operate satisfactorily and another will not. This is still a matter of judgment fortified by a correlation of field experience with the calculations.

The critical angles recorded in table I are the load angles $\delta_1$–$\delta_1'$ where $\delta_1$ is found as described in appendix *C* and $\delta_1'$ is the no-load angle of machine 1 referred to the infinite bus 3. The oscillation of machine 4 was neglected (i.e., $k = 0$), since it was assumed that the machine being investigated would have the largest amplitude of oscillation. Also it was found that the necessary load angles were only slightly affected by the operating angle $\delta_4$ of machine 4. It is therefore possible to use the simplified formula (8*b*.1) for nearly every case by simply substituting the value of $z_3$ ($z_3 = r_3 + jx_3$) paralleled with $z_4$ for the $z_3$ of equation (8*b*.2).

A more exact study of a system may be made by taking the amortisseur windings of the machines into account and computing the damping coefficients by the methods of reference 25 for every probable mode of vibration. The modes of vibration corresponding to the 2 principal natural frequencies of the system of figure 9, or to any impressed forces, can be very simply calculated if the inertia constants of the machine are known. This will not usually be necessary, however, since sufficient information can be obtained from a study of the system neglecting amortisseur windings and a knowledge of the general effects of such windings. (See, for example, reference 19.)

**Table I**

| Condition | Critical Load Angle ($\delta_1 - \delta_1'$) of Machine 1 (Degrees) |

## Section III—Self-Excitation of Induction Motors

### A. General

It is well known that an induction machine will operate as a generator and that such operation depends on the supplying of excitation from either a synchronous machine or a capacitor even though in case of the capacitor the operation has not previously been very well understood.

Now consider an induction motor supplied through a line containing a series capacitor. Then in addition to the currents flowing due to normal operation of the motor, under certain conditions the motor may act as an induction generator of current of lower than normal frequency. This low-frequency current is limited only by the impedance of the supply circuit at the low frequency, and may reach relatively large values. These large low-frequency currents manifest themselves not only as current surges and voltage swings but also as strong oscillations of the motor rotor caused by the large pulsating torques produced.

This phenomenon of self-excitation will not always take place and may always be entirely eliminated by sufficient line or shunt resistance, or by judiciously locating the capacitor. It may, moreover, be calculated with reasonable certainty and accuracy by equations given in appendix *C*, if the circuit constants and operating conditions are known.

Figures 10 to 13 show the regions in which self-excitation is likely to occur for the case of a purely induction motor load. Figures 10 and 11 show the effect of series

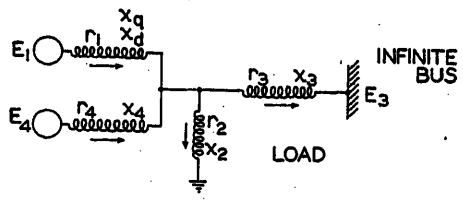

**Figure 9. Circuit diagram of 2 synchronous machines connected to infinite bus and impedance load**

line resistance in preventing self-excitation, while figures 12 and 13 show how a resistance in shunt with the capacitor can eliminate the phenomenon. For any practical case the reactance of the series capacitor will of course be much less than $x'$, probably about half of $x'$, since $x'$ is the short-circuit reactance of the motor including line reactance and since the capacitor reactance will usually be no greater than line reactance. Therefore figure 14 is given, showing the shunt resistance necessary to prevent self-excitation in the useful range of capacitance, for 2 sets of system constants.

The values of shunt resistance given in the curves will usually be conservative because the effect of series line resistances and machine losses, which themselves tend to damp out self-excitation, has been neglected. Equations are given in appendix *C* which take both shunt and series resistance into account and which should be used to analyze any specific problem. These are based on the analysis presented in reference 20. Figure 15 shows an example of how the value of $\alpha$ necessary for stability decreases with increasing line resistance.

## B. Discussion of Results

Figure 10 shows that as long as the capacitive reactance is less than half of the system short-circuit reactance, self-excitation will not occur for a normally loaded group of induction motors. This is because the line resistance is usually great enough to damp out any tendency to self-excite. However, as soon as a certain critical value of short-circuit reactance is exceeded the amount of series resistance required begins to increase rapidly. This critical value of reactance is, of course, a function of the motor characteristics and the impedance of the connected circuit. If the line is relatively short (i.e., if its reactance is less than the motor reactance) it may be compensated more than if it is long, unless a shunt resistor is added to prevent self-excitation.

Figure 11 shows that as the motor speed decreases the region of self-excitation moves down along the $x_c$ ordinate. That is, the tendency to self-excite occurs at a lower value of capacitive reactance at lower motor speeds. Such low speeds occur during starting and during periods of overload. We should thus expect some oscillations as the motor comes up to speed. This is especially true if a starting resistance is used in the rotor, as figures 10 and 12 indicate that an increase of rotor resistance increases the tendency to self-excite. In general it will not be necessary to eliminate these transient oscillations. Actually, in service when the system behaves correctly under normal operating conditions no trouble during starting has been experienced. If, however, the system does not have very much margin at normal load, a sustained overload may produce self-excitation.

## C. Calculations and Test Results

In order to check the theory offered for this so-called "self-excitation phenomenon," tests were conducted on a miniature set-up, in order to get good control of the variables. A 3-phase $^3/_4$-horsepower wound-rotor induction motor was connected to a power source through a series capacitor and 0.39 per unit external reactance. The values of series capacitance were varied over the complete range of self-excitation, and the corresponding value of shunting resistance to insure normal operation was determined. These tests results, and corresponding calculated points on the curve are shown plotted in figure 16. The agreement between test and calculated values was very gratifying. It is felt that the equations offered can be used with confidence in predetermining these regions of abnormal operation.

The motor was tested running light, hence the speed was taken as unity to simplify the calculations. The armature resistance of the motor and external circuit was 0.10 per unit. This high circuit resistance is the reason for the curve in figure 16 intersecting the $\alpha = 0$ point at such a high value of $x_c$. The rotor resistance was likewise very high, hence the motor had a correspondingly small rotor time constant. The small rotor time constant gives the motor a greater tendency to self-excite as shown in figures 10 and 12.

In view of the type of motor tested, that is, one having high resistances, these test results should not be generalized as significant of normal motor performance.

The line of demarkation between normal operation and

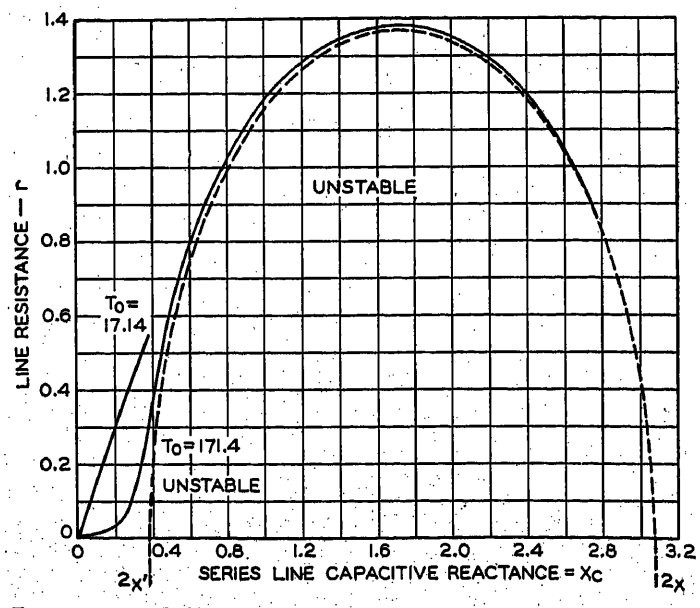

**Figure 10. Self-excitation of induction motors with series capacitors**

Showing series resistance required for stable operation as a function of the line capacitance and showing effect of varying rotor resistance

$x' = 0.4$ $x = 3.24$ $T_o = 171.4$ and 17.14 $\omega = 0.975$

self-excitation was very sharp up to $x_c = 0.6$. Calculations and tests both showed this. Beyond $x_c = 0.6$ the calculated curve became more difficult to determine because it seemed to be very broad in the upper regions, that is, it was difficult by ordinary slide rule methods to get a smooth curve, indicating the critical region was not very sharply defined. Tests bore this point out in the upper regions. The test points plotted are the largest values of $\alpha$ found for each value of $x_c$. The current wave was watched through an oscilloscope and self-excitation could be readily recognized by a change in the wave. In the lower regions below $x_c = 0.6$, the phenomenon was more violent and critical. A change of a few per cent in the value of shunting resistance $R$ in this region, would be sufficient to change the circuit from normal to a definite state of self-excitation. The region of self-excitation in the practical and useful range of $x_c$ can be readily recognized by calculation since this range is below $x_c = 0.6$.

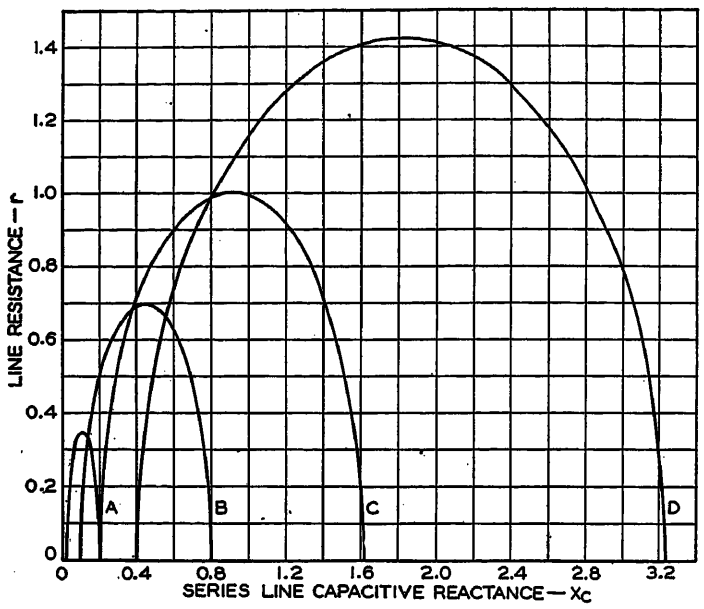

**Figure 11. Self-excitation of induction motors with series capacitors**

Showing effect of varying motor speed
$A$—$\omega = 0.25$ $B$—$\omega = 0.5$ $C$—$\omega = 0.707$ $D$—$\omega = 1.0$
$x' = 0.4$ $x = 3.24$ $T_o = 171.4$

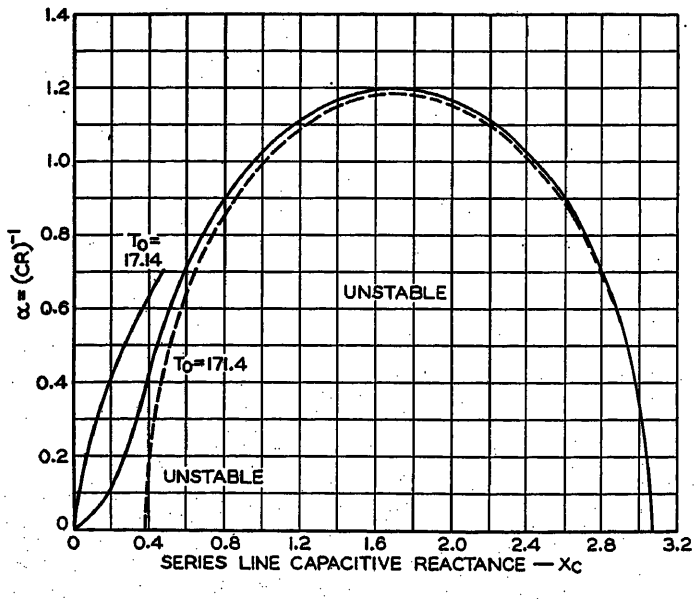

**Figure 12. Self-excitation of induction motors with series capacitors**

Showing resistance (in shunt with the capacitor) required for stable operation as a function of the line capacitance and showing effect of varying rotor resistance
$x' = 0.4$ $x = 3.24$ $\omega = 0.975$ $r = 0$

Figure 17 is an oscillogram of the current flowing in one phase during the motor starting period, and of the subsequent flow of current when the circuit is in the state of self-excitation. It will be noted that in this case the motor came up to speed in the normal manner, with normal inrush and sustained current. However in several cycles the current built up to several times normal with obvious superposed frequencies, which are identified as the natural currents of the system having positive decrement factors. These currents are ultimately limited in magnitude by saturation and the current builds up until the circuit constants change to a value that will not permit further self-excitation.

## D. Self-Excitation of Synchronous Machines

It has been stated above that in circuits containing series capacitors and induction motors, there may be a tendency to self-excite and that in circuits containing series capacitors and synchronous machines there may be a tendency toward hunting. It is evident, however, that the tendency to self-excite (that is, to generate amplifying current oscillations even though the rotor inertia prevents hunting) exists also in synchronous machines. It has been possible to obtain a satisfactory explanation of operating experience with synchronous machines on the basis of hunting alone but it is conceivable that under certain conditions purely electrical self-excitation may be encountered.

While this matter has not been thoroughly studied, the phenomenon is familiar in relation to the determination of the line charging capacity of synchronous generators. S. B. Crary,[21] M. Takahashi,[22] and Y. H. Ku[23] have made a study of this subject and have shown the tendency of line resistance to reduce the self-excitation. By means of the theory given in reference 20, it may further be shown that a resistance in shunt with the capacitor may also be used to eliminate the self-excitation (see appendix *D*). Figure 18 shows, for the same generator as in figure 1 of reference 21, the effect of shunt resistance.

Since the effect of rotor circuits in addition to the main field has not yet been determined, no definite conclusions can be drawn from this curve, but it is believed worthwhile to point out the existence of such self-excitation and to indicate that it may be corrected exactly as in the case of induction motors. The phenomena of self-excitation and hunting may of course exist simultaneously and are mutually dependent to a limited extent. Their mutual effects have not yet been studied exactly.

The ideal procedure, from a mathematical point of view,

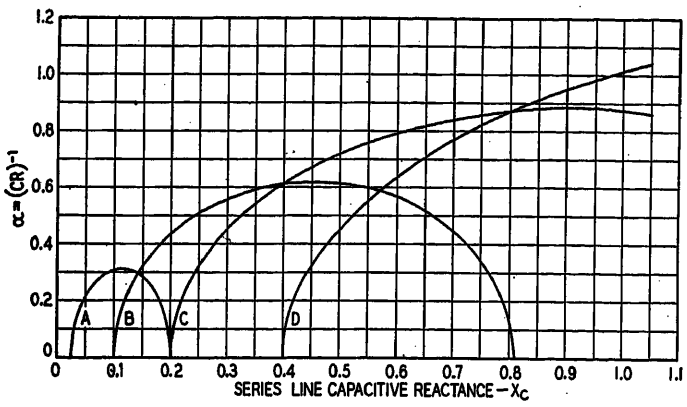

**Figure 13. Self-excitation of induction motors with series capacitors**

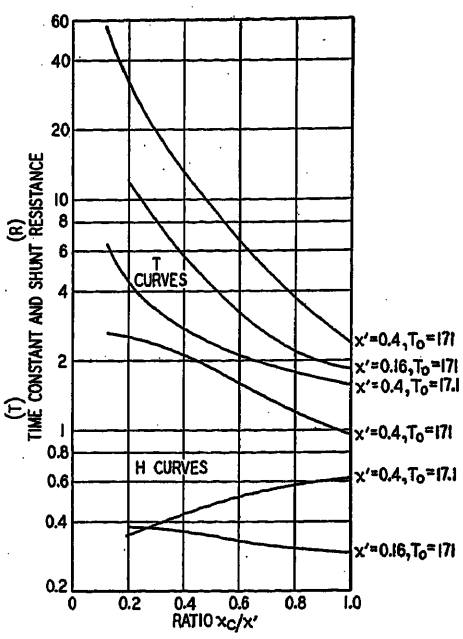
Showing effect of varying motor speed

$A$—$\omega = 0.25$ $x' = 0.4$ $B$—$\omega = 0.5$ $x = 3.24$ $C$—$\omega = 0.707$ $T_o = 171.4$ $D$—$\omega = 1.0$ $r = 0$

would be to set up the equations of motion of the circuit including both electrical and mechanical motions, and then to find out whether the system as a whole was stable or unstable. This method brings out very clearly the basic identity of the phenomena of hunting and self-excitation but is, from an engineering point of view, at present impracticable because of the excessive labor involved in the calculations. It is believed that the results obtained by the approximate studies are practically the same as would be found by the unified method.

## Nomenclature

### Section I



$E$ = applied voltage, maximum value
$t$ = time in radians
$\alpha$ = phase angle of applied voltage
$r_1$ = line resistance
$i_1$ = line current
$i_2$ = current through $R_c$
$R_c$ = resistance shunting the capacitor
$L$ = line inductance
$C$ = capacitance
$\psi$ = flux linkage
$V_c$ = voltage across capacitor

### Sections II and III

$E$ = internal voltage
$e_d$, $e_q$ = direct and quadrature axis terminal voltages
$\psi_d$, $\psi_q$ = direct and quadrature axis flux linkages
$i_d$, $i_q$ = direct and quadrature axis currents
$x_d$, $x_q$ = direct and quadrature axis synchronous reactances (section II)
$r$ = stator line resistance per phase
$\delta$ = angle of voltage $E$ from some reference point
$\theta$ = angular displacement of rotor
$\omega = p\theta$ = rotor speed
$x_c$ = line series capacitive reactance
$T_o$ = rotor time constant with open-circuited stator
$x$ = direct or quadrature axis synchronous reactance of induction motor including line reactance
$x'$ = direct or quadrature axis transient reactance of induction motor including line reactance
$\alpha = x_c/R$

**Figure 14. Self-excitation of induction motors with series capacitors**

Showing resistance (in shunt with the capacitor) required for stable operation as a function of the line capacitance for various systems
$x = 3$ $r = 0$
$\omega = 0.975$

$R$ = resistance in shunt with the capacitor
$k = \dfrac{\partial \delta_m}{\partial \delta_n}$
$m, n$ = subscripts given to currents, voltages, impedances, and angles in relating them to certain machines and circuits as used in section II

## Appendix A—Derivation of Equations Set Up on the Differential Analyzer

The single-phase circuit analyzed is represented in figure 2. The magnetization curves shown in figure 8 are the 2 iron characteristics that were investigated and discussed in the body of the paper.

The differential equations applying to this circuit are:

$$E \sin (t + \alpha) = r_1 i_1 + L\frac{di_1}{dt} + \frac{1}{C}\int (i_1 - i_2)dt + \frac{d\psi}{dt} \qquad (1a)$$

$$i_2 R_c = \frac{1}{C}\int (i_1 - i_2)dt \qquad (2a)$$

Rearranging and integrating (1$a$) into a form applicable to the differential analyzer, there is:

$$Li_1 + \psi = \int \left[ E \sin (t + \alpha) - r_1 i_1 - \frac{1}{C}\int (i_1 - i_2)dt \right] dt \qquad (3a)$$

The schematic hook-up of the analyzer, giving the solution to equations 2$a$ and 3$a$ is shown in figure 3. The input voltage was actually not cranked in by an operator. Instead an auxiliary set-up was made that gave the solution to the differential equation

$$\frac{d^2x}{dt^2} = -x \qquad (4a)$$

which is a sinusoid, and it was impressed automatically into the hook-up. An operator was needed to crank the current into the system by keeping a pointer representing $\psi$, the linkage, on the linkage-current characteristic. Values of applied voltage, linkage, capacitor voltage, and total current were plotted by the output tables.

The procedure used to determine the points on the resistance-capacitive reactance curves of figure 7 was as follows. The differential analyzer was started at a point corresponding to application of the voltage at the zero point of the wave and the several dependent variables of the circuit plotted automatically on an output table.

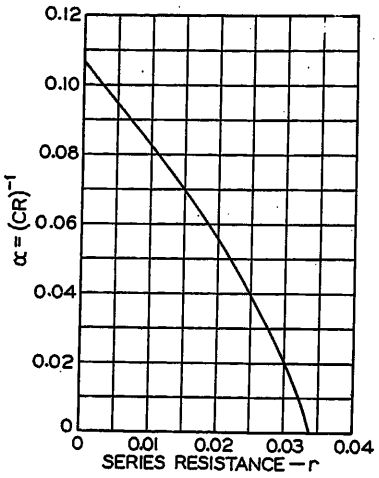


**Figure 15. Relation between line resistance and $\alpha$ required to prevent self-excitation**

$x = 3.24$ $x' = 0.4$
$x_c = 0.2$

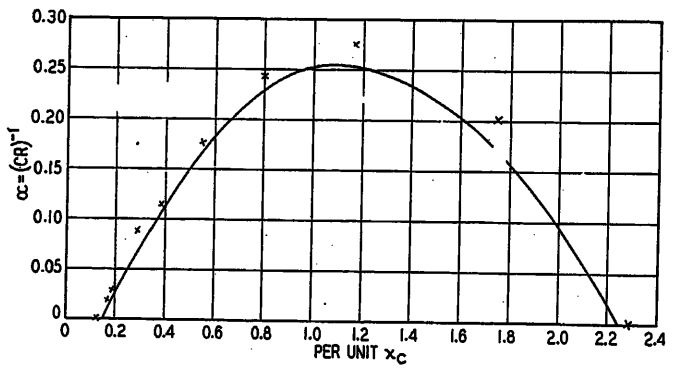

**Figure 16 (below). Self-excitation of induction motors with series capacitors**

Comparison of calculated and test results
X—Test points
Curve—Calculated
$x' = 1.03$ $x = 2.32$
$\omega = 1.0$ $r = 0.10$

As indicated by the equation above there are several variables which can be used in the interpretation of the analyzer results. The quantities which would ordinarily be measured in test of an actual circuit are the transformer voltage and current. However, it was found by experience that the most significant quantities, as far as the efficient determination of a criterion for proper circuit operation was concerned, were the capacitor voltage and transformer flux. Since, as shown in the oscillograms, the current only appears as an appreciable magnitude at widely separated intervals of time (e.g., figures 1*a* and 4*c*) and, when it does appear, it is likely to bear no obvious relation to its previous value, thus it is very difficult to use current as a continuous indication of the behavior of the circuit. On the other hand, the transformer flux, which bears a direct functional relation to the current as given by the saturation curve, is always of a reasonably large magnitude and of a nearly sinusoidal wave shape. It appears, as shown in figures 4 to 6, as a sinusoidal wave having a slowly varying displacement, and the rate of change and magnitude of this displacement were found to be useful factors in determining as quickly as possible from a given analyzer run, whether or not the circuit would approach its proper steady state.

The capacitor voltage was found to be still more useful in this respect; that is, if one had to judge from the behavior of only one quantity whether the circuit was to approach a normal or abnormal condition, one would choose the capacitor voltage. This voltage determined by its magnitude the rate of change of flux wave displacement, by its rate of discharge the effectiveness of the shunt resistor, by its duration the continuance of the shifting of displacement of the flux wave. In general, it was discovered that if ever the capacitor voltage increased in magnitude from cycle to cycle (it will be understood here that by "cycle" is meant the apparent cycle of the low frequency current pulsations and not that of the applied voltage), for example, if it ever went higher the second time than it did the first, the system behavior was abnormal. On the other hand, if it continually decreased in magnitude from cycle to cycle the circuit operation was sure to be normal. This is illustrated by figure 6 which shows curves of capacitor voltage taken at 2 different values of shunt resistance, one just sufficient to produce normal operation, the other slightly higher.

## Appendix B—Criteria for Negative Damping of Synchronous Generators Neglecting Amortisseur Winding

Consider the circuit of figure 9 with 2 generators connected to an infinite bus with a shunt load at the branch point and with resistances and reactances as indicated.

The effects of salient poles will be considered only in machine number 1, the stability of which is being investigated, while machine number 4 is considered to be round rotor. Moreover, the reactance $x_4$ will usually be taken as the transient reactance or some modified value depending on the frequency of the oscillation being studied.

The steady-state equations for this circuit are:

$$\begin{array}{cccccc}
 & & -i_{q1}+i_{q2}+i_{q3}-i_{q4} & = & 0 & \\
x_d i_{d1}+x_2 i_{d2} & & +r_1 i_{q1}+r_2 i_{q2} & = & E_1 & \\
x_2 i_{d2}-x_3 i_{d3} & & +r_2 i_{q2}-r_3 i_{q3} & = & E_3\cos\delta_1 & \\
-i_{d1}+i_{d2}+i_{d3}-i_{d4} & & & = & 0 & \\
-r_1 i_{d1}-r_2 i_{d2} & & +x_q i_{q1}+x_2 i_{q2} & = & 0 & \\
r_2 i_{d2}-r_3 i_{d3} & & -x_2 i_{q2}+x_3 i_{q3} & = & E_3\sin\delta_1 & \\
x_2 i_{d2} & +x_4 i_{d4} & +r_2 i_{q2} & +r_4 i_{q4} & = E_4\cos(\delta_1-\delta_4) & \\
r_2 i_{d2} & +r_4 i_{d4} & -x_2 i_{q2} & -x_4 i_{q4} & = E_4\sin(\delta_1-\delta_4) & \text{(1b)}
\end{array}$$

If the effect of the amortisseur windings is neglected it has been shown[12] that the load angle below which negative damping of generator number 1 may occur is accurately given by the condition (when the frequency of the mechanical oscillation is small compared to normal-voltage frequency),

$$\frac{d}{d\delta_1} i_{d1} = 0 \qquad \text{(2b)}$$

Solving equations 1*b* for $i_{d1}$, we find

$$\Delta i_{d1} = \begin{vmatrix}
0 & 0 & 0 & 0 & -1 & 1 & 1 & -1 \\
E_1 & x_2 & 0 & 0 & r_1 & r_2 & 0 & 0 \\
E_3\cos\delta_1 & x_2 & -x_3 & 0 & 0 & r_2 & -r_3 & 0 \\
0 & 1 & 1 & -1 & 0 & 0 & 0 & 0 \\
0 & -r_2 & 0 & 0 & x_q & x_2 & 0 & 0 \\
E_3\sin\delta_1 & r_2 & -r_3 & 0 & 0 & -x_2 & x_3 & 0 \\
E_4\cos(\delta_1-\delta_4) & x_2 & 0 & x_4 & 0 & r_2 & 0 & r_4 \\
E_4\sin(\delta_1-\delta_4) & r_2 & 0 & r_4 & 0 & -x_2 & 0 & -x_4
\end{vmatrix} \qquad \text{(3b)}$$

where $\Delta$ is the determinant of the coefficients of the currents in equations 1*b*.

Differentiating with respect to $\delta_1$, there is

$$\Delta\frac{d}{d\delta_1} i_{d1} = \begin{vmatrix}
0 & 0 & 0 & 0 & -1 & 1 & 1 & -1 \\
0 & x_2 & 0 & 0 & r_1 & r_2 & 0 & 0 \\
-E_3\sin\delta_1 & x_2 & -x_3 & 0 & 0 & r_2 & -r_3 & 0 \\
0 & 1 & 1 & -1 & 0 & 0 & 0 & 0 \\
0 & -r_2 & 0 & 0 & x_q & x_2 & 0 & 0 \\
E_3\cos\delta_1 & r_2 & -r_3 & 0 & 0 & -x_2 & x_3 & 0 \\
-E_4(1-k)\sin(\delta_1-\delta_4) & x_2 & 0 & x_4 & 0 & r_2 & 0 & r_4 \\
E_4(1-k)\cos(\delta_1-\delta_4) & r_2 & 0 & r_4 & 0 & -x_2 & 0 & -x_4
\end{vmatrix} \qquad \text{(4b)}$$

where $k = \frac{\partial\delta_4}{\partial\delta_1}$, i.e., $k$ is the ratio of the motion of machine number 4 to that of machine number 1. For sinusoidal oscillations $k$ may be taken as the ratio of the amplitude of the machine oscillations.

Equation 4*b*, together with equation 2*b*, may be written

$$0 = \Delta\frac{d}{d\delta_1} i_{d1} = -E_3(M_{31}\sin\delta_1 + M_{61}\cos\delta_1) - E_4[M_{71}\sin(\delta_1-\delta_4) + M_{81}\cos(\delta_1-\delta_4)](1-k) \qquad \text{(5b.1)}$$

or

$$\tan \delta_1 = -\left[\frac{M_{61} + (1-k)\frac{E_4}{E_3}(M_{81}\cos\delta_4 - M_{71}\sin\delta_4)}{M_{81} + (1-k)\frac{E_4}{E_3}(M_{71}\cos\delta_4 + M_{81}\sin\delta_4)}\right] \tag{5b.2}$$

The relation $\frac{d}{d\delta_1} i_{d1} = 0$ thus leads to a transcendental equation which may be solved numerically for $\delta_1$ as a function of $\delta_4$.

In equations 5*b*, there is

$$M_{31} = \begin{vmatrix} x_2 & 0 & r_1 & -r_2 & 0 \\ -r_2 & 0 & x_q & -x_2 & 0 \\ r_2 + r_3 & -r_3 & x_3 & x_2 + x_3 & x_3 \\ x_2 & x_4 & 0 & -r_2 & r_4 \\ r_2 & r_4 & 0 & x_2 & -x_4 \end{vmatrix} \tag{6b.1}$$

$$M_{61} = \begin{vmatrix} x_2 & 0 & r_1 & r_2 & 0 \\ x_2 + x_3 & -x_3 & -r_3 & r_2 + r_3 & -r_3 \\ -r_2 & 0 & x_q & x_2 & 0 \\ x_2 & x_4 & 0 & r_2 & r_4 \\ r_2 & r_4 & 0 & -x_2 & -x_4 \end{vmatrix} \tag{6b.2}$$

$$M_{71} = \begin{vmatrix} x_2 & 0 & r_1 & -r_2 & 0 \\ x_2 & x_3 & 0 & -r_2 & -r_3 \\ -r_2 & 0 & x_q & -x_2 & 0 \\ r_2 & r_3 & 0 & x_2 & x_3 \\ r_2 + r_4 & -r_4 & x_4 & x_2 + x_4 & -x_4 \end{vmatrix} \tag{6b.3}$$

$$M_{81} = \begin{vmatrix} x_2 & 0 & r_1 & r_2 & 0 \\ x_2 & -x_3 & 0 & r_2 & -r_3 \\ -r_2 & 0 & x_q & x_2 & 0 \\ r_2 & -r_3 & 0 & -x_2 & x_3 \\ x_2 + x_4 & x_4 & -r_4 & r_2 + r_4 & r_4 \end{vmatrix} \tag{6b.4}$$

In the special case for which the motions of the 2 machines are the same ($k = 1$), equations 5*b* reduce to

$$\tan \delta_1 = -\frac{M_{61}}{M_{81}} \tag{7b}$$

but this is not likely to be a useful case. If $k = 0$, there is no simplification.

If machine number 4 is eliminated by letting $x_4$ and/or $r_4$ be infinite, $M_{71}$, $M_{81}$ become negligible compared to $M_{31}$, $M_{61}$, and equations 5*b* reduce to:

$$\tan \delta_1 = \frac{\begin{vmatrix} x_2 & -r_1 & r_2 \\ x_2 + x_3 & r_3 & r_2 + r_3 \\ -r_2 & -x_q & x_2 \end{vmatrix}}{\begin{vmatrix} x_2 & r_1 & -r_2 \\ -r_2 & x_q & -x_2 \\ r_2 + r_3 & x_3 & x_2 + x_3 \end{vmatrix}} \tag{8b.1}$$

**Figure 17. Starting and self-excited current of induction motor with series capacitance in primary circuit**

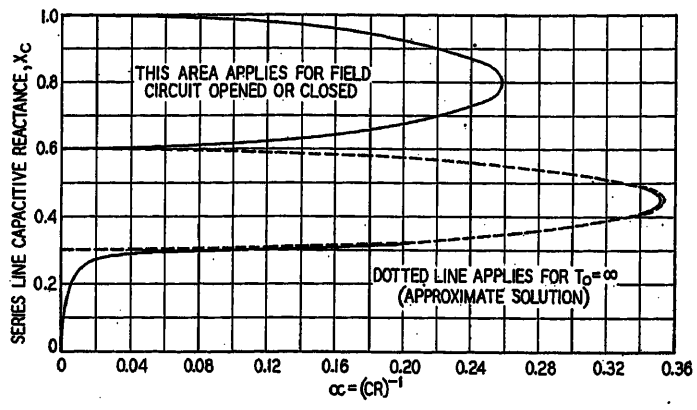

**Figure 18. Regions of self-excitation of synchronous machine with armature capacitance as affected by shunt resistance R**

$x_d = 1.0$ $x_q = 0.6$ $x_d' = 0.30$ $T_o = 1{,}000$ $r = 0$

or

$$\tan \delta_1 = \frac{Z_2^2(r_1 + r_3) + x_q(r_3x_2 - x_3r_2) + r_1(x_2x_3 + r_2r_3)}{Z_2^2(x_q + x_3) + x_q(x_2x_3 + r_2r_3) + r_1(x_3r_2 - x_2r_3)} \tag{8b.2}$$

where

$$Z_2^2 = r_2^2 + x_2^2$$

The right-hand side of equation 8*b*.2 is recognized as the ratio of the real to the imaginary part of the transfer impedance from machine number 1 to the infinite bus if $x_q$ is used for the machine reactance. Further, if the shunt load is removed ($Z_2 = \infty$) it checks the criterion of reference 11.

If the shunt load is removed but machine number 4 is kept, the form of equation 5*b* is unchanged but equations 6*b* are reduced to:

$$-M_{31} = \begin{vmatrix} -r_3 & x_q + x_3 & x_3 \\ x_4 & -r_1 & r_4 \\ r_4 & x_q & -x_4 \end{vmatrix} \tag{9b.1}$$

$$-M_{61} = \begin{vmatrix} x_3 & r_1 + r_3 & r_3 \\ -x_4 & r_1 & -r_4 \\ r_4 & x_q & -x_4 \end{vmatrix} \tag{9b.2}$$

$$-M_{71} = \begin{vmatrix} -x_3 & r_1 & r_3 \\ r_3 & x_q & x_3 \\ -r_4 & x_q + x_4 & -x_4 \end{vmatrix} \tag{9b.3}$$

$$-M_{81} = \begin{vmatrix} x_3 & r_1 & r_3 \\ -r_3 & x_q & x_3 \\ -x_4 & r_1 + r_4 & -r_4 \end{vmatrix} \tag{9b.4}$$

If in equations 5*b* $E_4 = 0$, or if $x_4$ and/or $r_4 = \infty$, there is,

$$\delta_1 = -\tan^{-1}\frac{M_{61}}{M_{31}} \tag{10b}$$

which is equation 7*b* if $E_4 = 0$, and is equation 8*b* if $x_4$ or $r_4 = \infty$. If $E_4 = 0$ but $x_4$ and $r_4$ are finite, equation 10*b* may of course be put in the form 8*b* by paralleling $Z_2$ and $Z_4$, i.e., in equation 8*b* replace $r_2$ and $x_2$ by the corresponding real and imaginary parts of the parallel values of $Z_2$ and $Z_4$. This reasoning shows that since tan $\delta$ in (8*b*.2) equals the ratio of the real and imaginary components of the transfer impedance from machine number 1 to the infinite bus (number 3) therefore $-M_{61}/M_{31}$, where $M_{61}$ and $M_{31}$ are given by (6*b*.1) and (6*b*.2), must also be the ratio of the real and imaginary parts of the transfer impedance of machine number 1 to the infinite bus with $Z_4$ finite. In fact, directly from equation 3*b* it may be seen that since:

$$\Delta i_{d1} = -M_{31}E_1 + M_{61}E_3\cos\delta_1 - M_{61}E_4\sin\delta_1 + M_{71}E_4\cos(\delta_1 - \delta_4) - M_{81}E_4\sin(\delta_1 - \delta_4) \tag{11b}$$

Then:

$-M_{21}/\Delta$ is the imaginary part of the driving point admittance at machine number 1

$M_{31}/\Delta$ is the imaginary part of the transfer admittance from 1 to 3

$M_{61}/\Delta$ is the corresponding real part

$M_{71}/\Delta$ is the imaginary part of the transfer admittance from 1 to 4

$M_{81}/\Delta$ is the corresponding real part

It follows that since

$$\left(\frac{\text{real}}{\text{imaginary}}\right)_{\text{admittance}} = -\left(\frac{\text{real}}{\text{imaginary}}\right)_{\text{impedance}} \tag{12b}$$

we have

$$-\frac{M_{61}}{M_{31}} = \left(\frac{\text{real}}{\text{imaginary}}\right)_{\text{impedance 1–3}} \tag{13b}$$

and

$$-\frac{M_{81}}{M_{71}} = \left(\frac{\text{real}}{\text{imaginary}}\right)_{\text{impedance 1–4}} \tag{14b}$$

All of these transfer impedances and admittances are computed for *a direct-axis current* in machine number 1. Also, since it is only the relative magnitude of the components of impedance which enter into the final criteria, the impedances calculated entirely by means of $x_q$ can be used. That is, even though $x_d$ occurs in $\Delta$ and affects the true values of the impedances, $\Delta$ does not appear in the results.

The method of extension to more than 2 machines is evident from equations 2*b*, 3*b*, and 4*b*.

## Composite Loads

If the shunt load of figure 9 is a composite load[18] of any kind all the criteria given here may be used unchanged if $r_2$, $x_2$ are defined by the relation:

$$\frac{de_2}{di_2} = r_2 + jx_2 \tag{15b}$$

at the load voltage $e_2$.

# Appendix C—Self-Excitation of Induction Motors

The object of this appendix is to present criteria to determine the limits of stable operation of induction motors with series line capacitors. Under certain conditions of load it is found in practice that there will exist undamped current pulsations of apparently low frequency and large magnitude. These pulsations are here considered to be caused by undamped or negatively damped (amplifying) free electrical oscillations. Thus, to determine whether a given (electrical) system is stable or unstable the natural currents are examined. The time variation of these natural currents is specified by the roots of the characteristic determinant of the system. If the real part of any one or more of these roots is positive the system is unstable since then the corresponding component of the transient current is amplifying rather than decaying and will tend to increase indefinitely until limited by changes in the circuit caused by saturation, slowing down or oscillating of the motor rotor, etc. Thus, it is not necessary actually to solve for the roots but only to find the signs of their real parts. To find the actual frequency of the unstable oscillation it is necessary to solve the equation, which is of the sixth degree (or of the third degree if expressed with complex coefficients) and has in general 3 conjugate pair of complex roots or 3 natural frequencies.

## Analysis

For an induction or synchronous machine with capacitance and resistance in shunt connected to the terminals, there are the equations (see reference 20):

$$\begin{aligned}(p+\alpha)[e_d - p\psi_d + ri_d + \omega\psi_q] + x_c i_d &= \omega[e_q - p\psi_q + ri_q - \omega\psi_d] \\ (p+\alpha)[e_q - p\psi_q + ri_q - \omega\psi_d] + x_c i_q &= -\omega[e_d - p\psi_d + ri_d + \omega\psi_q]\end{aligned} \tag{1c}$$

where, for an induction motor with completely symmetric rotor and stator,

$$\begin{aligned}\psi_d &= -x(p)i_d \\ \psi_q &= -x(p)i_q\end{aligned} \tag{2c}$$

and

$$x(p) = \frac{x'T_0p + x}{T_0p + 1} \tag{3c}$$

Substituting (2*c*) in (1*c*) and rearranging; there is:

$$\{(p+\alpha)[px(p) + r] + x_c - \omega^2x(p)\}i_d - \omega\{(p+\alpha)x(p) + px(p) + r\}i_q = -(p+\alpha)e_d + \omega e_q \tag{4c}$$

$$\omega\{(p+\alpha)x(p) + px(p) + r\}i_d + \{(p+\alpha)[px(p) + r] + x_c - \omega^2x(p)\}i_q = -\omega e_d - (p+\alpha)e_q$$

and for constant rotor speed the characteristic determinant (the denominator of the expression for current as a function of voltage),

$$\Delta = \{(p+\alpha)[px(p) + r] + x_c - \omega^2x(p)\}^2 + \omega^2\{(p+\alpha)x(p) + px(p) + r\}^2 \tag{5c}$$

Substituting (3*c*) in (5*c*) and rearranging in descending powers of $p$, there is:

$$\begin{aligned}(T_0p+1)^2\Delta = \Delta' = {} & p^6(x'^2T_0^2) \\ & + p^5[(2x'T_0)(x + \alpha x'T_0 + rT_0)] \\ & + p^4[(x + \alpha x'T_0 + rT_0)^2 + (2x'T_0)\times \\ & \qquad (\alpha x + \omega^2x'T_0 + r + \alpha rT_0 + x_cT_0)] \\ & + p^3[2x'T_0(x_c + \omega^2x) + 2(x + \alpha x'T_0 + rT_0)\times \\ & \qquad (\alpha x + \omega^2x'T_0 + r + \alpha rT_0 + x_cT_0)] \\ & + p^2[(\alpha x - \omega^2x'T_0 + r + \alpha rT_0 + x_cT_0)^2 + \\ & \qquad 2(x + \alpha x'T_0 + rT_0)(x_c - \omega^2x) + \\ & \qquad (\alpha x'T_0 + 2x + rT_0)^2\omega^2 + 4\omega^2x'T_0(\alpha x + r)] \\ & + p[2(\alpha x - \omega^2x'T_0 + r + \alpha rT_0 + x_cT_0)\times \\ & \qquad (x_c - \omega^2x) + 2\omega^2(\alpha x'T_0 + 2x + rT_0)\times \\ & \qquad (\alpha x + r)] + (x_c - \omega^2x)^2 + (\alpha x + r)^2\omega^2\end{aligned} \tag{6c}$$

Equation 5*c* is of the form ($\Delta' = a^2 + b^2$) and so may be factored as [$\Delta' = (a + jb)(a - jb)$] thus at once reducing the order of the equations to be solved by half. However, this is accomplished at the price of introducing complex coefficients. The real parts of the roots of the 2 factors are identical in pairs; the imaginary parts equal and opposite. Thus only one factor need be considered, but it is found that all methods for determining the character of the roots or solving the equation require about the same amount of work as doubling the order and in effect obtaining equation 6*c*.

In complex form the equation may be written as:

$$\begin{aligned}a + jb = {} & x'T_0p^3 + [(x + \alpha x'T_0 + rT_0) + j\omega 2x'T_0]p^2 + \\ & [(x_cT_0 - \omega^2x'T_0 + \alpha x + r + \alpha rT_0) + j\omega(2x + \alpha x'T_0 + \\ & rT_0)]p + [(x_c - \omega^2x) + j\omega(\alpha x + r)]\end{aligned} \tag{7c}$$

with a similar conjugate expression for $(a - jb)$.

It will be observed that equations 6*c* and 7*c* are almost symmetrical in $r$ and $\alpha$ except that $\alpha$ has sometimes the coefficient $x'$ and sometimes $x$, which destroys the symmetry. It is therefore expected that all the conclusions and curves obtained will be very similar if the effect of shunt and series resistances are investigated separately, using $\alpha$ as the variable in case of the shunt resistance. Here $\alpha$ may be thought of as the reciprocal of the time constant of the $RC$ circuit considered by itself. It is the negative of the coefficient of time in the exponential solution of the $RC$ circuit equations.

### Approximate Criterion for Instability

It will be found that a very simple and sufficient condition for instability is that the coefficient of $p$ in equation 6*c* be negative. That is, if this coefficient is negative the system is surely unstable,

but if it is positive the system is not necessarily stable. Putting the coefficient equal to zero there is:

$$x_c = \frac{1}{2}\left[(x+x')\omega^2 - \alpha r - \frac{(\alpha x + r)}{T_o}\right] = \left\{\frac{(x-x')^2\omega^4}{4} - \frac{\omega^2}{2}(x+3x')\alpha r + \frac{1}{4}\left[\alpha r + \frac{(\alpha x + r)}{T_o}\right]^2 - \omega^2(xx'\alpha^2 + r^2) - \frac{\omega^2}{2}(3x+x')\frac{(\alpha x + r)}{T_o}\right\}^{1/2} \quad (8c)$$

The 2 values of $x_c$ obtained from (8c) for a given system determine the limits of a region which is theoretically surely unstable.

If a set of circuit constants is selected, leaving $r$ and $x_c$ free, then $r$ is varied and $x_c$ computed, a region is outlined as in figure 10 (dashed curve). This figure shows $r$ as a function of $x_c$ if there is no shunt resistor ($\alpha = 0$). If the effect of shunt resistance alone is determined, letting $r = 0$, the dashed curve of figure 12 is obtained.

Equation 8c outlines the unstable region very close to the true boundary over most of the range of instability. However it indicates that instability lies wholly in the range,

$$\omega^2 x' < x_c < \omega^2 x \quad (9c)$$

so that if $x_c < \omega^2 x'$ the system is stable when in fact there is required a certain finite series or shunt resistance to assure stability. Equation 8c is therefore not a good criterion when $x_c$ is small as in the case of series capacitors for line reactance compensation except when the motor is running at low speeds.

### Exact Criterion

To find the true boundary in the region $x_c < \omega^2 x'$ the criterion of Routh[24] is used. This is carried out numerically by assigning values to all of the system constants and testing equations 6c or 7c for stability with various values of line or shunt resistance. The boundaries found in this manner are shown in figures 10 and 12 (solid lines). These figures are calculated for a motor of 0.16 per unit transient reactance and an external reactance of 0.24. In figures 10 and 12 there are also plotted boundaries corresponding to operation at the same speed but with some external rotor resistance, the total rotor resistance being 10 times the rotor winding resistance.* The effects of series and shunt resistors have been determined separately in order to show as simply as possible the orders of magnitude of the various quantities involved. However, since there is always some line resistance present, the value of $\alpha$ required need not be as large as that given by the curves of figure 12. Figure 15 shows an example of how the $\alpha$ necessary for stability can be decreased with increasing line resistance, and has been computed from equation 6c by Routh's[24] method.

### Effect of Rotor Speed

Equations 6c or 7c may be used to determine exactly the regions of unstable operation at any rotor speed. However, the effect of speed may be more clearly and easily seen from the approximate expression (8c). Since the rotor open-circuit time constant is usually rather large, equation 8c may be further simplified by neglecting terms containing $T_o$, whence

$$\frac{x_c}{\omega^2} = \frac{1}{2}\left[x + x' - \left(\frac{\alpha}{\omega}\right)\left(\frac{r}{\omega}\right)\right] = \sqrt{\frac{(x-x')^2}{4} - \left[xx'\left(\frac{\alpha}{\omega}\right)^2 + \left(\frac{r}{\omega}\right)^2\right] - \frac{(x+3x')}{2}\left(\frac{\alpha}{\omega}\right)\left(\frac{r}{\omega}\right) + \frac{1}{4}\left(\frac{\alpha}{\omega}\right)^2\left(\frac{r}{\omega}\right)^2} \quad (10c)$$

Equation 10c shows that as the speed $\omega$ is varied the scales of the $r$ versus $x_c$ or $\alpha$ versus $x_c$ diagram are simply changed so that

$x_c$ is proportional to $\omega^2$
$r$ and $\alpha$ are proportional to $\omega$ (11c)

* If rotor resistance is zero ($T_o = \infty$) there is no instability. Also if $T_o = 0$ or $\omega = 0$ there is obviously no instability.

Since at low speeds the capacitive reactance at which the maximum series resistance or shunt conductance is required is shifted toward the actual capacitive reactance likely to be used in the circuit, equation 10c or 8c then becomes a useful criterion. Having the boundary curve of instability at any one speed, those at any other speed may then be quickly estimated by the relations 11c. Figures 11 and 13 show the effect of varying the rotor speed as determined by equation 10c. Figure 11 shows the effect on the value of series resistance requirod if there is no shunt resistance, while figure 13 shows a similar curve of $\alpha$ versus $x_c$ if $r = 0$.

Equation 10c also provides a means of determining quickly an approximate expression for the value of $\alpha$ required to eliminate instability completely at any speed. This expression is found by equating the radical in equation 10c to zero, which locates a point very close to the maximum of the $\alpha$ versus $x_c$ or $r$ versus $x_c$ boundary curve. Then

$$\left(\frac{\alpha}{\omega}\right)_{max} = -\frac{(x+3x')r'}{4xx' - r'^2} + \frac{1}{4xx' - r'^2} \times \sqrt{(x+3x')^2 r'^2 + (4xx' - r'^2)[(x-x')^2 - 4r'^2]} \quad (12c)$$

where $r' = r/\omega$.

If $r = 0$, there is

$$\left(\frac{\alpha}{\omega}\right)_{max} = \frac{(x-x')}{2\sqrt{xx'}} \quad (13c.1)$$

which occurs at

$$\frac{x_c}{\omega^2} = \frac{x+x'}{2} \quad (13c.2)$$

Similarly if $\alpha = 0$, there is

$$\left(\frac{r}{\omega}\right)_{max} = \frac{(x-x')}{2} \quad (13c.3)$$

which occurs at the same $x_c$ as in equation 13c.2. These last relations determine equations,

$$r^2 = \frac{(x-x')^2 x_c}{2(x+x')} \text{ for } \alpha = 0 \quad (14c.1)$$

and

$$xx'\alpha^2 = \frac{(x-x')^2 x_c}{2(x+x')} \text{ for } r = 0 \quad (14c.2)$$

which are the equations of the loci of the maxima of the $r$ versus $x_c$ and $\alpha$ versus $x_c$ curves as the speed $\omega$ is varied. Then, if the capacitive reactance $x_c$ in a given circuit is known equations 14c determine the value of $r$ or $\alpha$ needed to eliminate self-excitation at all speeds. However, as mentioned in the body of the paper, it will not in general be necessary to do this.

### Frequency and Time Constant of the Amplifying Oscillation

The frequencies and time constant of all these components of the transient currents may of course be found directly by solving equations 6c or 7c. However, it has been found that within the normal range of circuit constants only one of these currents is amplifying and so likely to be observed as a large current pulsation. Moreover, this current is that corresponding usually to a small root of 7c, over most of the range of $x_c$. It should therefore be possible to find the root approximately by neglecting higher powers of $p$ in equation 7c whence the solution is

$$p_1 = \frac{(x_c - \omega^2 x) + j\omega(\alpha x + r)}{[(x_c - \omega^2 x')\alpha r)T_o + \alpha x + r] + j\omega[(\alpha x' + r)T_o + 2x]} \quad (15c)$$

A further obvious simplification is obtained by neglecting the terms in the denominator which do not contain $T_o$. If $p_1 = p_r + jq$ then $p_r$ is the decrement factor and $(\omega + q)$ the frequency of the possibly amplifying oscillation. The frequency is $\omega + q$ rather than

$q$ since the solution is for $i_d$, $i_q$. The phase currents are obtained by Park's[25] equations

$$i_a = i_d \cos\theta - i_q \sin\theta, \text{ etc.}$$

and it may be shown that the component of phase current of frequency $\omega - q$ vanishes identically.

If the real part $p_r$ of $p_1$ is equated to zero (corresponding to the point at which the oscillation is just neutral) equation 8$c$ is arrived at by a different route.

The approximate equation 15$c$ holds only for $x_c > \omega^2 x'$ and so in the useful range of capacitance at normal motor speeds, equation 7$c$ must be solved directly. It is still possible to avoid the solution of a cubic equation if it is desired to find the frequency only at points on the boundaries between the stable and unstable regions, since at such points the root is obviously pure imaginary and if $p = jq$, equation 7$c$ may be split up as

$$\begin{aligned} a + jb = &-[(x + \alpha x' T_o + r T_o) q^2 + \omega(2x + \alpha x' T_o + r T_o) q - \\ &(x_c - \omega^2 x)] - j[x' T_o q^3 + \omega 2x' T_o q^2 - (x_c T_o - \omega^2 x' T_o + \\ &\alpha x + r + \alpha r T_o) q - \omega(\alpha x + r)] \end{aligned} \tag{16c}$$

and the real and imaginary components of (16$c$) equated separately to zero. Sets of system constants on the boundary may then be first found by Routh's[24] method and $q$ then obtained by solving the quadratic equation $a = 0$ in equation 16$c$. Of the 2 real roots thus found only one will in general satisfy the cubic equation $b = 0$ of (16$c$) and this will of course be the proper frequency. For example, taking circuit constants corresponding to the points $x_c = 0.2$, $r = 0.035$ in figure 10, the frequency is found to be very nearly 0.7 times normal (rotor speed). At values of $x_c > x'$ the frequency is always very close to, and slightly less than that corresponding to the rotor speed.

M. Takahashi[22] has an approximate solution of equation 7$c$ for the case of no shunt resistance and has determined regions of self-excitation for this case. His results are in general agreement with those given here.

## Appendix D—Self-Excitation of Synchronous Machines

From equations 15 of reference 20, the equations of a synchronous machine operating at synchronous speed, with only one rotor winding, with series capacitance and resistance in the armature circuit, and with additional resistors shunting the capacitors, are:

$$\begin{aligned} (p + \alpha)(e_d - p\psi_d + r i_d + \psi_q) + x_c i_d &= e_q - p\psi_q + r i_q - \psi_d \\ (p + \alpha)(e_q - p\psi_q + r i_q - \psi_d) + x_c i_q &= -e_d + p\psi_d - r i_d - \psi_q \end{aligned} \tag{1d}$$

where

$$\psi_d = -x_d(p) i_d = -\frac{x_d' T_o p + x_d}{T_o p + 1} i_d \tag{2d}$$

$$\psi_q = -x_q(p) i_q = -x_q i_q \tag{3d}$$

If (1$d$) are solved for the currents $i_d$, $i_q$ in terms of the applied voltages $e_d$, $e_q$, it is found that the operational common denominator of the 2 formulas for current is:

$$\begin{aligned} \Delta' = &\; p^5 x_q x_d' T_o \\ &+ p^4[x_q x_d + r T_o(x_q + x_d') + 2\alpha T_o x_q x_d'] \\ &+ p^3[(2x_q x_d' + x_c\{x_q + x_d'\}) T_o + r(x_d + x_q + r T_o) + \\ &\quad \alpha(2x_d x_q + \alpha x_q x_d' T_o) + 2\alpha r T_o(x_q + x_d')] \\ &+ p^2[2x_d x_q + x_c(x_d + x_q) + r(T_o\{2x_c + x_q + x_d'\} + r) + \\ &\quad \alpha(T_o x_c\{x_q + x_d'\} + 2T_o x_q x_d' + \alpha x_d x_q) + \alpha r(2x_d + \\ &\quad 2x_q + 2T_o r + T_o\alpha\{x_q + x_d'\})] \\ &+ p[T_o(x_c - x_q)(x_c - x_d') + r(x_d + x_q + 2x_c + r T_o) + \\ &\quad \alpha(x_c\{x_d + x_q\} + 2x_d x_q + \alpha x_q x_d' T_o) + \alpha r(2x_c T_o + 2r + \\ &\quad \alpha\{x_d + x_q\} + \alpha r T_o)] \\ &+ [(x_d - x_c)(x_q - x_c) + r^2 + \alpha^2 x_d x_q + 2\alpha r x_c + (\alpha r)^2] \end{aligned} \tag{4d}$$

If the same generator as in reference 21 is taken, with $r = 0$, and the stability of the system as affected by $\alpha$ is studied by means of Routh's[24] criterion, the results of figure 18 are obtained. Also in a manner similar to that of reference 21 there is found an approximate formula for the lower region:

$$+ \alpha^2 = \frac{(x_q - x_c)(x_d' - x_c)}{-x_q x_d'} \tag{5d}$$

or

$$x_c = \frac{x_q + x_d'}{2} \pm \sqrt{\frac{(x_q - x_d')^2}{4} - x_q x_d' \alpha^2} \tag{6d}$$

Similarly, an exact formula for the upper region is obtained by replacing $x_d'$ by $x_d$ in equation 5$d$, whence

$$+ \alpha^2 = \frac{(x_q - x_c)(x_d - x_c)}{-x_q x_d} \tag{7d}$$

or

$$x_c = \frac{x_q + x_d}{2} \pm \sqrt{\frac{(x_q - x_d)^2}{4} - x_q x_d \alpha^2} \tag{8d}$$

# Transformer Current and Power Inrushes Under Load

By E. B. KURTZ
FELLOW AIEE

## Introduction

THE PHENOMENON of starting currents in transformers has been quite fully studied by several investigators,[1,2] especially when the transformer is without load. Little information, however, can be found in the technical literature on this subject when the transformer is loaded, let alone the effect of various load power factors.

This paper presents results of studies on starting currents and powers when loaded transformers are connected to their supply lines. Both primary and secondary switching are investigated, and unity, lagging, and leading load power factors are considered.

In this study the moving average is introduced as a means of analyzing oscillographic records. By its use the trends of the effective current and average power may be more readily observed. This in turn makes possible the determination of the primary transformer power factor variation during the transient period.

## Galvanometer Connections

A schematic diagram of the galvanometer connections employed is shown in figure 1. The transformer used was a distribution-type transformer having similar primary and secondary windings designed for 220–110-volt operation. A one-to-one transformation ratio was used throughout the investigation. In the figure,

$e$ represents the primary voltage galvanometer
$i_p$ represents the primary current galvanometer
$i_s$ represents the secondary current galvanometer
$w$ represents the primary watt galvanometer

A special relay[3] developed for these studies was used for closing the primary or secondary circuit at the desired point on the primary voltage wave. In all cases of primary switching the core was completely demagnetized before the transformer was energized.

Figure 2 is a photograph of the laboratory setup showing all equipment in place.

## No-Load Transients

Since the no-load starting current transient was needed for the predetermination of starting current transients with load, it is included herewith as oscillogram 1. In this oscillogram the circuit was closed on the zero of the voltage wave, this being the condition for maximum current inrush with zero residual flux. As previously mentioned, the transformer core was demagnetized before the switch was closed. Still larger values of starting current will result if positive residual flux is present at starting, and smaller values if negative residual magnetism is present. These extreme inrushes, however, are not considered in this paper because of the difficulty in controlling the magnitude of such residuals.

## Predetermination of Starting Current Under Load

An approximate value of the maximum primary transient current under load (for zero residual flux) may be found by adding the primary no-load transient current of oscillogram 1 to a load component equal and opposite to the assumed secondary current. Greater accuracy, however, can be obtained by taking account of the effect of the increased $iR$ drop in the primary winding due to the presence of the load component upon the magnetizing flux.

To include this effect the fundamental primary voltage equation,

$$Ri_m + N\frac{d\phi^*}{dt} = E_M \sin(\omega t + \lambda) \tag{1}$$

must be modified thus,

$$R(i_m + i_L) + N\frac{d\phi}{dt} = E_M \sin(\omega t + \lambda) \tag{2}$$

or

$$N\frac{d\phi}{dt} = E_M \sin(\omega t + \lambda) - R(i_m + i_L) \tag{3}$$

Equation 3 shows that the induced voltage under load conditions differs from the induced voltage under no-load conditions by the factor $Ri_L$. This factor decreases the peaks of the magnetizing current. The extent of the decrease naturally depends upon the magnitude of $i_L$ as well as upon its phase position.

Figure 3 shows 3 assumptions of load component currents. They represent, respectively, a unity power factor or resistance-load current, a 45-degree lagging or $RL$ load current (with natural secondary transient d-c component), and a 50-degree leading or $RC$ load current.

The adjusted no-load current component inrush may be determined by writing equation 3 as follows, and using the "finite difference method"

$$N\Delta\phi = [E_M \sin(\omega t + \lambda) - Ri_m]\,\Delta t - Ri_L\,\Delta t$$

A paper recommended for publication by the AIEE committee on electrical machinery. Manuscript submitted April 19, 1937; released for publication June 25, 1937.

E. B. KURTZ is head of the electrical engineering department of The State University of Iowa, Iowa City. The author wishes to acknowledge the helpful suggestions of G. F. Corcoran, associate professor of electrical engineering, and the assistance of R. L. Witzke, research assistant, both of The State University of Iowa.

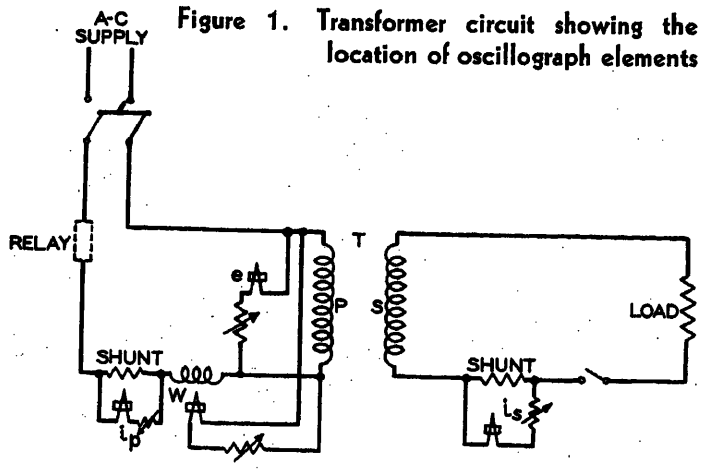
* $\phi$ represents both the primary leakage flux and the mutual flux of the transformer.



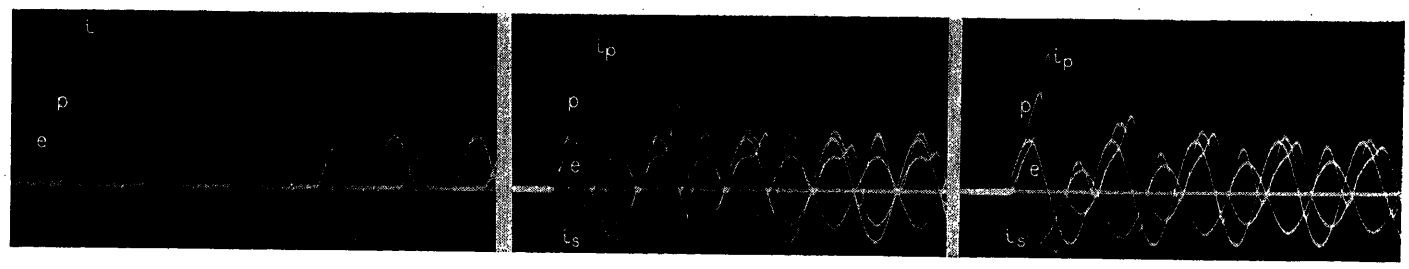


**Figure 1. Transformer circuit showing the location of oscillograph elements**

for each of the 3 load currents assumed and the corrected flux variations. The latter graphs show that the flux is only slightly reduced for the $RC$ load, somewhat more for the $R$ load, and still more for the $RL$ load. The $RL$ current is most effective in decreasing the positive flux values and increasing the negative values due to the d-c component in the secondary current and the resulting increase in

$$\sum Ri_L\Delta t$$

Naturally, this effect decreases as the d-c component dies out. In figure 5 are shown the corresponding magnetizing-current graphs. These values were obtained from the magnetization curve and correspond to the values of flux in figure 4.

Peak $i_p$—149 amperes
Peak $p$—10.4 kw
Steady-state condition: primary power = 2,160 watts; primary current = 26.6 amperes; secondary current = 25.8 amperes; load power factor = 0.700 lagging; ratio of transformation = 1

**Oscillogram 4. Current and power delivered to a transformer connected to a 0.685 leading - power - factor load, and energized at the time the voltage wave passes through zero**

$e$—Applied electromotive force (60 cycle)
$i_p$—Primary current
$p$—Primary power
$i_s$—Secondary current
$E$ (effective)—115 volts
Peak $i_p$—162 amperes
Peak $p$—6,554 watts
Steady-state condition: primary power = 2,216 watts; primary current = 25.6 amperes; secondary current = 25.8 amperes; load power factor = 0.685 leading

This equation is the same as for the no-load condition with the exception of the $Ri_L\Delta t$ term. Therefore if the flux variation for the no-load transient is decreased by the summation of $Ri_L\Delta t$, from $t = 0$ to $t = t$, the flux variation under load may be found. The current corresponding to this corrected flux will be the magnetizing current for the load condition. Figure 4 shows the summations of $Ri_L\Delta t$

It now merely remains to combine the magnetizing and load component currents to obtain the total primary current. This was done in figure 6. Corresponding values from figures 3 and 5 were combined to give the resultant currents shown. Because of the effect of phase position the $RL$ load peak now exceeds the no-load peak, whereas the $R$ load is somewhat lower and the $RC$ load is much lower, being only a little more than half of the $RL$ peak value.

## Oscillographic Verification

Oscillograms 2, 3, and 4 substantially confirm the anticipated load starting currents of figure 6. In each case the transformer core was demagnetized prior to the energizing of the transformer. Furthermore, in each of these oscillograms the primary circuit was closed on the zero value of the supply voltage, or when $\lambda = 0$. This created the maximum possible disturbance for zero residual flux.

The load was connected to its secondary before the primary circuit was closed.

An inspection of these 3 oscillograms shows that the secondary load current starts with approximately steady-state values. The primary currents in each case, however, contain a large transient component.

A comparison of actual and calculated values of the first loop with *RL* load is shown in figure 7. This shows substantial agreement between actual and predetermined values.

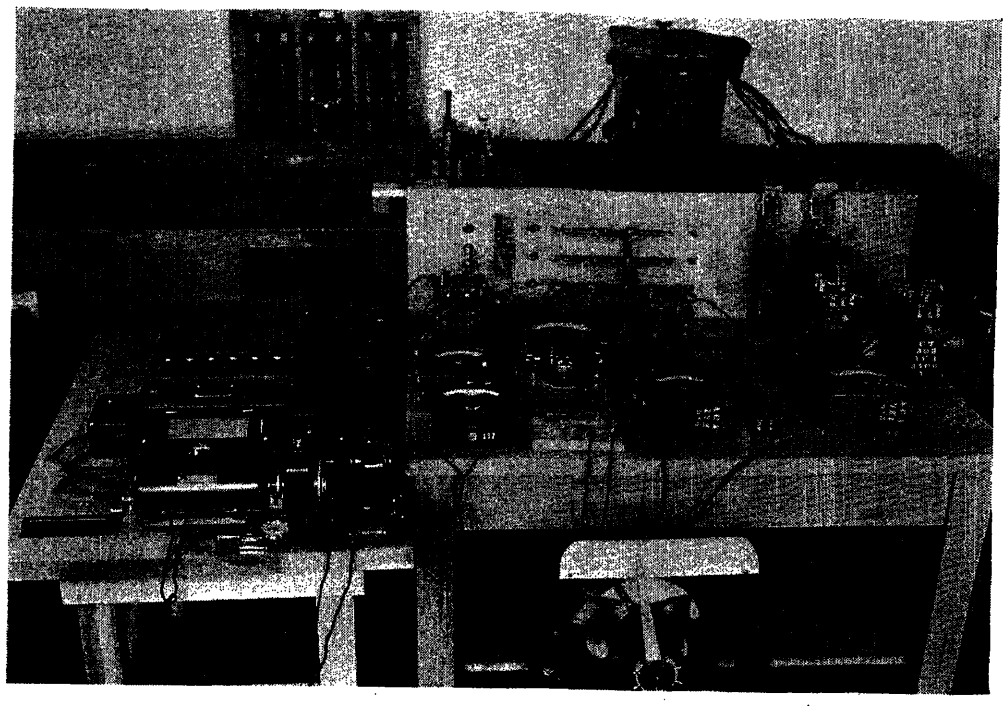

**Figure 2. Transformer, oscillograph, wave point switch, meters, and load used in tests**

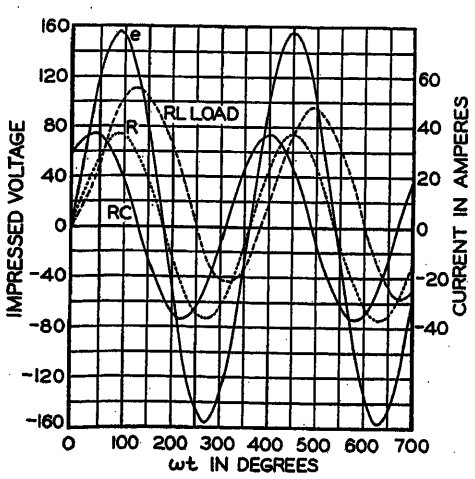
## Primary Switching With $\lambda = 90$



When a transformer is in normal operation its flux is approximately zero when the impressed voltage is at its maximum value. Therefore, a demagnetized transformer connected to the line at the instant of maximum voltage will be under steady-state conditions from the start. Oscillograms 5, 6, and 7 illustrate this fact for unity, lagging, and leading power factors, respectively. Except for the difference in $\lambda$ the conditions are the same as for oscillograms 2, 3, and 4. In the case of *RL* loading the secondary voltage was not exactly at its peak value and therefore a small d-c component is noticeable in the load current which in turn is reflected in the primary current. In the case of leading power factor the load consisted of *R* and *C* in parallel. This permitted the condenser to draw an abnormal current during the first quarter of a cycle.

## Secondary Switching

In taking oscillograms numbers 8 to 13 inclusive, the primary circuit was first closed and the flux allowed to become normal before the secondary load circuit was closed. Any transient appearing in the primary will then be due to disturbances caused in the secondary circuit. Oscillograms numbers 8, 9, and 10 are for unity, lagging, and leading power factors when the secondary switch is closed at $\lambda = 0$, while 11, 12, and 13 are corresponding oscillograms for $\lambda = 90$.

In oscillograms 8 and 11 with resistance loading no transients are expected, and this is confirmed by the rec-

ords. In oscillogram 9, however, with $RL$ loading and $\lambda = 0$ a large d-c component is present in the load current which is of course reflected in the primary current. In oscillogram number 13 the condenser draws a large initial current in an attempt to bring its $q/C$ voltage up to the impressed electromotive force. A series $RC$ connection would have partially avoided this difficulty.

## Oscillogram Analysis

In oscillograms like those shown above, where the current and power variations are large and irregular, it is quite difficult to draw satisfactory conclusions. For this reason it was thought desirable to analyze them and make the current, power, and power factor trends more apparent. To this end the "moving average," long used by statisticians, was introduced as a means of ironing out the wide and irregular variations. It was applied in particular to oscillograms 2, 3, and 4.

## The Moving Average Applied to Power

To apply this method of analysis to a power oscillogram, readings of instantaneous values of power were read and tabulated for 15-degree intervals from an enlarged oscillogram as shown in table I, columns 1 and 2. The first value under the heading $\Sigma p$ in column 3 is the sum of the instantaneous power ordinates for the first 360 degrees, and the first value in column 4 is the average

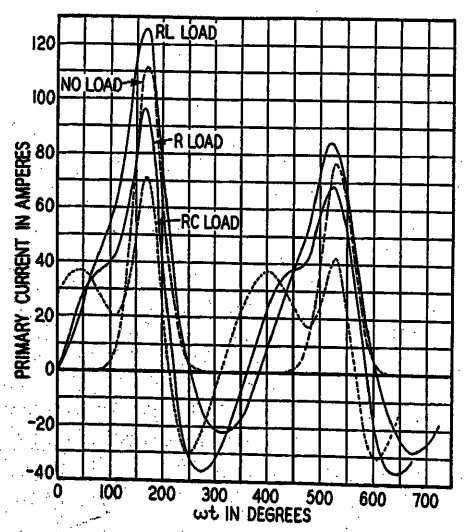

Figure 6. Predetermined total primary currents for 3 assumed loads

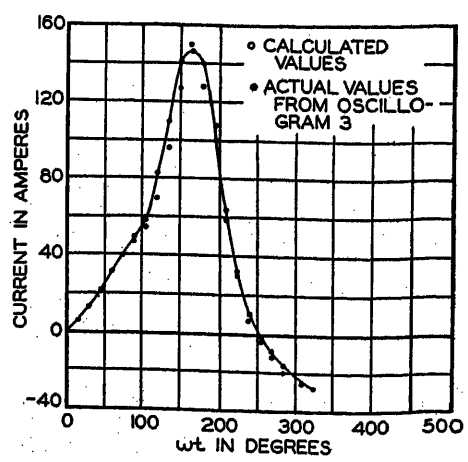

Figure 7. Comparison of actual and calculated values of primary current with RL load

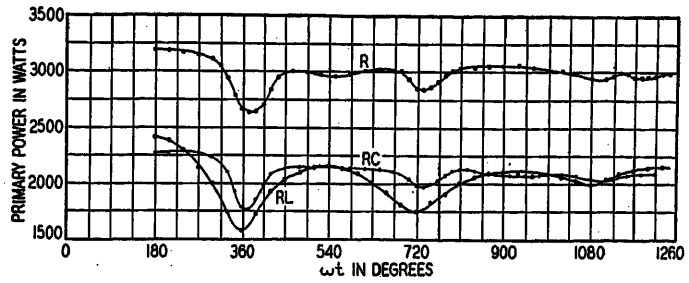

**Figure 8. Trends of average values of primary power corresponding to oscillograms 2, 3, and 4**

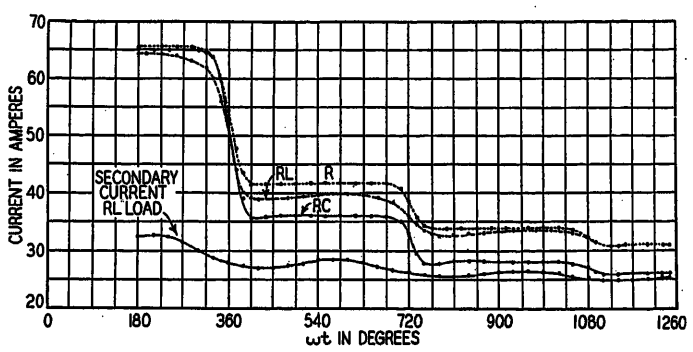

**Figure 9. Trends of the effective values of primary current corresponding to oscillograms 2, 3, and 4**

of these ordinates, and therefore the "average power." It is plotted in figure 8 as the average value of the power at 180 degrees. In like manner succeeding values of average power are obtained by averaging ordinates over a 360-degree span and plotting this value at the midpoint of the span. Figure 8 shows these values for a little over 3 cycles for oscillograms 2, 3, and 4. These graphs show the average power to remain fairly constant throughout the transient period. The *RL* and *RC* are less in value due to reduced values of power factor.

It is interesting to note that the average power during the transient period never goes to values higher than for steady-state values, in spite of the high peaks shown on the oscillogram. These high peak values represent power used in building up a magnetic field which is nearly all returned to the source.

**Table I. Calculations of Average Power and Power Factor**

| 465 | 690 | 4,854 | 2,020 | 0.454 |

## Moving Average Applied to Current

The procedure in finding the current trend is slightly different since the root-mean-square value is required and not the average. Instantaneous values for 15-degree intervals are read from the oscillogram and tabulated as shown in columns 1 and 2 table II. In column 3 the squared values are given. Column 4 is the sum of these squared values for 360 degrees, column 5 gives the average squared value, and column 6 the square root of this value, or the effective value. This value is plotted at the midpoint of the 360-degree span, namely at the 180-degree point. Succeeding values are obtained in the same manner. Values so obtained for oscillograms 2, 3, and 4 are plotted in figure 9 for about 4 cycles. This figure shows the currents to decrease in steps at the rate of one step per cycle. The total reduction is from a value of 65 amperes to the steady-state value of 26 amperes. The *RL* cur-

rent decreases somewhat more rapidly due to the coincident decrease of the secondary current.

## Transient Power Factor

After the effective current and average power are known the power factor can be calculated since the effective voltage is also known. The values of power factor corresponding to the current and power trends are tabulated in table I and plotted in figure 10. These graphs show

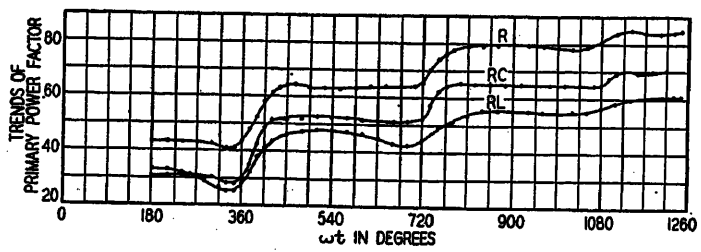

Figure 10. Trends of primary power factor corresponding to oscillograms 2, 3, and 4

that the power factors start with low values and increase in steps simultaneously with the decrease of the currents.

## Conclusions

Some of the more important conclusions which may be drawn from this study can be briefly stated as follows:

1. The finite differences method will give satisfactory results when used to calculate transformer transients.

2. The load power factor has a decided effect upon the initial current and power variations in the case of loaded transformers.

3. The inductive load causes the maximum and the capacitive load the minimum disturbance in the primary current.

4. The effective value of the transient current, as calculated by the method of moving averages over a 360-degree span, decreases in steps.

5. The average power during the transient period, as calculated by the method of moving averages over a 360-degree span, does not vary much from its normal steady-state value.

6. The power factor is very low at the beginning of the transient and increases to its normal value in steps.

7. The magnetizing component of the primary current experiences little transient effect when a load is connected to the secondary.

# Some Effects of Welding on Ship Construction

SHIPBUILDING PRACTICE has been affected more in the last decade by the introduction and general adoption of welding than by any other one innovation, according to James B. Hunter in a paper presented during the spring meeting of The Society of Naval Architects and Marine Engineers at Chester, Pa., June 22, 1937. Design has been modified, particularly because a ship's hull must be assembled without annealing and so-called built-in stresses should be avoided as far as possible. The maximum amount of prefabrication on the ground or in the shop is desirable. Intricate forgings often can be replaced by simple welded parts, and welding is used extensively in parts for major machinery.

Erection and assembly procedure has been greatly modified by the use of welding, primarily because of the omission of holes and flanges for fastening individual members together and also because of the various methods adopted to take care of shrinkage and buckling, particularly on the lighter structures. In assembly, welding in most instances requires greater time because of sequence in order to avoid distortion and the introduction of so-called locked-up stresses. Such sequence usually entails completion of one section before starting work on the adjacent section. The greater amount of erection time directly affects shipyard capacity. Sheet-metal and pipe shops have also been affected greatly by the use of welding.

Different types of vessels require different methods and shop equipment. Welding has advanced recently to a great degree in the building of naval vessels, but in the design of this type the urge to save weight, because of treaty limitations, justifies increased cost, since military characteristics can be provided which would otherwise be impossible Such reasoning, however, cannot be applied to merchant vessels except in very special cases.

# Magnetic Generation of a Group of Harmonics

L. R. WRATHALL
NONMEMBER AIEE

## Synopsis

A harmonic generator circuit is described which produces a number of harmonics simultaneously at substantially uniform amplitudes by means of a nonlinear coil. Generators of this type have been used for the supply of carrier currents to multichannel telephone systems, for the synchronization of carrier frequencies in radio transmitters, and for frequency comparison and standardization.

A simple physical picture of the action of the circuit has been derived from an approximate mathematical analysis. The principal rôles of the nonlinear coil may be regarded as fixing the amount of charge, and timing the charge and discharge of a condenser in series with the resistance load. By suitably proportioning the capacity, load resistance, and saturation inductance of the nonlinear coil, the amplitudes of the harmonics may be made to approximate uniformity over a wide frequency range. The sharply peaked current pulse developed by condenser discharge passes through the nonlinear coil in its saturated state and so contributes nothing to the eddy-current loss in the core. In this way the efficiency of frequency transformation is maintained at a comparatively high value for the harmonics in a wide frequency band, even with small core structures. The theory has also been adequate in establishing a basis for design, and in evaluating the effects of extraneous input components.

## I. Outline of Development

THE USE of nonlinear ferromagnetic core coils to generate harmonics started with a simple type of circuit due to Epstein[1] which appeared in 1902. Application of the idea was not made to any great extent until it was elaborated by Joly[2] and by Vallauri[3] in 1911. The frequency multipliers thus developed were limited to doublers and to triplers, polarization being required for the doubler. In these, as well as in subsequent developments, single and polyphase circuits were used, and various arrangements were adopted for the structure of the magnetic core and for the circuit, by which unwanted components were balanced out of the harmonic-output path. Later developments had to do with improvements in detail, and with the generation of higher harmonics in a single stage and in a series of stages. The applications of perhaps greatest importance were to high power, long-wave radiotelegraph transmitters, where the fundamental input was obtained from an alternator. Other applications of the idea of harmonic production by magnetic means have been made in the power and communication fields.[4]

It appears that these circuits were all developed primarily to generate a single harmonic. Comparatively good efficiencies were obtained, values from 60 to 90 per cent being reported for the lower harmonics. The theory of frequency multiplication was investigated by a number of workers, among whom may be mentioned Zenneck[5] and Guillemin.[6] The latter, after analysis which determined the optimum conditions for the generation of any single harmonic, found experimentally that the efficiency of harmonic production decreased as the order of the harmonic increased. He obtained efficiencies of 10 per cent for the ninth harmonic, and 3 per cent for the thirteenth harmonic of 60 cycles.

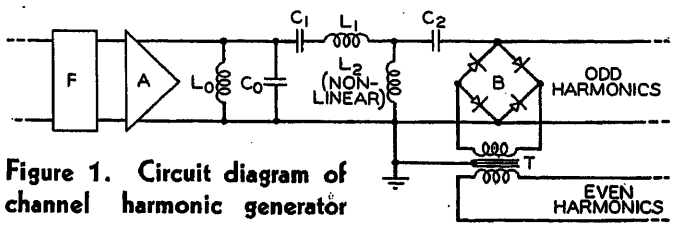

**Figure 1. Circuit diagram of channel harmonic generator**

Where the circuits are properly tuned and the losses low, free oscillations may be developed. The frequencies of these free oscillations may be harmonic, or subharmonic as in the circuit described by Fallou;[7] they may be rational fractional multiples of the fundamental, or incommensurable with the fundamental, as in Heegner's circuit.[8] The amplitudes of these free oscillations are usually critical functions of the circuit parameters and input amplitudes, and where the developed frequencies are not harmonic, they are characterized by the fact that the generated potentials are zero on open circuit. The theory of the effect has been worked out by Hartley.[9] It is presumably this effect which is involved in the generation of even harmonics by means of an initially unpolarized ferromagnetic core, an observation which has been attributed to Osnos.[10]

## II. Circuit Description

The harmonic producer circuit which forms the subject of the present paper differs from those mentioned in that it is designed to generate simultaneously a number of harmonics at approximately the same amplitude.

Harmonics developed in circuits of this type have been used for the supply of carrier currents to various multichannel carrier telephone systems, for synchronizing carriers used in radio transmitters, and for frequency com-

A paper recommended for publication by the AIEE committee on communication. Manuscript submitted May 18, 1937; released for publication June 18, 1937.

E. PETERSON is circuit research engineer, and J. M. MANLEY and L. R. WRATHALL are members of the technical staff of Bell Telephone Laboratories, Incorporated, New York, N. Y.

1. For all numbered references, see list at end of paper.

parison and standardization. Only odd harmonics are generated by the harmonic producer when the core of the nonlinear coil is unpolarized, as is the case here. To generate the required even harmonics, rectification is employed. This is accomplished by means of a well-balanced copper-oxide bridge, which provides the even harmonics in a path conjugate to the path followed by the odd harmonics.

A typical circuit used for the simultaneous generation of a number of odd and even harmonics at approximately

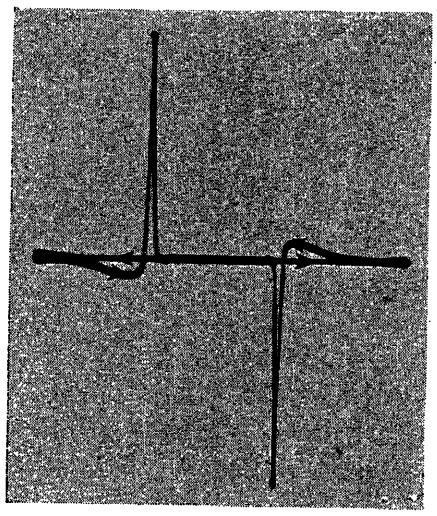

**Figure 2. Cathode-ray oscillogram of output-current wave form with fundamental input current as abscissa**

equal amplitudes is shown schematically in figure 1. Starting with the fundamental frequency input, a sharply selective circuit $F$ is used to remove interfering components, and an amplifier $A$ provides the input to the harmonic generator. The shunt resonant circuit $L_0C_0$ tuned to the fundamental serves primarily to remove the second harmonic generated in the amplifier. The elements $C_1L_1$ are inserted to maintain a sinusoidal current into the harmonic producer proper, as well as to tune out the circuit reactance.

$L_2$ is a small permalloy core coil which is operated at high magnetizing forces well into the saturated region. The circuit including $L_2$, $C_2$, and the load impedance, which is practically resistive to the desired harmonics, is so proportioned that highly peaked current pulses rich in harmonics flow through it. Two such pulses, oppositely directed, are produced during each cycle of the fundamental wave, the duration of each being a small fraction of the fundamental period. The typical output wave shown in figure 2 was obtained by means of a cathode-ray oscillograph, the ordinate representing the current in the load resistance, and the abscissa representing the fundamental current into the coil. The desired odd harmonics are selected by filters connected across the input terminals of the copper-oxide bridge. The even harmonics are obtained by full-wave rectification in the copper-oxide bridge, and are taken off from the conjugate points of the bridge through an isolating transformer to the appropriate filters. Thus the harmonics are produced in 2 groups, with the even harmonics separated from the odds to a degree depending largely upon the balance of the copper-oxide bridge, as well as upon the amount of second harmonic passed on from the amplifier. In this way the required discrimination properties of any filter against adjacent harmonics are reduced to the extent of the balance.

A particular application of the circuit described above to the generation of carriers for multichannel carrier telephone systems uses a fundamental frequency of 4 kilocycles, from which a number of harmonics are developed. Of these the sixteenth to the 27th are used as carriers. A photograph of an experimental model of this carrier supply system (developed by Mr. J. M. West) is shown in figure 3. The top panel includes an electromagnetically driven tuning fork serving as the highly selective circuit $F$, the amplifier $A$, the output stage of which consists of a pair of pentodes in push-pull, and the tuned circuit $L_0C_0$. The next panel includes the elements $L_1C_1$, $L_2$, $C_2$, $B$, and $T$,

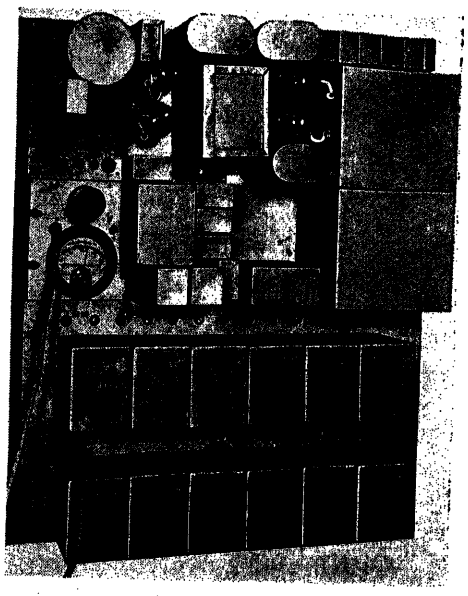

**Figure 3. Carrier supply unit, furnishing 12 harmonics of 4 kilocycles (experimental model)**

together with a thermocouple and meter terminating in a cord and plug for test and maintenance purposes. The last 2 panels include the 12 harmonic filters, with test jacks and potentiometers for close adjustment of the output of each harmonic.

A few of the more interesting performance features are given in figure 4. The harmonic power outputs shown in figure 4*a* represent measurements at the input terminals of the filters. The variation observed is produced by the nonuniform impedance of the filters. When these are corrected, the variations due to the harmonic generator proper are less than $\pm 0.2$ decibels from the sixteenth to the 27th harmonic. Outside this region the amplitudes gradually decrease to the extent of 4 decibels at the third and 35th harmonics, and 11 decibels at the fundamental and the 61st harmonic. The variation of harmonic output with change of amplifier plate potential is given for the 2 harmonics indicated in figure 4*b*. Figure 4*c* shows the 104-kilocycle output as a function of the 4-kilocycle input. Arrows are used to indicate normal operating points. The input amplifier is operated in an overloaded state so that,

beyond a critical input, the fundamental output of the amplifier and the harmonic output corresponding are but little affected by change of input amplitude. With a linear amplifier the harmonic output current would vary roughly as the 0.4 power of the input current.

Another application involving higher frequencies has been made to the generation of the so-called "group" carriers used in conjunction with a coaxial conductor.[11] There only odd harmonics of 24 kilocycles from the ninth to the 45th are required. These are generated at substantially uniform amplitudes. The circuit differs from figure 1 in that the copper-oxide bridge is omitted, and the nonlinear coil is provided with 2 windings to facilitate impedance matching. The performance of an experimental model is similar to that of the generator described above.

In both applications the required harmonics are generated at amplitudes high enough to avoid the necessity for amplification. A notion of the physical size and construction of the nonlinear coils used may be had from the photographs of figure 5.

## III. Theory of Operation

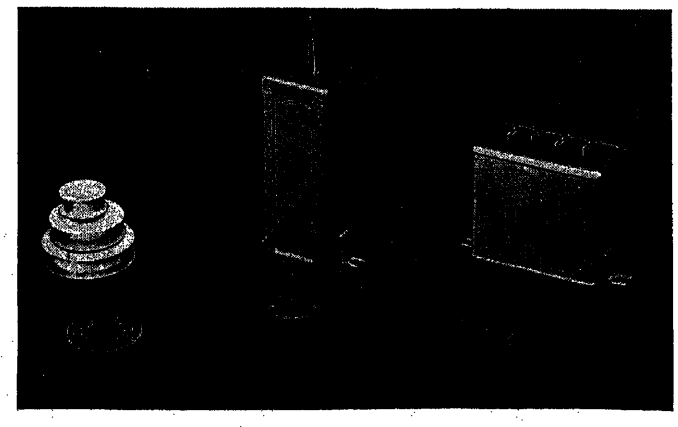
The analysis of operation of the harmonic-generating circuit described above meets with difficulties, since a high degree of nonlinearity is involved in working the coil well into its saturated region.

To avoid these difficulties, an expedient is adopted by which the hysteresis loop is replaced by a single-valued characteristic made up of connected linear segments[6] as shown in figure 6*b*. It is then possible to formulate a set of linear differential equations with constant coefficients, one for each linear segment. The solutions are readily arrived at and may be pieced together by imposing appropriate conditions at the junctions, so that a solution for the whole characteristic is thereby obtained. From this solution the wave form of current or voltage associated with any circuit element may be calculated. Resolution of the wave form into components may then be accomplished by an independent Fourier analysis.

The assumed $B$-$H$ characteristic of figure 6*b* is made up of but 3 segments. While it is manifestly a naïve representation of a hysteresis loop, it will be shown by comparison with experiment that the main performance features of harmonic generators may be reproduced by this crude model.

It will be noted on figure 6*b* that the differential permeability of the assumed nonlinear core, a quantity proportional to $dB/dH$, takes on one of 2 values, determined by the absolute value of the magnetizing force. These are designated by $\mu$ in the permeable region and $\mu_s$ in the saturated region. The corresponding inductances are $L_{20}$ and $L_{2s}$, $L_{20}$ being many times greater than $L_2$. The values of current through the coil at which the differential inductance changes are designated $\pm I_0$, corresponding to the magnetizing forces $\pm H_0$. With this simple representation of the nonlinear inductance, the operation of the circuit shown in figure 6*a* will be described over a complete cycle of the fundamental input wave.

The current flowing in the input mesh is made practically sinusoidal by tuning $L_1$, $C_1$. If now we start at the negative peak of the sinusoidal input current of amplitude $I_1$ and frequency $p/2\pi$, the nonlinear coil is worked in the saturated state where its inductance $L_{2s}$ is low. Since the resistance of the winding is small, the potential drop across the coil is correspondingly small. The current $i_2$ which charges the condenser $C_2$, assuming the latter to have zero



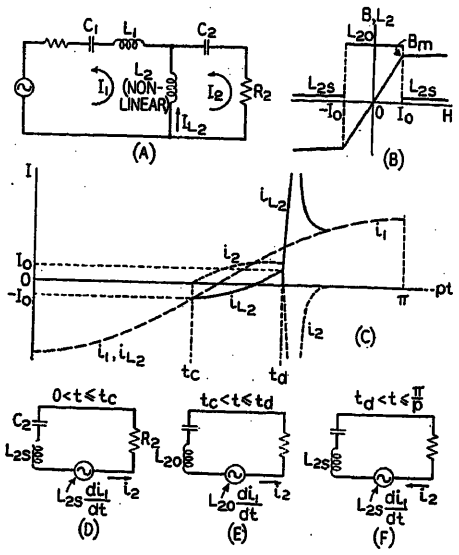


**Figure 5. Construction of experimental nonlinear coils used for harmonic generation, showing core forms, magnetic tape, wound coils, and assembled units**

charge at the start, is therefore negligible as indicated in figure 6*c*. This state of affairs is maintained until the current through $L_2$ reaches the value $-I_0$, at time $t_c$. At this point the inductance of the coil increases suddenly to $L_{20}$ and the voltage across the coil tends to increase. Hence the current $i_2$ increases and $C_2$ is charged much more rapidly than in the preceding interval. Charging continues until the current through the coil increases through $I_0$ at time $t_d$. At that time, the coil inductance returns to

A—Harmonic generator circuit

**Figure 6. Diagrams illustrating operation of the harmonic generator**

the low saturation value $L_{2s}$, and the potential across the coil decreases. The condenser potential is no longer opposed by the potential drop across the coil and the condenser discharges through $R_2$ and $L_{2s}$; $i_2$ reverses its direction, maintaining the coil in the saturated region. The form and duration of the sharply peaked discharge pulse characteristic of this type of harmonic generator are determined by the values of the elements just mentioned. The resistance, capacity, and saturation inductance effectively in circuit are adjusted to permit the current to rise to a high maximum, to damp the pulse, and to shorten the pulse duration to the point at which the highest harmonic required reaches the desired amplitude. Under the working conditions which will be assumed in the following, this insures that the pulse dies away before the end of the half-cycle as shown in figure 6*c*. At that time the currents and potentials are the same, except for reversals of sign, as those at the start, so that the current wave consists of an alternating succession of these pulses. Equivalent circuits for the 3 respective time intervals of a half-cycle are shown in figures 6*d*, 6*e*, 6*f*. The similarity of the load-current wave form derived above, and that experimentally observed and shown in figure 2, is to be noted.

The course of events described above parallels closely conclusions drawn from the mathematical analysis. This picture attributes to the coil $L_2$ a sort of switching property which permits the condenser $C_2$ in the load circuit to be charged and discharged alternately. The charge starts when the large inductance $L_{20}$ is switched across the primary and secondary meshes, thus permitting energy to flow from the primary circuit into the condenser $C_2$. This corresponds to that part of the wave described above during which the load current slowly rises as the charge accumulates on $C_2$. Discharge starts when the large inductance $L_{20}$ is switched out and the much smaller inductance $L_{2s}$ is switched in. This sharply reduces the voltage across $L_2$, and the condenser is discharged through the load resistance and the saturation inductance. During this interval the secondary circuit is practically isolated from the primary. The switching process is sustained by the alternations of the sinusoidal primary current and is periodic, as we have seen, since similar conditions exist at the start of each pulse. The times at which switching occurs are those at which the current through the coil passes through the critical values ($\pm I_0$) where the inductance changes.

Since the narrow discharge pulse provides the principal contribution to the higher harmonics in which we are interested, and since this charge takes place in the secondary independently of the primary, the elements of the secondary mesh during discharge determine the form of the output spectrum. From this viewpoint we may regard the condenser as the source of energy for these harmonics and hence as a possible location for equivalent harmonic generator electromotive forces. In this light, the discharge circuit becomes a half-section of low-pass filter terminated in resistance $R_2$, with $L_{2s}$ as the series element and $C_2$ as the shunt element.

## IV. Quantitative Results of Analysis

To connect the 3 solutions which hold for the 3 linear regions of the *B-H* characteristic, conditions at the junctions are introduced, which lead to transcendental equations. These may be solved graphically when definite values are assigned to the circuit parameters. From these may be obtained the maximum value $Q_m$ of charge on $C_2$ which is reached at the end of the charging stage.

By plotting a representative group of these final charges over a range of parameters ordinarily encountered, an empirical equation has been deduced for $Q_m$ as follows:

$$Q_m = \sqrt{2}\,\frac{I_1}{p}\left(\frac{pL_{20}}{R_2}\right)^{0.75}(pC_2R_2)^{0.05}\left(\frac{I_0}{I_1}\right)^{0.6} \qquad (1)$$

For the usual operating conditions the narrow peaked discharge part of the current pulse is most important in the determination of the higher harmonics (say beyond the ninth) with which we are concerned here. The charging interval then may be neglected in calculating the higher harmonics. The form of the discharge pulses is determined by the parameters $pC_2R_2$ and $k$, where

$$k = L_{2s}/R_2^2C_2$$

The familiar criterion for oscillation in a series circuit containing inductance, capacity, and resistance may be expressed in terms of $k$. If $k > 1/4$, the discharge is an exponentially decaying oscillation; if $k \leq 1/4$, the discharge is

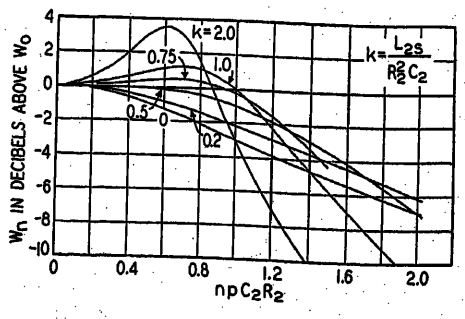

**Figure 7. Harmonic power spectrum plotted from equation 2 as function of $npC_2R_2$ with k as parameter**

an exponentially decaying pulse. This last condition is the one assumed in the description of operation given above.

If the discharge is oscillatory, and if further the second peak is large enough, the current through the coil may become less than $I_0$ during the discharge interval. Thus $L_2$ will return to its larger value, and recharging of the condenser will result. This process may lead to large and undesired variations in the harmonic amplitudes. To maintain the frequency distribution as uniform as possible over the frequency range of interest, the circuit parameters are usually adjusted so that recharging does not occur.

Harmonic analysis shows that the $n$th harmonic amplitude under the above assumptions is given by

$$I(n) = \frac{(2/\pi)\, pQ_m}{\sqrt{1 + (1 - 2k)\,(npC_2R_2)^2 + k^2\,(npC_2R_2)^4}} \qquad (2)$$

where $n$ is odd. This expression neglects the contributions due to the charging stage, which are usually small for harmonics higher than the ninth.

The corresponding harmonic power output is

$$W_n = \frac{I(n)^2 R_2}{2} \frac{W_0}{1 + (1 - 2k)\,(npC_2R_2)^2 + k^2\,(npC_2R_2)^4} \qquad (3)$$

where $W_0$ is a convenient parameter which does not vary with $n$ and hence serves as an indication of the power of the output spectrum. It is related to $W$, the total power delivered to the load resistance, by the equation

$$W_0 = \frac{4}{\pi}\, pC_2R_2W$$

For purposes of calculation $W_0$ may be found from (1) and (2) to be

$$W_0 = \frac{10^{-7}}{\pi^2}\, pB_m\, Ad\, H_1 \left(\frac{H_0}{H_1}\right)^{0.2} (pC_2R_2)^{1.8} \left(\frac{pL_{20}}{R_2}\right)^{0.5} \text{watts} \qquad (4)$$

where

$$L_{20} = \frac{4N^2A\mu 10^{-9}}{d}$$

$$H_1 = 0.4\, N\, I_1/d$$

$$H_0 = 0.4\, N\, I_0/d$$

and $N$ is the number of turns wound on the toroidal core of diameter $d$ centimeters and cross-sectional area $A$ square centimeters.

In figure 7 the power spectrum is shown by plotting $W_n$ in decibels above or below $W_0$ as a function of $npC_2R_2$ for several values of $k$. These curves illustrate the degree of uniformity obtainable in harmonic amplitudes under different conditions. It may be shown from (3) that $W_n$ has a maximum with respect to $n$ when $k$ is greater than 1/2, if

$$npC_2R_2 = \frac{1}{k}\sqrt{k - \frac{1}{2}}$$

and that its value at this point is

$$(W_n)_{max} = W_0k^2/(k - 1/4)$$

A number of relations may be derived from these equations which are useful for design purposes. Thus the form of harmonic distribution is fixed by $k$ and $pC_2R_2$. The power for a given magnetic material worked at a given fundamental magnetizing force then depends solely upon the volume of core material. Finally, the impedance is fixed by the number of turns per unit length of core. If the impedances desired for primary and secondary circuits differ, separate windings may be used for each circuit.

## V. Calculated and Observed Performance

In order to make practical use of the results given above, we need some basis for deriving the assumed parameters of the nonlinear coil from the physical properties of the magnetic materials used in harmonic producers.

The fact that the actual magnetization curve is a loop instead of a single-valued curve as assumed requires increased power input to the circuit to provide for the hysteresis and eddy losses in the core. Other than this, the principal remaining effect of the existence of a loop is a lag in the time at which the pulses occur, an effect which is of no great moment in determining the form or magnitude of the resulting pulses.

The next point requiring consideration is the effect introduced by the assumed abrupt change of slope contrasted to the smooth approach to saturation actually observed. While no rigorous comparisons can be drawn, the effect of the more gradual approach to saturation was approximated analytically by introducing an additional linear segment between the permeable region and each saturated region of the $B$-$H$ characteristic, at a slope intermediate between the two, so as to form a $B$-$H$ characteristic of 5 segments in place of the original 3. The solutions for these 2 characteristics were found to yield negligibly small differences in the amplitudes of the higher harmonics. It was inferred from this result that no substantial change would be introduced by a smooth approach to saturation.

Finally, the actual $B$-$H$ characteristic has a slight curvature in the saturated region, while the analysis considered a small linear variation. A rough approximation for the effect of this curvature, which leads to fair agreement with experiment, consists in taking for $L_{2s}$ the average of the actual slope, from its minimum value reached during the discharge peak down to the point at which the slope is $^1/_{10}$ maximum. To this is added the linear inductance contributed by the dielectric included within the winding.

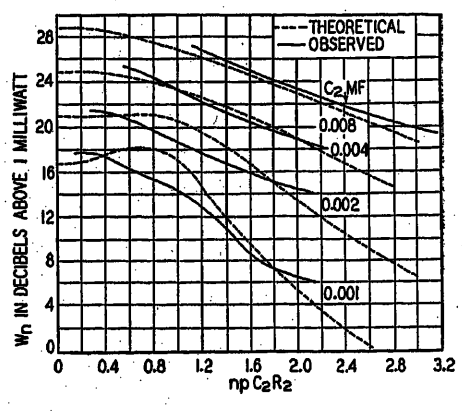

**Figure 8. Comparisons of calculated and measured harmonic distributions, plotted as functions of $npC_2R_2$, with $C_2$ as parameter; fundamental (4-kilocycle) magnetizing force 8.1 oersteds**

To summarize then, the harmonic outputs obtained from the analysis with the assumed $B$-$H$ characteristic may be brought into line with experimental observations by the introduction of quantities obtained from actual $B$-$H$ loops at appropriate frequencies and magnetizing forces. In these the maximum slope found on the loop is taken for $L_{20}$, the average slope over the saturated region is taken for $L_{22}$, and the energy corresponding to the area of the real $B$-$H$ loop must be added to that originally supplied the harmonic generator input.

A comparison between measured and calculated harmonic distributions obtained with a 4-kilocycle fundamental input is shown in figure 8. In this case the harmonic distributions were measured for 4 different values of the secondary condenser $C_2$ as shown by the plotted points. The power output of each harmonic is plotted in terms of the quantity $npC_2R_2$. Calculated values are indicated by dashed lines. It is observed that while the agreement between calculation and experiment is perhaps as good as could be expected for the 2 highest curves, a substantial divergence is noticed in the 2 lowest sets; the forms of the 2 sets are significantly different, and it seems that the divergence might become even greater at larger values of $npC_2R_2$ than those shown. Upon examination of the equations, however, it turns out that the conditions existing for the lowest pair of curves are just those for which recharging occurs, so that the conditions for which the equations were framed hold no longer. The calculated distributions might be expected to be too low for the higher harmonics, since we have taken an average value for the saturation inductance. This means that the peak of the discharge pulse will be sharper than that calculated, with a corresponding effect upon the higher harmonics.

Another comparison between calculated and observed values is shown in figure 9 for a fundamental input of 120 kilocycles with 2 values of resistance load. Fair agreement is observed over the greater part of the frequency range, which extended to 5 megacycles. The distribution curve for the smaller resistance load undulates as the load resistance is reduced, since multiple oscillations and recharging are then promoted, in consequence of which the output power tends to become concentrated in definite bands of harmonics. In general, agreement within a few decibels is found over a wide range of circuit parameters when working into a resistance load, provided that recharging does not occur.

When the resistance termination is replaced by a bank of filters as it is in practice, the resistance termination is approximated over the frequency band covered by the filters. Where the band is wide the results obtained do not differ greatly from those with the pure resistance load, but when only a few harmonics are taken off by filters and the impedances to the other harmonics of large amplitude vary widely over the frequency range, then the wave form of the current pulse is substantially altered, with corresponding effect upon the frequency distribution, and the calculations for a pure resistance termination do not apply.

A difficulty sometimes arises in getting a desired value of fundamental current into the coil. Under certain circuit conditions the current amplitude is found to change rapidly as the input voltage is smoothly varied. This phenomenon has been described by various terms such as Kippeffekt, ferroresonance, and current-hysteresis.[13] If the operating point is located close to one of these discontinuities, the fundamental input and harmonic output may vary widely with small changes in supply potentials and circuit parameters. This troublesome source of variation may be avoided in a number of different ways, of which the simplest is to increase the resistance of the resonant mesh. In the present case this is effectively accomplished without sacrificing efficiency by using pentodes, which have high internal resistances, in the amplifier stage connected to the resonant mesh.

The efficiency of power conversion from fundamental to harmonics may be found from the fundamental power input to the circuit, as derived from measurements on a cathode-ray oscillograph, and from the total harmonic output measured by means of a thermocouple. The maximum efficiency obtainable with the low power circuits described in the second section is in the neighborhood of 75 per cent, and decreases with increasing fundamental frequency because of the increased dissipation due to eddy currents. It should be noted that this figure does not include losses in the primary inductance $L_1$. When only a few harmonics are used, the efficiency of obtaining this useful power naturally drops to a much lower value, which for the particular cases mentioned in the second section, is between 15 and 25 per cent.

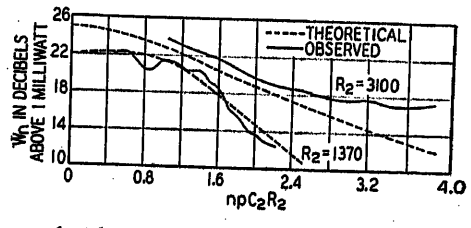

**Figure 9. Comparisons of calculated and measured harmonic distributions, plotted as functions of $npC_2R_2$ with $R_2$ as parameter; fundamental (120 kilocycle) magnetizing force 9.8 oersteds**

## VI. Effect of Extraneous Components

In any practical case the fundamental input to the harmonic producer is accompanied by extraneous components introduced by crosstalk, by modulation, or by an impure source. Thus if the fundamental is derived as a harmonic of a base frequency, small amounts of adjacent harmonics will be present. Or if the amplifiers are a-c operated, side frequencies are produced differing from the fundamental by 60 cycles and its multiples. Extraneous components of this sort in the input modulate the fundamental and produce side frequencies about the harmonics in the output. When the harmonics are used as carriers, the accompanying products must be reduced to a definite level below the fundamental if the quality of the transmitted signal is to be unimpaired. The requirements imposed by this condition can be calculated by simple analy-

sis, the results of which agree rather well with experimental values.

The method of analysis used is to consider the extraneous component at any instant as introducing a bias[14] to the nonlinear coil. The primary effect of a small bias $b$ is to shift the phase of the discharge pulse by $\mp b/H_1$ radians, $H_1$ being the amplitude of the fundamental magnetizing force. The sign of the shift alternates so that intervals between pulses are alternately narrowed and widened.

The effect of this shift on the harmonics produced may be found by straightforward means in which the amplitude of any harmonic is expressed in terms of the bias. Hence when the extraneous component or components vary with time, the sidebands produced may be evaluated when the bias is expressed by the appropriate time function.

If the bias is held constant, the wave is found to include both odd and even harmonics, the amplitudes of which are given by

$$\left.\begin{aligned} I_n &= I(n)\left|\cos nb/H_1\right| \quad (n \text{ odd}) \\ &= I(n)\left|\sin nb/H_1\right| \quad (n \text{ even}) \end{aligned}\right\} \tag{5}$$

$I(n)$ being the harmonic distribution in the absence of bias as given by equation 2.

If the extraneous input component is sinusoidal, we have

$$b = Q \sin (qt + \phi) \tag{6}$$

Substituting this expression for $b$ in the equation for the harmonic components yields odd harmonics of the fundamental, and modulation products with the angular frequencies $mp \pm lq$, which may be grouped as side frequencies about the odd harmonics. The amplitude of the $n$th (odd) harmonic is

$$I_n = I(n)\left|J_0\left(\frac{nQ}{H_1}\right)\right| \tag{7}$$

and the amplitude of the modulation product $mp \pm lq$ is

$$I_{m,\pm l} = I(m)\left|J_l\left(\frac{mQ}{H_1}\right)\right| \qquad (m + l \text{ odd}) \tag{8}$$

where $J_l(x)$ is the Bessel function of order $l$.

Considering the side frequencies about the $n$th harmonic, the largest and nearest of these are $(n + 1)p - q$ and $(n - 1)p + q$, $n$ being odd. The ratio of the amplitudes of either side frequency to the $n$th harmonic is

$$\frac{I_{n\pm1,\mp1}}{I_n} = \left|\frac{J_1[(n \pm 1)Q/H_1]}{J_0(nQ/H_1)}\right| \tag{9}$$

on the assumption that the harmonic distribution in the neighborhood of $n$ is uniform so that $I(n \pm 1) \doteq I(n)$. If the arguments of the Bessel functions are less than 0.4, a good approximation to the right member of equation 9 is $(n \pm 1)Q/2H_1$. Hence with sufficiently small values of interference, the sidebands produced are proportional to the amplitude of the interference, and increase linearly with the order of the harmonic. These relations apply to harmonic generators which produce sharply peaked waves in general, and are not peculiar to the magnetic types.

Neighboring modulation products involving the interfering component $q$ more than once have much smaller amplitudes in normal circumstances than the product considered above. Because of the tuning in the input mesh, interfering components far removed in frequency from the fundamental are greatly reduced and the most troublesome interference is likely to be close in frequency to the fundamental.

It may be noted that where the interference is produced by amplitude modulation of the fundamental, so that 2 interfering components enter the input, the distortion

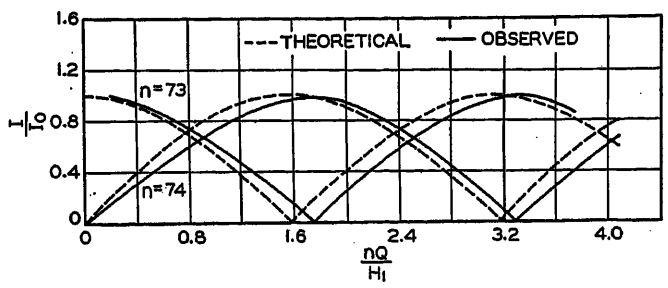

**Figure 10. The 73rd and 74th harmonic amplitudes as functions of direct current flowing through nonlinear coil. Ordinate is ratio of harmonic amplitude, with bias indicated, to that of 73rd harmonic with zero bias; abscissa is harmonic number multiplied by the ratio of bias to fundamental; dashed lines calculated from equation 5, full lines measured; fundamental 4 kilocycles**

produced may be approximated by doubling the amplitudes of the side frequencies produced by one of the interfering components. If the disturbance is the second harmonic of the fundamental, the effect is nearly the same as that for constant bias, and the relations (5) may be used if $b$ is taken as the amplitude of the second harmonic magnetizing force.

To illustrate the effects of d-c bias, figure 10 shows the amplitudes of the 73rd and 74th harmonics of 4 kilocycles as functions of the parameter $nQ/H_1$. The agreement between measured and calculated values indicates that the most important effects of bias have been included in the simple analysis.

# Transmission Lines at Very High Radio Frequencies

By LESTER E. REUKEMA
MEMBER AIEE

## Summary

Radiation resistance, although ordinarily neglected, is actually of dominant importance in determining the selectivity factor $Q$ and the input impedance $Z_s$ for both parallel-wire and concentric lines at high radio frequencies, and therefore materially changes the optimum design of the line, whether used as a low-loss inductive or capacitive reactance or to give high selectivity or high impedance as a resonant line. Accurate design equations for maximum selectivity and for maximum impedance are developed in this paper for both parallel-wire and concentric lines, and curves are included showing radiation resistance, selectivity, input impedance, optimum values of spacing, conductor radius, etc. It is shown that for maximum $Q$ the optimum ratio of spacing to wire radius for parallel-wire lines is $D/r = 6.186$, and the ratio of outer conductor radius to inner conductor radius for concentric lines is $b/a = 4.22$, as compared with values of about 3.6 for both ratios when radiation resistance is neglected. For maximum impedance corresponding values are $D/r = 20.96$ and $b/a = 14.3$, as compared with values of 8 and 9.2, respectively, predicted neglecting radiation resistance. Moreover, $Q$ and $Z_s$ are not proportional to $D$ and $b$, as indicated in previous analyses; instead definite values of $D$ and $b$ give maximum $Q$ and slightly larger values give maximum $Z_s$, and even a small departure from the best value produces a large decrease in $Q$ or in $Z_s$. $Q$ and $Z_s$ for optimum design are both *inversely* proportional to the cube root of the frequency for parallel-wire lines and inversely proportional to the 0.4 power of the frequency for concentric lines, whereas previous analyses showed both *increasing* as the square root of the frequency.

## Introduction

RADIO COMMUNICATION in recent years has experienced a greatly increased utilization of the ultrahigh frequencies (those above 30,000,000 cycles), and the near advent of television will undoubtedly make these frequencies among the most valuable and most used in the entire spectrum. At these very high frequencies resonant transmission lines offer advantages in many ways which are not even closely approached by their nearest competitors. For instance the oscillating crystal, almost invariably used at lower frequencies to give radio transmitters a high degree of frequency stability, can be used at ultrahigh frequencies only in conjunction with several stages of frequency multiplication, since the $Q$ of the crystal (the ratio of its inertia reactance to its frictional resistance, and therefore a measure of its frequency stabilizing ability) is inversely proportional to frequency and assumes such a low value at the ultrahigh frequencies as to be practically worthless for frequency stabilization. For instance at 30,000,000 cycles the $Q$ of an $X$-cut quartz crystal is approximately 170, and at 300,000,000 cycles it is only about 17. To obtain values even as high as these requires careful mounting to keep the external work done by the oscillating crystal as small as possible. On the other hand, properly designed resonant transmission lines at these frequencies are extremely selective. For instance at 300,000,000 cycles as short-circuited quarter-wave parallel-wire line (approximately 10 inches long) of number 10 copper wire spaced 0.32 inch between wire axes has a $Q$ of 771. A concentric line of the same length and of optimum design has a $Q$ of 4,560. (The $Q$ of any electrical circuit is defined as

$$Q = \frac{2\pi fL}{R} = \frac{2\pi cL}{\lambda R} = \frac{2\pi L}{\lambda R\sqrt{LC}} = \frac{2\pi Z_0}{\lambda R}$$

where $R$, $L$, and $C$ are respectively resistance, inductance, and capacity per unit length of 2-wire line, $c = 1/\sqrt{LC} = 3 \times 10^{10}$ centimeters per second is the velocity of propagation of an electromagnetic wave in space and, at the ultrahigh frequencies, also the velocity along a wire, $\lambda$ is the wave length in centimeters and equals $c/f$, and $Z_0 = \sqrt{L/C}$ is the characteristic impedance of the line.) Evidently at the ultrahigh frequencies a comparatively tiny resonant line can give frequency stabilization far superior to that obtained by means of a crystal and at a small fraction of the expense. The high $Q$ of such lines also gives them a unique place as voltage step-up devices, the step-up ratio for an open-circuited quarter-waveline equaling $4Q/\pi$. Thus at 300,000,000 cycles, at which frequency the ordinary tuned radio-frequency transformer is of little value, a quarter-wave open-circuited concentric line gives a voltage step-up of 5,810.

Moreover, the high impedance obtainable by the use of resonant lines makes them ideally adapted as coupling elements between stages of vacuum-tube amplifiers at these high frequencies. Approximately a million ohms resistance may readily be obtained by means of a shorted quarter-wave concentric line. The quarter-wave line is also used extensively as an impedance matching device,[1] as a means of holding current at the receiving end of the line constant regardless of large changes in the magnitude and angle of the load impedance,[2] and as an impedance inverting device.[3]

A short-circuited transmission line of less than a quarter wave length acts as a high-quality low-loss inductive re-

A paper recommended for publication by the AIEE committee on communication. Manuscript submitted June 7, 1937; released for publication June 30, 1937.

LESTER E. REUKEMA is associate professor of electrical engineering at the University of California, Berkeley.

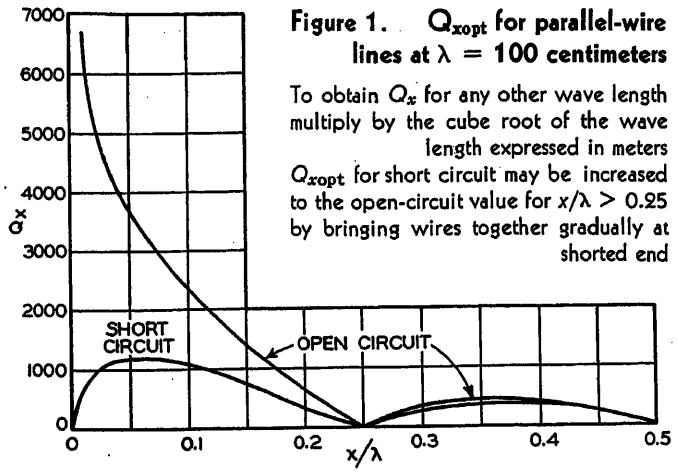

**Figure 1. $Q_{xopt}$ for parallel-wire lines at $\lambda$ = 100 centimeters**

To obtain $Q_x$ for any other wave length multiply by the cube root of the wave length expressed in meters

$Q_{xopt}$ for short circuit may be increased to the open-circuit value for $x/\lambda > 0.25$ by bringing wires together gradually at shorted end

actance with a $Q$ at the ultrahigh frequencies far superior to that of any coil. An open-circuited line of less than a quarter wave length acts as a high $Q$ capacitive reactance. If a capactive reactance which will pass direct current is desired, a short-circuited line of about $^3/_8$ wave length may be used, preferably a concentric line. Transmission lines, especially those of the concentric type, are therefore ideally adapted for use as circuit elements for electric filters and as tuning devices in general at ultrahigh frequencies.

The use of transmission lines as circuit elements at ultrahigh frequencies has been considered in several previous papers, of which Terman's "Resonant Lines in Radio Circuits," published in ELECTRICAL ENGINEERING, July 1934, is the most comprehensive. However, in all of these papers the effect of radiation resistance in altering the effective resistance of both parallel-wire and concentric lines has been neglected. In addition, the effect of proximity of the 2 wires in a parallel-wire line, in altering the constants $L$, $C$, and $R$, and therefore the input impedance and the $Q$ of the line although mentioned in some of the papers, has not been taken into account with rigid mathematical accuracy. The proximity effect is small for the optimum ratio of spacing to wire radius, decreasing $L$ and $Z_0$ by about 1.5 per cent each, increasing $C$ by about 1.5 per cent, and increasing $R$ by about 5.5 per cent. Of course there is no proximity effect in a concentric line. Consideration of these factors, and especially of the radiation resistance, very materially changes the optimum design of the line, whether used as a low-loss inductive or capacitive reactance or to give high selectivity or high impedance as a resonant line.

Specifically the following changes are introduced:

1. When radiation and the proximity effect are neglected, the analysis *seems* to show that both the resonant input impedance $Z_s$ and the resonant $Q$ are directly proportional to the square root of the frequency for both parallel-wire and concentric lines. That is, the analysis appears to show that $Q$ *increases* as frequency increases. However, when radiation resistance and the proximity effect are taken into consideration it is found that for parallel-wire lines $Q$ is *inversely* proportional to the cube root of the frequency, and for concentric lines is inversely proportional to the 0.4 power of the frequency. In other words, $Q$ actually *decreases* as frequency increases for both parallel-wire and concentric lines.

2. When radiation resistance and the proximity effect are neglected, the analysis seems to show that the resonant $Q$ and $Z_s$ are proportional to the spacing for parallel-wire lines, and proportional to the outer diameter for concentric lines, and designers have therefore been urged to use large values of spacing and diameter, respectively. Taking radiation resistance and the proximity effect into account, however, shows that for any frequency and length of line a definite spacing for parallel-wire lines and a definite outer diameter for concentric lines give maximum $Q$, and slightly larger values of spacing and outer diameter, respectively, give maximum values for $Z_s$. Moreover these values, in general, especially for the very high frequencies, are considerably smaller than the values which have been recommended on the basis of the older analysis, and even a small departure from the best value produces a relatively large decrease in $Q$ or in $Z_s$.

3. Disregarding radiation resistance and the proximity effect gives a false optimum value of $D/r = 2.72$ for a parallel-wire line, and $b/a = 3.6$ for a concentric line to give maximum $Q$.
$D$ is spacing between wire axes for parallel wires,
$r$ is wire radius for a parallel-wire line,
$b$ is inner radius of outer tube of a concentric line, and
$a$ is outer radius of inner conductor.
Taking radiation resistance and the proximity effect into account changes these values to

$D/r = 6.186$ for parallel-wire lines
$b/a = 4.22$ for concentric lines
} Optimum values for maximum $Q$ for a line of any length, whether resonant or not

4. Disregarding radiation resistance and the proximity effect, the analysis seems to show that $Q$ is independent of the number of quarter wave lengths of line used and of the line termination. Actually $Q$ is a function of line length and in general is quite different for open-circuit than for short-circuit termination.

5. Disregarding the radiation resistance and the proximity effect gives a false optimum value of $D/r = 8$ for a parallel-wire line, and $b/a = 9.2$ for a concentric line if maximum input impedance is desired. Taking radiation resistance and the proximity effect into account changes these values to

$D/r = 20.96$ for parallel-wire lines
$b/a = 14.3$ for concentric lines
} Optimum ratios for maximum $Z_s$ at resonance

The higher the frequency the more important radiation resistance becomes. For instance, at 300,000,000 cycles the analysis, disregarding radiation resistance and proximity effect, would seem to show that a parallel-wire line, a quarter wave length long and short-circuited, would have a $Q$ of 2,655 if constructed of wires 0.5 inch in diameter

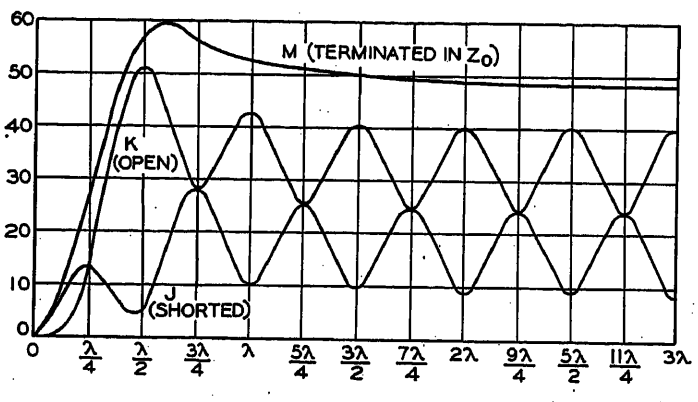

**Figure 4**

Multiply by $(\pi^4/\lambda^4)(b^2 - a^2)^2$ to obtain radiation resistance for concentric line

and spaced 0.68 inch between wire axes. Actually, however, the neglected radiation resistance in this case is almost 8 times as large as all other resistance. The correct value of $Q$ is only 423. If, however, the diameter of the wire is *decreased* to 0.262 centimeter (0.103 inch) and the spacing to 0.812 centimeter (0.319 inch), the optimum values for this frequency, a $Q$ of 771 is obtained. If, instead of using a shorting bar to short the line, the 2 wires are brought together gradually, this $Q$ can be increased to over 1,000. Both diameter and spacing must, however, be increased about 50 per cent over the values given above.

Similarly for a quarter-wave short-circuited concentric line to be operated at 60,000,000 cycles Hansell and Carter (April 1936, IRE *Proceedings*, page 599) recommend values of $b = 30$ centimeters (11.8 inches) and $a = 8.25$ centimeters (3.25 inches). Neglecting radiation resistance they compute that the $Q$ of the line would equal 20,000. Actually here also the effect of the radiation resistance, which was neglected, is approximately 5.6 times as large as that of all other resistance. So, instead of a $Q$ = 20,000, it actually is only 3,420. If the optimum design, considering radiation resistance, had been used, the $b$ and $a$ could have been decreased to 16.95 centimeters and 4.02 centimeters respectively, which would have raised $Q$ for the quarter-wave shorted line to 8,680. Moreover, if a half-wave concentric line, shorted at both ends and fed at any intermediate point on the line, had been used the $Q$ could have been raised to 12,000.

## Fundamental Transmission Line Equations

Whether a transmission line is to be used to carry hundreds of thousands of kilowatts at commercial power frequencies, or fractions of a watt at the audio frequencies as in a telephone line, or power in varying amounts at radio frequencies, the same equations, derived in many textbooks (see Woodruff's "Electric Power Transmission and Distribution") hold accurately, namely

$$\left.\begin{aligned} E_s &= E_r \cosh px + I_r \sinh px \\ I &= I_r \cosh px + \frac{E_r}{Z_0} \sinh px \\ Z_s &= E_s/I_s \end{aligned}\right\} \quad (1)$$

where

$E_r$ and $I_r$ are voltage and current respectively at the receiving or load end of the line,
$E_s$ and $I_s$ are voltage and current at the sending end of the line,
$x$ is length of line (in our work the unit of length is the centimeter),
$p = (\alpha + j\beta)$ is the propagation constant per unit length of line,
$\alpha$ is the attenuation constant per unit length of line,
$\beta$ is the wave length constant per unit length of line,
$Z_0 = \sqrt{Z/Y}$ is the characteristic impedance of the line,
$Z$ is the series impedance per unit length of line,
$Y$ is the admittance between conductors per unit length of line.

At high radio frequencies

$$\alpha = \frac{R}{2}\sqrt{\frac{\bar{C}}{L}} = \frac{R}{2Z_0}$$

$$\beta = \frac{2\pi}{\lambda}$$

where $\lambda$(lambda) is the wave length.

If the wave length is expressed in centimeters, $\lambda = 3 \times 10^{10}/f$, where $f$ is frequency.

## The Line as a Low-Loss Inductive or Capacitive Reactance

For open circuit, $I_r = 0$, so

$$Z_s = \frac{E_r \cosh px}{\frac{E_r}{Z_0} \sinh px} = Z_0 \frac{\cosh \alpha x \cos \beta x + j \sinh \alpha x \sin \beta x}{\sinh \alpha x \cos \beta x + j \cosh \alpha x \sin \beta x}$$

Eliminating the $j$ term from the denominator by multiplying by

$$\frac{\sinh \alpha x \cos \beta x - j \cosh \alpha x \sin \beta x}{\sinh \alpha x \cos \beta x - j \cosh \alpha x \sin \beta x}$$

and collecting terms gives

$$Z_s = Z_0 \frac{(\alpha x - j \cos \beta x \sin \beta x)}{(\alpha x)^2 \cos^2 \beta x + \sin^2 \beta x} \quad (2)$$

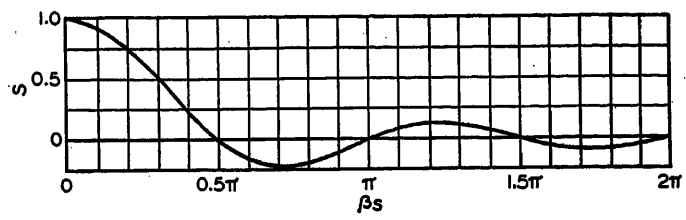

**Figure 5. S versus βs**

$S = (\sin 2\beta s)/2\beta s$

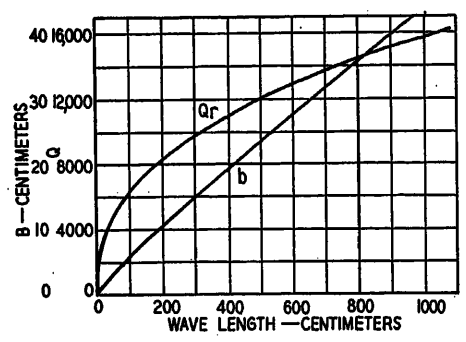

**Figure 6. Optimum $Q_r$ and b versus λ for half-wave concentric line shorted at both ends and fed at any intermediate point**

since for $x$ only a few wave lengths long, $\alpha x$ at the ultra-high frequencies is so small that cosh $\alpha x = 1.0$ and sinh $\alpha x = \alpha x$ (both ordinarily within one part in $10^6$). Except for $x$ *very* close to $n\lambda/2$, where $n$ is any integer, $(\alpha x)^2$ is negligible compared with $\sin^2\beta x$, and

$$Z_s = Z_0\left(\frac{\alpha x}{\sin^2 \beta x} - j \operatorname{ctn} \beta x\right) = Z_0 \operatorname{ctn} \beta x\left(\frac{Rx}{Z_0 \sin 2\beta x} - j\,1.0\right) \tag{3}$$

Evidently such a line acts as a condenser with a $Q_x = (Z_0 \sin 2\beta x)/Rx$.

*Note:* We differentiate throughout the paper between the $Q$ of a line acting as an inductive or capacitive reactance, which we designate $Q_x$, and the $Q$ of the resonant line, which we designate $Q_r$. In general, the $2Q$'s have very different values.

*Example:* For a parallel-wire line, for $\lambda = 100$ centimeters ($f$ = 300,000,000 cycles), and $x = \lambda/20 = 5$ centimeters, with optimum radius of wire and spacing for minimum loss,

$Z_0$ = 215.2 ohms
$Z_s$ = 661 (0.000266 − $j$ 1.0)
$Q_x$ = 3,750 (from curve in figure 1)

Similarly for short circuit

$$Z_s = Z_0 \frac{\alpha x + j \sin \beta x \cos \beta x}{\cos^2 \beta x + (\alpha x)^2 \sin^2 \beta x} \tag{4}$$

Except for $x$ *very* close to $(2n + 1)\lambda/4$, $(\alpha x)^2$ is negligible compared with $\cos^2 \beta x$, so

$$Z_s = Z_0\left(\frac{\alpha x}{\cos^2 \beta x} + j \tan \beta x\right) = Z_0 \tan \beta x\left(\frac{Rx}{Z_0 \sin^2 \beta x} + j\ 1.0\right) \tag{5}$$

Thus a short-circuited line, less than a quarter wave length long, acts as an inductive reactance with a $Q_x = (Z_0 \sin 2\beta x)/Rx$.

*Example:* For a parallel-wire line, for $\lambda = 100$ centimeters, and $x = 5$ centimeters, if line is designed for minimum loss, then

$Z_0$ = 215.2 ohms
$Z_s$ = 69.9 (0.000867 + $j$ 1.0)
$Q_x$ = 1,154 (from curve in figure 1)

*Example:* For a concentric line, and same λ and $x$ as above,

$Z_0$ = 86.4 ohms
$Z_s$ = 28 (0.0000865 + $j$ 1.0)
$Q_x$ = 11,550 (from curve in figure 2)

Compare this $Q_x$ with a $Q$ of about 17 for a quartz crystal at this frequency.

## Equations for Resonant Lines

When an open-circuited line is *very* nearly any multiple of a half wave length long, equation 2 is evidently a poor expression for $Z_s$, since neither $(\alpha x)^2 \cos^2\beta x$ nor $\sin^2\beta x$ is negligible compared with the other. In this case it is better to express the input impedance as

$$Z_s = Z_0 \frac{\cosh^2 \alpha x \cos^2 \beta x + \sinh^2 \alpha x \sin^2 \beta x}{\cosh \alpha x \sinh \alpha x + j \sin \beta x \cos \beta x} = \frac{Z_0}{\alpha x} \frac{1}{1 + j \dfrac{\sin \beta x \cos \beta x}{\alpha x}}$$

since cosh $\alpha x = 1$ and sinh $\alpha x = \alpha x$ (within one part in $10^6$) and for $\beta x$ *very* close to $n\pi$, $\cos^2 \beta x = 1$ (very nearly), and $\sinh^2 \alpha x \sin^2 \beta x$ is considerably less than $10^{-6}$, so is negligible compared with 1.0. Moreover for $\beta x$ very close to $\beta_r x = n\pi$,

$$\cos \beta x = (-1)^n \text{ and } \sin \beta x = (-1)^n \frac{x\pi}{\lambda}\left(\frac{f}{f_r} - \frac{f_r}{f}\right)$$

So

$$Z_s = \frac{Z_0}{\alpha x} \frac{1}{1 + j \dfrac{\pi}{\alpha\lambda}\left(\dfrac{f}{f_r} - \dfrac{f_r}{f}\right)} = \frac{2Z_0^2}{Rx} \frac{1}{1 + j \dfrac{2\pi Z_0}{R\lambda}\left(\dfrac{f}{f_r} - \dfrac{f_r}{f}\right)} \tag{6}$$

where $f_r$ is the frequency which would make the line *exactly* a multiple of a half wave length long, and $f$ is the frequency under consideration, differing only slightly from $f_r$, as would be the case if the line were used for frequency control. An open-circuited line very nearly any multiple of a half wave length long evidently acts as a *parallel* resonant circuit, with a $Z_s$ at resonance $= 2Z_0^2/Rx$ and a $Q_r = 2\pi Z_0/R\lambda$.

Similarly when the open-circuited line is very nearly any *odd* multiple of a quarter wave length long, equation 2 may be readily transformed to

$$Z_s = \frac{Rx}{2}\left[1 + j \frac{2\pi Z_0}{R\lambda}\left(\frac{f}{f_r} - \frac{f_r}{f}\right)\right] \tag{7}$$

Thus an open-circuited line very nearly any odd multiple of a quarter wave length long acts exactly as a *series* resonant circuit, with a $Q_r$ of exactly the same value as for equation 6.

Equation 6 holds not only for an open-circuited line very nearly any multiple of a half wave length long, but

also for a short-circuited line very nearly any odd multiple of a quarter wave length long. Similarly equation 7 holds not only for an open-circuited line very nearly any odd multiple of a quarter wave length long, but also for a short-circuited line very nearly any multiple of a half wave length long.

## Transmission Line Constants

At commercial power frequencies with wide spacing between wires, for a parallel-wire line

$$L = \left(\mu + 4 \ln \frac{D}{r}\right) 10^{-9} \text{ henrys per centimeter length of 2-wire line}$$

$$C = \frac{1}{\left(4 \ln \frac{D}{r}\right) 9 \times 10^{11}} \text{ farads per centimeter line to line}$$

$$R = R_{d-c} = \frac{2\rho 10^{-9}}{\pi r^2}$$ ohms per centimeter length of 2-wire line, where $r$ is wire radius and $\rho$ (rho) is resistivity (1,724 for copper of 100 per cent conductivity and slightly larger for commercial copper)

To take account of the proximity effect if the wires are close together and of skin effect at high radio frequencies, these equations are changed to

$$L = \left\{\sqrt{\frac{2\rho}{\pi r^2 \omega \left[1 - \left(\frac{2r}{D}\right)^2\right]}} + 4 \ln \left[\frac{D}{2r} + \sqrt{\left(\frac{D}{2r}\right)^2 - 1}\right]\right\} 10^{-9}$$

henrys per centimeter length of 2-wire line, assuming that wire is not of magnetic material

$$C = \frac{1}{\left\{4 \ln \left[\frac{D}{2r} + \sqrt{\left(\frac{D}{2r}\right)^2 - 1}\right]\right\} 9 \times 10^{11}}$$ farads per centimeter, line to line

$$R' = \frac{\sqrt{2\rho f}\, 10^{-9}}{r \sqrt{1 - \left(\frac{2r}{D}\right)^2}}$$ ohms per centimeter length of 2-wire line, *excluding effect of radiation resistance*

For a copper line,

$$R' = \frac{84\sqrt{f}\, 10^{-9}}{r \sqrt{1 - \left(\frac{2r}{D}\right)^2}} = \frac{0.01455}{\sqrt{\lambda r} \sqrt{1 - \left(\frac{2r}{D}\right)^2}} \quad (8)$$

$$R = R' + \frac{2 R_{rad}}{x(1 \doteq S)} \quad (9)$$

where $R_{rad}$ is radiation resistance of the line, a function of frequency, line length, and line termination. $S$ is discussed in detail later. It equals zero for a line any multiple of a quarter or half wave length long.

The first term in the equation for $L$ is negligible for very high frequencies, so the equation for inductance may be written

$$L = \left\{4 \ln \left[\frac{D}{2r} + \sqrt{\left(\frac{D}{2r}\right)^2 - 1}\right]\right\} 10^{-9}$$ (Accurate within 1 part in 1,200 at 300,000,000 cycles)

Then

$$Z_0 = \sqrt{Z/Y} = \sqrt{L/C} = 120 \ln \left[\frac{D}{2r} + \sqrt{\left(\frac{D}{2r}\right)^2 - 1}\right]$$

ohms for a *parallel-wire* line (10)

For a *concentric* line at high radio frequencies

$L = (2 \ln b/a)\, 10^{-9}$ henrys per centimeter length of line (both conductors)

$$C = \frac{1}{(2 \ln b/a)\, 9 \times 10^{11}}$$ farads per centimeter length of line (between conductors, for air dielectric)

$$R' = 42\sqrt{f}\, 10^{-9} \left(\frac{1}{a} + \frac{1}{b}\right) = \frac{0.007275}{b\sqrt{\lambda}} \left(\frac{b}{a} + 1\right)$$

ohms per centimeter of line (11)

$$R = R' + \frac{2 R_{rad}}{x(1 \doteq S)} \quad (12)$$

$$Z_0 = 60 \ln b/a \quad (13)$$

## Radiation Resistance of Parallel-Wire Lines

The radiation resistance of a line is defined as equal to the power radiated in watts divided by the square of the current in amperes at a point on the line where the current has a maximum value. For an open-circuited line a quarter wave length long, such a maximum current point or current loop is at the sending end; for a short-circuited quarter-wave line it is found at the receiving end. In general current loops are found at all odd quarter-wave points, measured from the open end, on open-circuited lines; they are found at all half-wave points, measured from the shorted end, on short-circuited lines. A line terminated in its characteristic impedance of course has no standing waves, so the current has the same effective value at all points (neglecting the very small loss along the line). Therefore $R_{rad}$ for a line terminated in its characteristic impedance is simply the power radiated divided by the square of the current.

The following equations, derived by the author, have been used in computing the data from which the curves for $F$, $G$, and $H$ in figure 3 were plotted.

$$R_{rad} = 120 \left(\frac{\pi D}{\lambda}\right)^2 \left[\frac{1}{3} - \frac{2}{Y^2} + \left(\frac{1}{3} + \frac{1}{Y^2}\right) \sin^2 Y + \frac{1}{Y^3} \sin 2Y\right] = \left(\frac{\pi D}{\lambda}\right)^2 F \quad (14)$$

for a short-circuited line. This does not include the radiation resistance of the shorting bar, which alone equals $80(\pi D/\lambda)^2$. Total radiation resistance of a shorted line if a shorting bar is used, is $(\pi D/\lambda)^2(80 + F)$.

We have for convenience written $Y$ for $\beta x$ in all of the radiation resistance formulas. For an open-circuited line the equation becomes

$$R_{rad} = 120 \left(\frac{\pi D}{\lambda}\right)^2 \left[1 - \left(\frac{1}{3} + \frac{1}{Y^2}\right) \sin^2 Y\right] = \left(\frac{\pi D}{\lambda}\right)^2 G \quad (15)$$

For a line terminated in its characteristic impedance the equation becomes

$$R_{rad} = 120 \left(\frac{\pi D}{\lambda}\right)^2 \left[\frac{4}{3} - \frac{2}{Y^2} + \frac{\sin 2Y}{Y^3}\right] = \left(\frac{\pi D}{\lambda}\right)^2 H \quad (16)$$

Note that $R_{rad}$ for the line terminated in its characteristic impedance equals the sum of $R_{rad}$ for open circuit and $R_{rad}$ for short circuit. (The derivation of these equations

and also those for the radiation resistance of concentric lines is contained in a paper by the author, entitled "Radiation Resistance of Parallel-Wire and Concentric Lines," accepted for presentation at the IRE convention to be held at Spokane, Wash., this fall. It is hoped that it will appear in an early issue of the *Proceedings* of the Institute of Radio Engineers.)

## Radiation Resistance for Concentric Lines

For short circuit

$$R_{rad} = 120\frac{\pi^4}{\lambda^4}\left[b^2 - a^2\right]^2\left[\frac{1}{15} + \frac{1}{Y^2} + \left(\frac{2}{15} + \frac{9}{Y^4}\right)\sin^2 Y - \frac{12}{Y^4} - \left(\frac{1}{Y^3} - \frac{6}{Y^5}\right)\sin 2Y\right] \quad (17)$$

$$= \frac{\pi^4}{\lambda^4}(b^2 - a^2)^2 J$$

Note that this is the total radiation resistance for this case, since the shorting disk for a concentric line does not radiate.

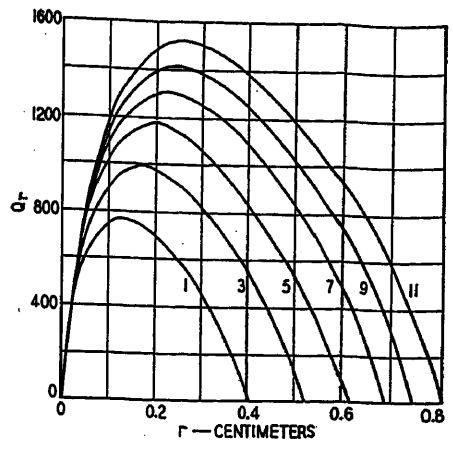
For open circuit

$$R_{rad} = 120\frac{\pi^4}{\lambda^4}(b^2 - a^2)^2\left[\frac{1}{3} + \frac{1}{Y^2} - \left(\frac{2}{15} + \frac{3}{Y^4}\right)\sin^2 Y + \frac{\sin 2Y}{Y^3}\right] = \frac{\pi^4}{\lambda^4}(b^2 - a^2)^2 K \quad (18)$$

As in the case of the parallel-wire line, so also for concentric lines the radiation resistance for the line terminated in its characteristic impedance is the sum of the radiation resistance of the open-circuited and short-circuited lines. It may be expressed

$$R_{rad}\text{ (for } Z_0 \text{ termination)} = \frac{\pi^4}{\lambda^4}(b^2 - a^2)^2 M \quad (19)$$

Curves for $J$, $K$, and $M$ versus $x$ are plotted in figure 4. A slight correction factor, depending on the values of $b/\lambda$ and $a/\lambda$, and very slightly on line length, has been neglected in these formulas. For optimum values of $b$ and $a$, the correction factor is less than 1 per cent. It has, however, been taken into account in computing and plotting the values of $J$, $K$, and $M$.



## Total Resistance of Line at High Radio Frequencies

The power lost in a line evidently equals the sum of the $I^2R$ loss and the power radiated (for leakage loss negligible, as is practically always justified in a radio-frequency line). For a line with standing waves, $I = I_0 \cos \beta s$ if the line is shorted, and $I = I_0 \sin \beta s$ if the line is open-circuited, $s$ being distance in centimeters measured from the receiving end and $I_0$ being the root-mean-square current at a current loop. Then for a shorted line

$$\text{power} = I_0^2 R_{rad\,(shorted)} + R'\int_0^x I_0^2 \cos^2 \beta s\, ds = I_0^2\frac{x(1+S)}{2}\left[R' + \frac{2R_{rad\,(shorted)}}{x(1+S)}\right]$$

**Figure 7. Parallel line, short circuit**

$Q_r$ versus $r$
$\lambda = 100$ centimeters
$D = D_{opt}$
Curve numbers refer to number of quarter wave lengths

where $S = (\sin 2\beta x)/2\beta x$. See figure 5 for a curve of $S$ versus $\beta x$. Therefore the equivalent resistance per centimeter length for a short-circuited line is

$$R = R' + \frac{2R_{rad\,(shorted)}}{x(1+S)}$$

For an open-circuited line the equivalent resistance per centimeter length comes out

$$R = R' + \frac{2R_{rad\,(open)}}{x(1-S)}$$

For $x$ any multiple of a quarter or half wave length, sine $2\beta x = 0$, so $S = 0$. So for both open and shorted lines at all multiples of a quarter or half wave length from the receiving end, $R = R' + 2R_{rad}/x$, the appropriate $R_{rad}$ being used in each case. For a line terminated in its characteristic impedance, $R = R' + R_{rad}/x$.

## Design of Resonant Parallel-Wire Lines for Maximum Selectivity (Maximum Q)

Equations 6 and 7 show that the $Q$ for lines at or very near their resonant frequencies is $Q_r = 2\pi Z_0/R\lambda$. Putting into this equation the values of $Z_0$ and $R$ for parallel-wire lines from equations 8, 9, 10, 14, and 15 gives

$$Q_r = \frac{240\,\pi \ln\left[\frac{D}{2r} + \sqrt{\left(\frac{D}{2r}\right)^2 - 1}\right]}{\frac{0.01455\sqrt{\lambda}}{r\sqrt{1 - \left(\frac{2r}{D}\right)^2}} + \frac{2\lambda}{x}\left(\frac{\pi D}{\lambda}\right)^2\left(\frac{80+F}{1+S}\text{ or }\frac{G}{1-S}\right)}$$

Use $(80 + F)/(1 + S)$ for shorted line, and $G/(1 - S)$ for an open line.

This expression has its maximum value when

$$\frac{0.01455\sqrt{\lambda}}{r\sqrt{1 - \left(\frac{2r}{D}\right)^2}} = \frac{4\lambda}{x}\left(\frac{\pi D}{\lambda}\right)^2\left(\frac{80+F}{1+S}\text{ or }\frac{G}{1-S}\right) \quad (20)$$

and

$$\ln\left[\frac{D}{2r} + \sqrt{\left(\frac{D}{2r}\right)^2 - 1}\right] = \frac{1.5\sqrt{1 - \left(\frac{2r}{D}\right)^2}}{1 - 2\left(\frac{2r}{D}\right)^2} \quad (21)$$

From 21 value of $D/r$ to give maximum $Q$ is

$$(D/r)_{opt} = 6.186 \tag{22}$$

Placing this value into 20 and solving for $D$ gives

$$D_{opt} = \frac{0.134\,\lambda^{5/6}}{\sqrt[3]{\frac{\lambda}{x}\left(\frac{80+F}{1+S} \text{ or } \frac{G}{1-S}\right)}} \tag{23}$$

This expression for optimum $D$ holds for both optimum $Q_r$ and $Q_x$. For any value of $x/\lambda$, the appropriate value of $F$ or $G$ may be taken from curves of figures 3 and the value of $S$ from figure 5. For instance, for a quarter-wave short-circuited line, $80 + F = 111.37$, $S = 0$, so $D_{opt} = 0.0172\,\lambda^{5/6}$.

Putting the optimum value of $D$ into the expression for $Q_r$ gives

$$Q_{r_{opt}} = \frac{1270\,\lambda^{1/3}}{\sqrt[3]{\frac{\lambda}{x}\left(\frac{80+F}{1+S} \text{ or } \frac{G}{1-S}\right)}} = \frac{9480}{\sqrt{\lambda}} D_{opt} \tag{24}$$

For a shorted quarter-wave parallel-wire line,

$$Q_{r_{opt}} = 166\,\lambda^{1/3} \tag{25}$$

For an open-circuited half-wave parallel-wire line,

$$Q_{r_{opt}} = 162\,\lambda^{1/3} \tag{26}$$

Since for the shorted quarter-wave line, 71.8 per cent of the radiation resistance is due to the shorting bar, the $Q_r$ may be substantially increased (by almost 50 per cent) if the wires are brought together gradually, thus eliminating the necessity for a shorting bar. Note, however, that this also changes slightly the value of $Z_0$ to be used in the equation for $Q_r$ and increases by 50 per cent the optimum $D$ to be used.

Note that the expression for $Q_{r_{opt}}$ which we have given holds accurately only for lines close to resonant lengths (any multiple of a quarter or half wave length), the only lengths for which $Q_r$ is of any importance. However, from this expression for $Q_r$, the value of $Q_x$ for a line of any length may be accurately determined. $Q_{x_{opt}} = Q_{r_{opt}} (\sin 2\beta x)/\beta x$ for both parallel-wire and concentric lines. Also $Q_x$ for any frequency may be easily computed from the curves of figures 1 and 2.

## Design of Resonant Concentric Lines for Maximum Selectivity

$$Q_r = \frac{2\pi Z_0}{R\lambda} = \frac{120\pi \ln b/a}{R'\lambda + \frac{2\lambda}{x}\frac{R_{rad}}{1 \pm S}}$$

$$= \frac{120\pi \ln b/a}{\frac{0.007275\sqrt{\lambda}}{b}\left(\frac{b}{a}+1\right) + \frac{2\lambda}{x}\frac{\pi^4}{\lambda^4}(b^2-a^2)^2\left(\frac{J}{1+S}\text{or}\frac{K}{1-S}\right)} \tag{27}$$

Solving for optimum $b/a$ and optimum $b$ gives

$$b/a_{opt} = 4.22 \tag{28}$$

$$b_{opt} = \frac{0.14051\,\lambda^{0.9}}{\sqrt[5]{\frac{\lambda}{x}\left(\frac{J}{1+S} \text{ or } \frac{K}{1-S}\right)}} \tag{29}$$

Use $J/1 + S$ for short circuit, use $K/1 - S$ for open circuit, obtaining values of $J$ and $K$ from curves of figure 4.

Putting these values into the expression for $Q_r$ gives

$$Q_{r_{opt}} = \frac{120\,\pi \ln 4.22}{1.25\,R'\lambda} = \frac{1{,}607\,\lambda^{0.4}}{\sqrt[5]{\frac{\lambda}{x}\left(\frac{J}{1+S} \text{ or } \frac{K}{1-S}\right)}}$$

$$= \frac{11{,}420}{\sqrt{\lambda}}\, b_{opt} \tag{30}$$

For a shorted quarter-wave concentric line, $J = 13.37$ and $S = 0$, so

$$b_{opt} = 0.0634\,\lambda^{0.6} \tag{31}$$

$$Q_{r_{opt}} = 725\,\lambda^{0.4} \tag{32}$$

For a half-wave concentric line shorted at both ends and fed at any intermediate point, $K = 5.43$ and $S = 0$, so

$$b_{opt} = 0.0873\,\lambda^{0.9} \tag{33}$$

$$Q_{r_{opt}} = 997\,\lambda^{0.4} \tag{34}$$

$Q_{r_{opt}}$ and $b_{opt}$ are plotted as functions of wave length in figure 6. The $Q_{r_{opt}}$ could be increased by using a longer line shorted at both ends. For instance $Q_{r_{opt}} = 1{,}310\,\lambda^{0.4}$ for $x = 3\,\lambda$. For a high $Q_r$ always use a concentric line, some multiple of a half wave length long, shorted at both ends and fed at the particular intermediate point which gives the desired input impedance.

Curves in figures 9 and 10 show how $Q_r$ decreases when $a$ is varied, in one case holding $b$ constant, in the other case holding the ratio $b/a$ constant. Figures 7 and 8 show the corresponding curves for parallel-wire lines.

## Design of Parallel-Wire Lines for Maximum Input Impedance

Equation 6 shows that any open-circuited line some multiple of a half wave length long, and also any short-circuited line some odd multiple of a quarter wave length long, has an input impedance

$$Z_{s_r} = \frac{2\,Z_0^2}{Rx} \quad \text{(True for both parallel-wire and concentric lines)}$$

Using the values of $Z_0$ and $R$ from equations 8, 9, 10, 14, and 15 gives

$$Z_{s_r} = \frac{28{,}800 \ln^2\left[\frac{D}{r} + \sqrt{\left(\frac{D}{2r}\right)^2 - 1}\right]}{\frac{0.01455\,x}{\sqrt{\lambda}\,r\sqrt{1-\left(\frac{2r}{D}\right)^2}} + 2\left(\frac{\pi D}{\lambda}\right)^2((80+F) \text{ or } G)} \tag{35}$$

Differentiating 35 with respect to $D$, and also with respect to $r$, and solving the resulting equations simultaneously, shows that 35 takes a maximum value when

$$D/r = 20.96 \tag{36}$$

and

$$D = \frac{0.198\,\lambda^{5/6}}{\sqrt[3]{\frac{\lambda}{x}((80+F) \text{ or } G)}} \tag{37}$$

When these values are used,

$$Z_{s_{opt}} = \frac{114{,}600\ \lambda^{1/3}}{\frac{x}{\lambda}\sqrt[3]{\frac{\lambda}{x}}\ ((80 + F) \text{ or } G)} \tag{38}$$

This value is evidently a maximum for the smallest parallel resonant value of $x/\lambda$, which is $^1/_4$ for the shorted line and $^1/_2$ for the open-circuited line.

For the quarter-wave shorted parallel-wire line $F = 31.37$, so

$$D_{opt} = 0.0259\ \lambda^{5/6} \text{ and } Z_{s_{opt}} = 60{,}150\ \lambda^{1/3} \tag{39}$$

For the half-wave open-circuited line, $G = 120$, so

$$D_{opt} = 0.0318\ \lambda^{5/6} \text{ and } Z_{s_{opt}} = 36{,}900\ \lambda^{1/3} \tag{40}$$

Evidently to obtain the highest possible impedance the quarter-wave line should be drawn together gradually at the shorted end, so as to eliminate the necessity for a shorting bar. In the case $z_0$ will be decreased somewhat, which tends to decrease the numerator of 39. However, the denominator is decreased so much more that the value of $Z_{s_{opt}}$ is increased approximately 33 per cent, giving

$$Z_{s_{opt}} \cong 80{,}000\ \lambda^{1/3} \tag{41}$$

For this case

$$D_{opt} = 0.0389\ \lambda^{5/6} \tag{42}$$

and $(D/r)_{opt}$ remains 20.96.

Evidently high impedances may be obtained in this way, for instance 371,000 ohms at $\lambda = 100$ centimeters ($f = 300{,}000{,}000$ cycles), and 800,000 ohms at $\lambda = 1{,}000$ centimeters.

## Design of Concentric Lines for Maximum Impedance

From equations 11, 12, 13, 17, and 18

$$Z_{s_r} = \frac{2Z_0^2}{Rx} = \frac{7{,}200 \ln^2 b/a}{\frac{0.007275}{\sqrt{\lambda}}\frac{x}{b}\left(\frac{b}{a}+1\right) + 2\frac{\pi^4}{\lambda^4}(b^2 - a^2)^2(J \text{ or } K)}$$

$$= \frac{7{,}200 \ln^2 b/a}{\frac{A}{b}\left(\frac{b}{a}+1\right) + B\,(b^2 - a^2)^2} \tag{43}$$

This is a maximum when

$$\frac{A}{b}\left(\frac{b}{a}+1\right) = 4\,B\,(b^2 - a^2)^2 \tag{44}$$

and

$$\ln b/a = \frac{2.5[(b/a)^2 - 1]}{(b/a)^2 - (b/a) + 1} \tag{45}$$

Solving 45 gives

$$(b/a)_{opt} = 14.3 \tag{46}$$

Putting this value into 44 gives

$$b_{opt} = \frac{0.1705\ \lambda^{0.9}}{\sqrt[5]{\frac{\lambda}{x}}\ (J \text{ or } K)} \tag{47}$$

and

$$Z_{s_{r_{opt}}} = \frac{62{,}600\ \lambda^{0.4}}{\frac{x}{\lambda}\sqrt[5]{\frac{\lambda}{x}}\ (J \text{ or } K)} \tag{48}$$

For a shorted quarter-wave line, $J = 13.37$, so

$$b_{opt} = 0.077\ \lambda^{0.9} \tag{49}$$

$$Z_{s_{r_{opt}}} = 113{,}000\ \lambda^{0.4} \tag{50}$$

For a half-wave line shorted at both ends and fed at an intermediate point on the line, $K = 5.43$, so

$$b_{opt} = 0.106\ \lambda^{0.9} \tag{51}$$

$$Z_{s_{r_{opt}}} = 77{,}750\ \lambda^{0.4} \tag{52}$$

Evidently the quarter-wave shorted concentric line should be used if an enormous impedance (a pure resistance) is desired. Such a line represents an impedance of 713,000 ohms at a wave length of 100 centimeters, an impedance of 1,793,000 ohms at a wave length of 1,000 centimeters, and correspondingly higher impedances for longer wave lengths (lower frequencies).

## Design for Low Loss When Line Is Terminated in Its Characteristic Impedance

For both the transmission and reception of high-radio-frequency waves, either parallel-wire or concentric lines may be used to connect the antenna to the transmitter or receiver. In airplanes and in police cars, equipped for 2-way ultrashort-wave radio communication, such transmission lines may be only a fraction of a wave length long. At commercial radio transmitting or receiving stations the transmission lines may be many wave lengths long. In any case it is important to terminate the line at both ends in an impedance equal in magnitude and phase to the characteristic impedance of the line, so as to prevent the formation of standing waves on the line. When a line is so terminated, the transmission line equations reduce to

$$E_s = E_r\,\epsilon^{px} = E_r\,\epsilon^{\alpha x}.\epsilon^{j\beta x}$$
$$I_s = I_r\epsilon^{px} = I_r\epsilon^{\alpha x}.\epsilon^{j\beta x}$$
$$Z_s = Z_r = Z_0$$
$$P_r = P_s\epsilon^{-2\alpha x}$$

($P_r$ and $P_s$ stand for power at receiving and sending ends of the line, respectively)

and the power loss expressed in decibels is

$$N_{db} = 8.686\ (\alpha x) = 8.686\frac{Rx}{2Z_0} = 8.686\frac{\pi x}{\lambda}\frac{R\lambda}{2\pi Z_0} = \frac{8.686\pi x}{\lambda Q_r}$$

the value of $Q_r$ being equal to $2\pi Z_0/R\lambda$, just as for open or short-circuited lines. Evidently the loss is a minimum when $Q_r$ is a maximum.

For parallel-wire lines, from equation 23, noting that $H/2$ is to be substituted for $(80 + F/1 + S)$ or $(G/1 - S)$,

$$D_{opt} = \frac{0.134\ \lambda^{5/6}}{\sqrt[3]{\frac{\lambda}{x}\frac{H}{2}}} \tag{53}$$

This was a good form in which to leave the equation in the case of open or short-circuited lines, in which $x$ was al-

most invariably either $\lambda/4$ or $\lambda/2$; however, it is better in the case of lines terminated in their characteristic impedance, where $x$ is ordinarily not an exact multiple of a quarter or half wave length, to express $D_{opt}$ as

$$D_{opt} = 0.169\,\lambda^{0.8}\sqrt[3]{\frac{x}{H}} \qquad (54)$$

$(D/r)_{opt} = 6.186$, as was found also for $Q_{r_{opt}}$.

Loss when optimum design is used is ($N_{db}$ stands for number of decibels loss)

$$N_{db} = 0.01705\,\frac{x}{\lambda}\sqrt[3]{\frac{H}{x}} \qquad (55)$$

*Example:* For $\lambda = 100$ centimeters and $x = 4\lambda$

$D_{opt} = 2.29$ centimeters
$r_{opt} = 0.37$ centimeter
$N_{db} = 0.0502$ decibel

Of this loss, exactly one third represents power radiated from the line. To see how much the loss is increased if optimum design is not used, refer to curves in figures 7 and 8. Although this line is 4 wave lengths long, whereas the longest line for which curves are drawn is 11 quarter wave lengths long, note that practically the same relations hold for all the curves. Therefore the error involved in using curve 11 in either figure 7 or figure 8 is negligible. Since the loss is inversely proportional to $Q_r$, evidently

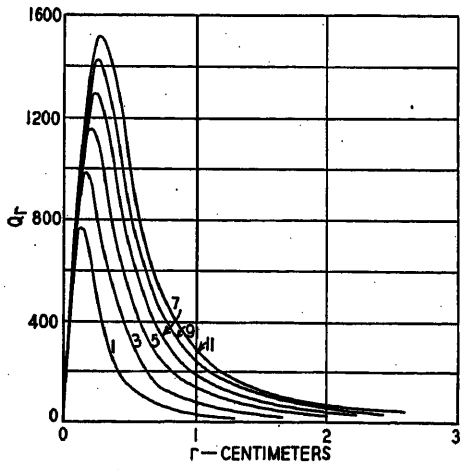


**Figure 8. Parallel line, short circuit**

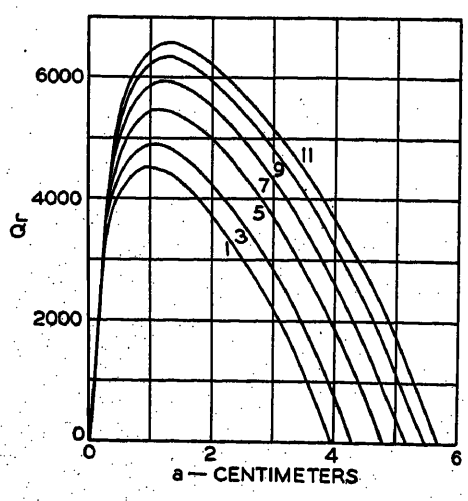
$\lambda = 100$ centimeters
$Q_r$ versus $r$
$D/r = D/r_{optimum}$
Curve numbers refer to number of quarter wave lengths



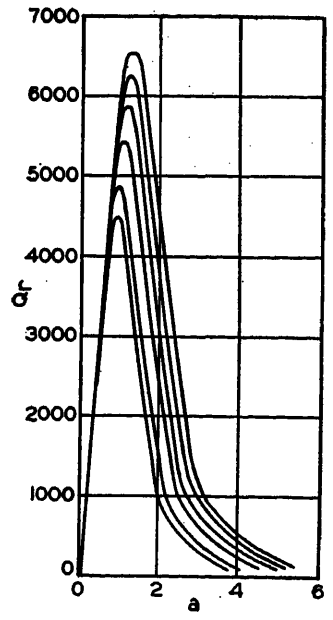


**Figure 9. Concentric lines, shorted**

$\lambda = 100$ centimeters
$b = b_{opt}$
$Q_r$ versus $a$

**Figure 10. Concentric line, short circuit**

$\lambda = 100$ centimeters
$Q_r$ versus $a$
$b/a = (b/a)_{opt}$

the curves showing $Q_r$ can be used to compute the variation in loss as the design is changed from the optimum one.

*Example:* How much would the loss be increased if $r$ were made $^1/_4$ of its optimum value, holding $D = D_{opt} = 2.29$ as just computed? Using curve 11 in figure 7, we see that $Q_{r_{opt}} = 1{,}530$ at $r = 0.255$ centimeter. At $r = 0.255/4 = 0.06375$, $Q_r = 955$. But $1{,}530/955 = 1.605$. So the loss has been increased by 60.5 per cent.

*Example:* How much would the loss be increased if $D/r$ remained $(D/r)_{opt}$, but both $D$ and $r$ were made 4 times their optimum values? In this case use curve 11 of figure 8. $Q_r = 1{,}530$ at $r = 0.255$ centimeter. At $r = 4 \times 0.255 = 1.02$ centimeters, $Q_r = 280$. Since $1{,}530/280 = 5.46$, evidently the loss has been increased from 0.0502 decibel (the loss for optimum design) to $5.46 \times 0.0502 = 0.274$ decibel. In this case it is interesting to note that 97 per cent of the total loss is due to radiation from the line, whereas for the optimum design only one third the loss was due to radiation.

For a concentric line, from equation 29, substituting $M/2$ for $(J/1 + S)$ or $(K/1 - S)$,

$$b_{opt} = \frac{0.14051\,\lambda^{0.9}}{\sqrt[5]{\frac{\lambda}{x}\,\frac{M}{2}}} = \frac{0.1615\,\lambda^{0.7}}{\sqrt[5]{\frac{M}{x}}} \qquad (56)$$

$\left(\frac{b}{a}\right)_{opt} = 4.22$ (same as for maximum $Q_r$), and $N_{db} =$

$$0.0148\,\frac{x}{\lambda}\sqrt[5]{\frac{M}{x\lambda}} \qquad (57)$$

For concentric lines, the loss due to radiation is one fifth of the total loss, if the line is designed for maximum $Q_r$ (or minimum loss). From the curves in figure 9 and figure 10 one may readily determine how much the loss is increased if the optimum design is not followed. Since for concentric lines the total loss is so small, it will often be advantageous to build the line with considerably less than the optimum dimensions, in the interest of over-all economy.

It is of interest to note that a concentric line, terminated

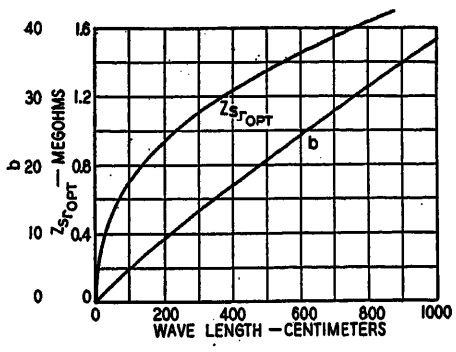

**Figure 11. Optimum $Z_{sr}$ and b versus λ for quarter-wave shorted concentric line**

in its characteristic impedance, has a maximum value of radiation resistance, and therefore radiates maximum power, when it is 0.6 of a wave length long. Note that $M = 59.5$ for this value of $x$, decreasing gradually as the line length increases until for all lengths above about 4 wave lengths its value is about 47.5. For parallel-wire lines also, as shown by the curve for $H$ in figure 3, if the line is at least 3 or 4 wave lengths long, further increase in length has no effect on the radiation resistance. So a line radiates the same amount of power whether it is 3 or 4 wave lengths long or 3,000 or 4,000 wave lengths long, if it is terminated in its characteristic impedance.

Note also that the radiation from an open-circuited concentric line cannot be decreased by partially closing the end. This follows immediately from the fact that the shorting disk used to short a shorted concentric line does not radiate. Since such a disk does not radiate power itself, it cannot prevent the radiation of power through it from the current in the line. Moreover, a line supposed to be open-circuited should never have the end partially closed with metal, since the presence of such metal greatly increases the capacity at the end, and in effect terminates the line with a low value of capacity reactance, instead of the desired open circuit.

# Radiotelephone Noise Reduction

(*Continued from page 974*)

such a control terminal. Speech entering the terminal from the left goes through the upper branch of the circuit, with volume regulating means and privacy apparatus, to the radio transmitter. Speech received from the distant terminal enters at the lower right from the radio receiver and proceeds through the privacy apparatus, the noise reducer, receiving regulating network and amplifier to the 2-wire line. Outgoing speech operates the transmitting path and disables the receiving path. Incoming speech operates the receiving amplifier detector, which disables the transmitting amplifier detector, thus preventing singing and reradiation of received waves.

Without the noise reducer the receiving relay may be operated by noise in the receiving path and such operation to an excessive extent will interfere with outgoing speech. To avoid this effect, it is customary to reduce its sensitivity so that noise may not operate it. This results in the weaker speech parts also failing to operate the receiving relay. This weak speech and noise returned to the transmitting path through the land-line connection may be strong enough to operate the transmitting relays and thus cut off incoming speech. This is avoided by reducing the volume to the land line. Therefore, any device which reduces noise in the receiving path in the absence of speech effects an improvement not only in the switching operation but also in the received volume. By placing the noise reducer in the receiving path false operation is diminished and volume increases of 5 to 15 decibels are realized. The noise reducer is applied to the receiving side of the terminal beyond the privacy apparatus so that it does not introduce any distortion in the privacy portion of the circuit. It is placed ahead of the receiving amplifier detector, thereby reducing noise between words which might affect the operation of this relay apparatus.

## Summary

The noise reducer, which is a voice-controlled variolosser with limited and controllable action, has been provided for use on short-wave radiotelephone circuits and has proved to be a valuable and relatively inexpensive means of securing noise reduction. Improved reception is obtained for many of the transmission conditions experienced on such circuits. This results in better intelligibility to the subscriber, greater margin in the operation of 2-way radiotelephone circuits, and a reduction of difficulties in the wire plant caused by connection to noisy radio circuits.

# The Vodas

By S. B. WRIGHT
MEMBER AIEE

## Introduction

THE INTERCONNECTION of ordinary telephone systems by means of long radiotelephone links presents some unique and interesting technical problems. Since radio noise is often severe as compared with that in wire lines, radio transmitter power capacity is relatively large and expensive, and it is in general economical to control the speech volumes so that the radio transmitter will be fully loaded and thus the effect of noise minimized for a given transmitter power rating. This volume control, to be fully effective, calls for voice-operated switching devices to suppress echoes and singing.

This paper describes the measures which have been developed for use at radio-wire junctions in the United States. They are based upon an arrangement called a "vodas." This word, devised to fill a need for verbal economy, is formed from the initial letters of the words "*v*oice-*o*perated *d*evice *a*nti-*s*inging"; and thus implies not only a suppressor of feedback or singing, but also automatic operation by voice waves.

The general principles and applications of the vodas have been discussed from time to time in various papers listed at the end of this text. The present paper goes somewhat more into detail regarding the transmission performance of the vodas, including a description of an improved form of circuit which discriminates between line noise and the syllabic characteristics of speech.

## Historical

The 2-way problem in telephony began with the invention of the telephone itself, and was the subject of considerable pioneering activity during the latter part of the nineteenth century. The invention of the amplifier brought about new problems when applied in a repeater for 2-way operation. Even before a practical repeater had been devised, inventors visualized controlling the direction of transmission through amplifiers in a line by relays controlled from switches associated with the subscribers' instruments, an idea which is in use today on airplanes and small boats and in special circuits where this type of 2-way operation is practicable. It is also used by amateur radiotelephone operators. But for public telephone service more rapid and automatic control of 2-way conversation is preferable.

To control the direction of transmission in a manner that would meet public convenience invention progressed through the early part of the twentieth century toward devices for switching the speech paths automatically by voice waves. During this period, long-distance radiotelephony was first demonstrated to be practical on a one-way basis.

From that time until the first trans-Atlantic radiotelephone circuit was placed in service on January 7, 1927, antisinging voice-operated devices underwent a process of development aimed at meeting the requirements of 2-way radiotelephone service. The vodas was one result. Since 1927, improvements have been made in cheapening and simplifying the equipment and in making a vodas that will operate better on speech and not so frequently on noise. It has also been possible to arrange a vodas so as to permit using the same privacy apparatus for both directions of transmission, thereby saving the cost of duplicate apparatus.

## The Radiotelephone Problem

The conditions encountered when joining 2-wire 2-way circuits by radio links are illustrated in figure 1 in which *a* shows a connection between 2 subscribers *W* and *E* while *b* shows the paths of direct transmission and echo when *E* talks. In addition to the talker and listener echoes which arise in such a connection, singing can occur around the closed circuit *CAFGDBC* if the amplification is great enough. Also, when the same frequency band is used to transmit in both directions, 2 cross-transmission paths *AB* and *DF* are set up, and echoes and singing can take place around the end paths *ABC* and *DFG*. Any echoes or singing are of course primarily due to reflections of energy at points of impedance irregularities in the 2-wire plant, including the subscribers' telephones themselves.

In wire circuits, simple hybrid coils and echo suppressors[2] are usually adequate to prevent such effects because the gains are not increased to provide for loading the cir-

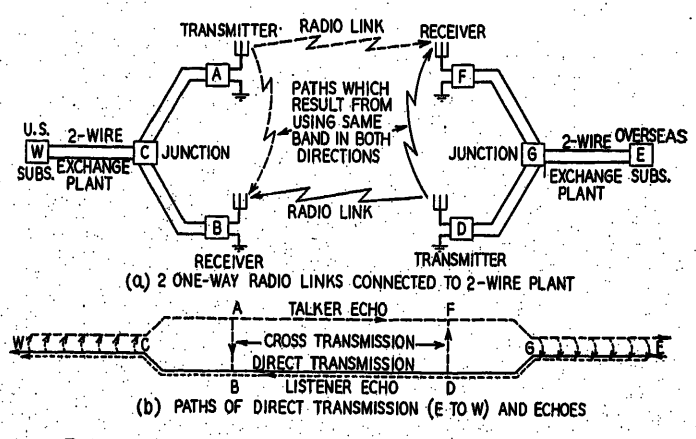

**Figure 1. Echoes in a radiotelephone connection**

A paper recommended for publication by the AIEE committee on communication. Manuscript submitted June 4, 1937; released for publication June 18, 1937.

S. B. WRIGHT is a member of the technical staff of the Bell Telephone Laboratories, Incorporated, New York, N. Y.

2. For all numbered references, see list at end of paper.

cuit with energy when speech is weak, and also because the cross-transmission paths are absent. In long radio circuits, however, singing may result from the adjustments of amplification made to load the radio transmitter in case of weak speech and thus override noise, even though separate frequency bands are used in the 2 directions. Moreover, it is desired that the users of the service have as good transmission over the entire connection including these radio links as that to which they are accustomed in their own wire telephone systems and even better transmission may be desired owing to differences in the language habits of the subscribers. Consequently, the overall transmission efficiencies of intercontinental radio circuits are sometimes better than those of the best land lines in the areas to be interconnected.

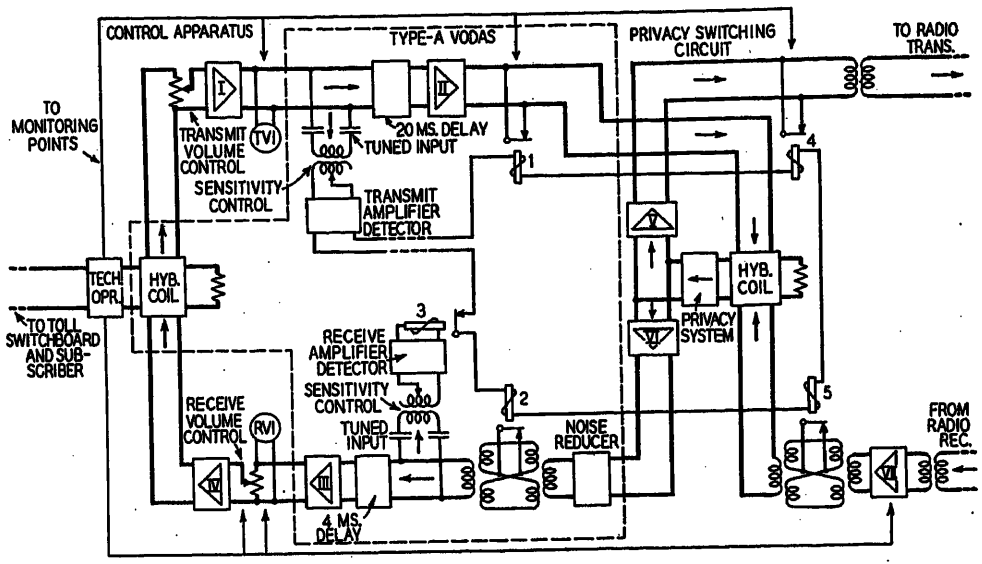

**Figure 2. Schematic of type-A control terminal**

## Fundamentals of Vodas Operation

A voice-operated device to suppress singing effects can be designed to have 3 possible arrangements:

1. The terminal can normally be blocked in one direction and connected through in the other.
2. Both directions of transmission can normally be blocked and activated in either but not both directions by the voice waves.
3. The circuit can remain activated in the last direction of speech and blocked in the other direction.

Where there is no noise on the transmission system under consideration any of these 3 arrangements will give satisfactory operation as there is then nothing to prevent making the voice-operated devices as sensitive as may be necessary to obtain full operation on weak as well as on strong voice waves. If there is any noise on the system which tends to operate the device it is necessary to make it less sensitive to avoid false operation. A point may be reached where the sensitivity is so low that the weakest parts of speech will not cause operation, and the weak consonants will be lost. The reduction in articulation has been found to be proportional to the time occupied by these lost or "clipped" sounds.[9]

If the device is located at a point in the circuit where the signal-to-noise ratio coming from one direction is poorer than that coming from the opposite direction it is obvious that a considerable advantage will be gained by using arrangement 1, since the device may be pointed in the direction in which the normally blocked path is exposed to the better signal-to-noise ratio and the normally activated path is exposed to the poorer signal-to-noise ratio. The vodas is, of course, arranged so that the normally blocked (transmitting) side is exposed to the land lines which are usually quieter than the radio links. In the receiving side, the device can be less sensitive because there is no need for having it completely operated under control of the voice waves. All that is necessary is to have this side sensitive enough to operate in response to comparatively large voice or noise waves which might otherwise, after reflection and passage into the outbound path, result in false operation of the more sensitive side associated with this path.

In the vodas the principle of balance is used to keep the

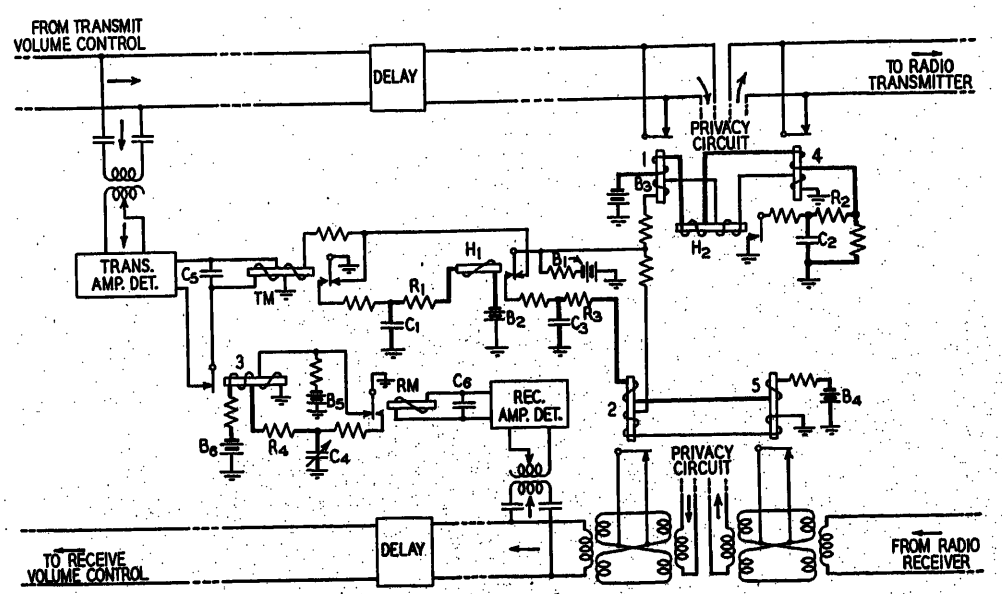

**Figure 3. Vodas relay circuits**

reflected currents small and thus allow the sensitivity of the normally activated device to be further reduced if necessary. Where a high degree of balance is not obtained and when noise from the radio limits the sensitivity of the receiving device it is sometimes necessary, particularly for weak outgoing volumes, to reduce the incoming volume so as to prevent echoes from operating the normally blocked transmitting side.

This echo limitation is primarily due to noise in the radio link, reflections from the 2-wire plant and weak volumes from the subscribers. It is difficult to produce any large improvement in talker volumes and balance; so it would appear that the solution of the difficulty would probably come from the direction of improving radio transmission. Some benefit has also been obtained by reducing the effect of radio noise on the vodas with special devices of which the "compandor"[17,18] and the "codan"[19,20] are examples. More recently, use has been made of a new voice-controlled device called a "noise reducer,"[21,22] which reduces the received noise between speech sounds.

## Vodas Design—Type-A Control Terminal

Figure 2 shows a schematic diagram of a vodas arranged to use the same privacy device for both transmitting and receiving. The vodas apparatus together with the volume-control devices and technical operator's circuits go to make up what is called a type-*A* control terminal. This is the type used on trans-Atlantic and other long routes. Since the operation of this arrangement has been described before,[18] it will not be repeated here.

The diagram of the relay circuit in figure 3 shows how various time actions are obtained. Relays 1, 2, 4, and 5 are operated from battery $B_1$ when the ground contact of relay $TM$ is opened. Thus the travel time of any relay armature is not a factor in securing fast initial operation. When the armature of relay $TM$ reaches its left-hand contact, relay $H_1$ operates and delays release of the relay train even if $TM$ is at once restored to normal. $H_1$ is delayed in releasing by the time required to charge condenser $C_1$. The final release of relays 1 and 4 is then controlled by the time constant of an auxiliary circuit involving relay $H_2$ and condenser $C_2$, while that of relays 2 and 5, which is made later so as to suppress delayed echoes, is controlled by the circuit charging $C_3$. On the receiving side, condenser $C_4$ is adjustable so as to permit the technical operator to select the shortest release time for suppressing the delayed echoes in a given land-line extension.

The vodas control terminal of the *A* type[8] used at New York consists of a line of technical operating positions

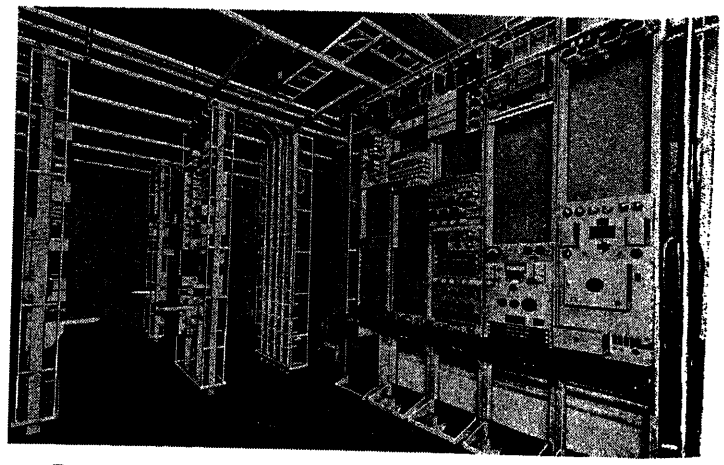

Figure 4. Type-A control terminal at San Francisco

with cross connections to other lines of equipment containing the delay units, repeaters, vodas amplifier-detectors, and privacy apparatus. Figure 4 shows an arrangement of a single terminal at San Francisco. The control bay is placed between 2 line-testing bays on the left and 2 transmission-testing bays on the right of the operating lineup. The distributing frame is in the center of the picture; and repeaters, ringers, and privacy apparatus are shown at its left. At the extreme left is the vodas bay.

## Syllabic Vodas—Type-B Control Terminal

The desire for a cheaper control terminal than the type *A* led to the development of a second type, known as type *B*, in which the vodas employs the same fundamental principles. In this vodas added protection against false operation from line noise is secured by the use of a new principle in voice-operated devices, called "syllabic" operation.

It is observed that in many types of noise a large component of the long-time average power is steady. Speech, however, comes as a series of wave combinations of relatively short duration. These facts suggested a device

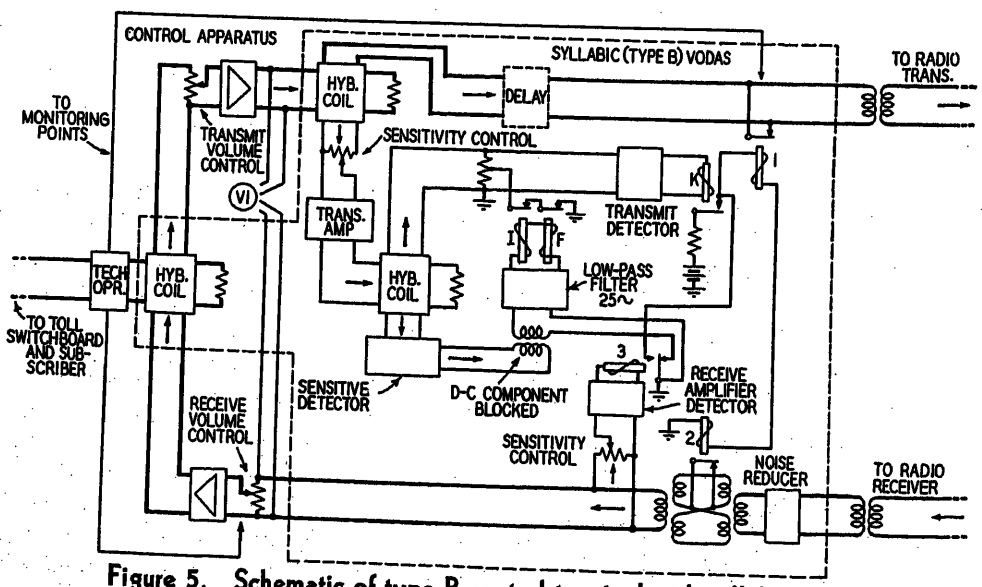

Figure 5. Schematic of type-B control terminal with syllabic vodas

which distinguishes between the rates of variation of the envelopes of the impressed waves. This is accomplished by a filter in the detector circuit which passes the intermodulated components of speech in the syllabic range, but suppresses those of line noise which are above or below this range.

Figure 5 shows a schematic diagram of the application of this device to a type-*B* control terminal. The privacy switching circuits are omitted from this drawing, as are also the circuits for delaying the release of the relays. In comparing this drawing with figure 2, it will be seen that relays 1, 2, and 3 perform the same functions, but the transmitting branch of the vodas consists of 2 portions, one a sensitive detector with a syllabic frequency filter, which on operation increases the sensitivity of the second portion.

Considering the action of figure 5 on transmitted speech, the output of the sensitive detector of the syllabic device is a complex function of the applied wave having intermodulated components in the range passed by the tuned input circuit, together with a d-c component and various low-frequency components set up by the syllabic nature of the speech. There are also various components of any noise waves which may be present including a d-c component. The first step in getting rid of the noise is to pass the detector output through a repeating coil which blocks the d-c component of both the speech and noise, but passes frequencies above about $^1/_2$ cycle per second. The resulting waves enter the low-pass filter, the output of which contains frequencies between $^1/_2$ and 25 cycles per second which "syllabic range" is between the d-c component of zero frequency and the fundamental frequency of the line noise. These syllabic-frequency currents cause momentary operations of relays *I* and *F*. Relay *I* operates when a speech wave is commencing and relay *F*, which is poled oppositely, operates while the impulse is dying out, thus sending current out of the filter in the opposite direction. Operation of either *I* or *F* effectively inserts gain ahead of the upper detector, thereby increasing the sensitivity of relay *K*, when speech is present. Even if the noise is strong enough to operate relay *K* over the upper branch when the gain is inserted, the release of relay *F* at the end of a speech sound will remove the gain and permit *K* to fall back. Thus, it is possible to work relay *K* more sensitively on weak speech than would be possible without the syllabic device.

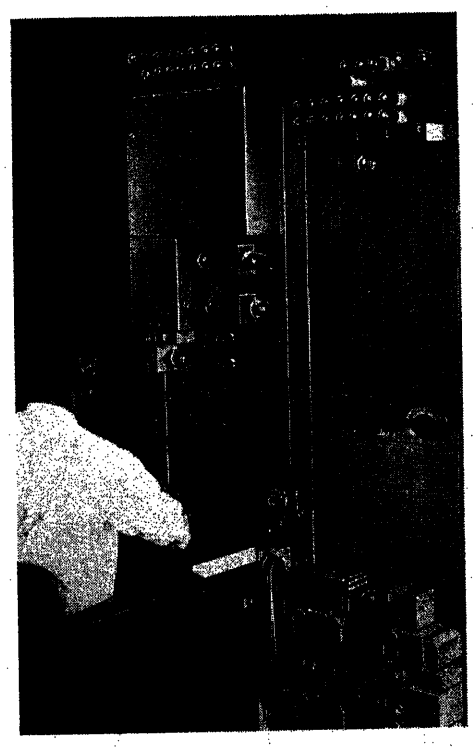

Figure 6 shows a photograph of a *B*-type terminal in ship-to-shore service at Forked River, N. J. The vodas and volume control apparatus are in the left-hand cabinet. The right-hand cabinet contains privacy apparatus, a signaling oscillator, and a vodas relay test panel.

## Performance

In any system employing voice-operated devices it is necessary for the time actions to provide for to-and-fro conversation with a minimum of difficulty when the subscribers desire to reverse the direction. The electromagnetic relays used in the vodas have advantages over other types of switching arrangements which have been proposed in that they (1) operate and release at definite current values; (2) have fast operating and constant releasing times; (3) have their windings and their contacts electrically separated, thus simplifying the circuits; and (4) operate in circuits having low impedances.

The operating times of the 2 types of vodas are shown in figure 7 as a function of the strength of suddenly applied single-frequency sine waves in the voice range. These measurements were made with a capacity bridge.[5] The sensitivities of the 2 types were adjusted so that observers noted an equivalent amount of clipping. The type-*A* vodas was provided with a 20-millisecond delay circuit, the type *B* had no delay. For the type-*A* vodas, the operating time is quite small and constant just above the threshold of operation.

For weak inputs the operating time of the syllabic device is determined by relay *I* and the filter, as shown in

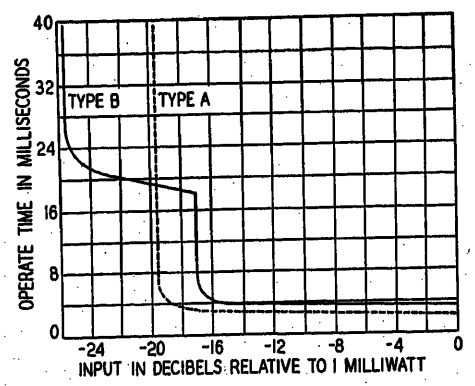

**Figure 7 (above). Vodas operating times with sine waves suddenly applied**

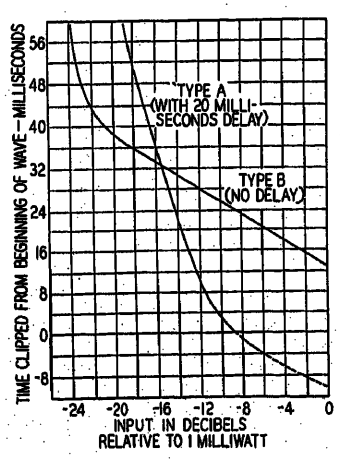

**Figure 8 (right). Operation on a 5-cycle-per-second sine wave**

**Figure 6 (left). Technical operator at Forked River, N. J., using a type-B control terminal to establish a circuit between a steamship and a shore telephone operator**

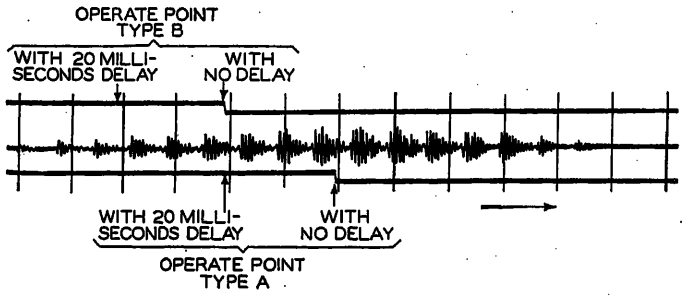

**Figure 9. Oscillogram of the word "six," illustrating clipping and its reduction by a delay circuit in the transmission path**

figure 7. As the suddenly-applied input is increased, a point is reached where the less sensitive detector operates relay *K*, reducing the operating time from around 20 milliseconds to values comparable with those of the type *A*.

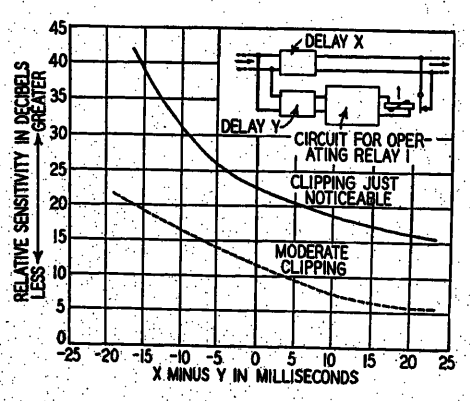
The operation was also tested on waves formed by applying simultaneously 2 sine waves of equal amplitude but slightly different frequencies. These waves were recorded on an oscillograph together with a d-c indication of the operation of each of the vodas relays, with the sensitivities adjusted the same as for figure 7. The time from the beginning of a beat wave (null point) to the time of operation was measured from these oscillograms and plotted against various values of total applied voltages. Figure 8 shows the results for a 5-cycle-per-second difference between the 2 frequencies. Negative values of time indicate that the path was cleared before the beginning of the wave, and these occur only with the type-*A* vodas due to the delay circuit. The curves for frequency differences of less than 5 cycles per second show more clipping and greater differences between the devices, while those for greater frequency differences show less time clipped and less difference between the 2 types of vodas. In the case of weak waves it is evident that the syllabic will give less clipping because the energy of the wave does not rise to the value required to operate the type-*A* device until after the syllabic device has operated; and for very weak waves, the type *A* does not operate at all. In the case of strong waves, the type-*A* vodas is better due to its delay circuit. However, since the clipped time is greater on weak sounds than on strong ones, the 2 types give performances on speech which are judged to be equivalent.

A comparison of operation of the 2 types of vodas on a speech wave is shown in figure 9. Reading from left to right the middle trace of this oscillogram shows the wave recorded by saying the word "six" over a telephone circuit transmitting a band of frequencies from about 800 to 2,000 cycles per second, which is the range normally effective in operating the vodas. The upper trace shows the point at which the syllabic type-*B* device operated and the lower trace shows the point at which the type-*A* device operated. Since the speech wave shown was used to operate both devices, the reduction of clipping by the delay circuit in the type-*A* vodas was not recorded. However, the effect of a transmission delay of 20 milliseconds is shown by subtracting 20 milliseconds from the point at which operation occurred. This is indicated on the oscillogram for both devices. It is concluded that on this wave the syllabic device without a delay circuit would give about the same clipping as the type-*A* vodas with its delay circuit. Figure 8 indicates that the type *A* would be better for stronger speech and the type *B* would be better for weaker speech. The advantage of a delay circuit is either case is evident.

It is evident from this analysis that the reason for using delay circuits is not primarily because the relays are slow in operating. When the sensitivity is limited by noise, clipping of initial consonants can occur with infinitesimal operating times. One way of reducing the clipping is to use long releasing times so that the relays remain operated between syllables. This has the disadvantage of making it harder for the opposite talker to break in. To avoid this difficulty, the relays in the vodas are given releasing times that permit the distant speech to break in about 1/6 second after a United States talker ceases to speak.

One advantage of delay circuits is to reduce the clipping of initial consonants and thus permit using short releasing times, thereby making it possible to reverse the circuit more readily. In addition, delay circuits permit using a lower relay sensitivity which has 2 advantages: First, more noise can be tolerated without causing false operation; second, more received volume can be delivered without the echoes causing false operation of the normally blocked transmitting side.

The advantage of artificial delay of various amounts has been determined using different types of normally blocked arrangements to find the relation between the delay and the sensitivity required to produce given amounts of clipping of initial sounds. The results are shown for a



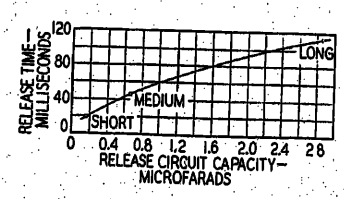


**Figure 10 (left). Typical delay versus sensitivity for certain clipping effects**

**Figure 11 (below). Release time versus capacity**

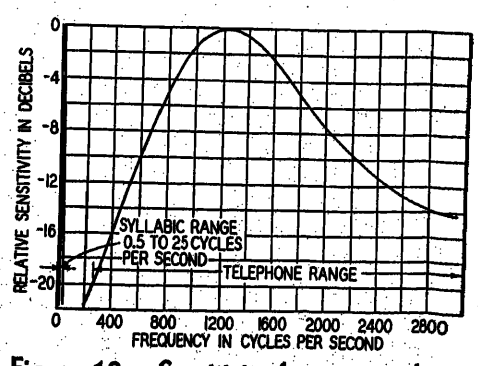

**Figure 12. Sensitivity-frequency characteristics of the vodas**

type-*A* vodas in figure 10. The curves for the syllabic device are similar. The setup was arranged so that various delays could be inserted in either the transmission circuit (delay *X*) or the relay circuit (delay *Y*). The left ends of the curves indicate that when delay *Y* is used, that is, when the net operating time of the relay is great, a point will be reached where no reasonable increase in sensitivity is sufficient to prevent intolerable clipping. The value of 20 milliseconds of delay *X* as compared to zero is equivalent to an increase of about 5 decibels in sensitivity for a given amount of noticeable clipping.

A reasonable release time is of value in preventing clipping, as it causes the relays to remain operated not only for trailing weak endings of sounds, but also when the energy is temporarily reduced by intermediate consonants which may be comparable with noise. Delayed release is also important when it is required to maintain the blocked condition while delayed echoes are being dissipated. For these echoes, the hangover or release times should be constant for various applied voltages. In the vodas, the change in release time over a wide range of inputs is less than one per cent. Adjustments are made by varying the condensers and resistances of the auxiliary circuits shown in figure 3. Typical values obtained by this method are indicated in figure 11.

The vodas amplifier-detectors have broadly tuned input circuits to exclude by frequency discrimination many of the frequencies induced by power sources and those which are unnecessary for speech operation. The sensitivity-frequency characteristic is shown on figure 12. This figure also shows the relatively narrow frequency range passed by the repeating coil and syllabic frequency filter of the type-*B* vodas.

## Operating Attendance

To insure proper operation of a vodas a technical operator[3] is in attendance. He is provided with circuits which enable him to talk and monitor on the circuit as indicated in figures 2 and 5. His duties include adjusting the sensitivity of the receiving relays for the particular value of radio noise existing and adjusting the transmitting and receiving speech volumes by the aid of potentiometers and volume indicators. He selects the proper hangover time and co-ordinates the operation of the circuit as a whole with the distant end. At times, he may be required to increase the sensitivity of the transmitting side of the vodas in the case of talkers with poor ability to operate relays or to decrease the sensitivity when weak volumes are supplied from land lines with more than the usual amount of noise.

## Summary

The vodas is used in radiotelephony to switch the voice paths rapidly to and fro, and thus prevent echoes and singing that would otherwise occur at unpredictable times. It is also used to save privacy apparatus by permitting the use of the same apparatus for both directions of transmission. The performance characteristics of the electromagnetic relays used in the vodas are very suitable in that they have small operating and constant releasing times.

Improved performance of the voice-operated relays in the presence of line noise can be secured by the use of a syllabic type of vodas which discriminates between the characteristic voltage-time envelopes of the noise and speech waves. Laboratory and field tests indicate that this device even without delay circuits, gives slightly better performance on most conditions than the original vodas with delay. When provided with a transmitting delay circuit, the syllabic device is decidedly better than the older vodas.

# Capacitance Control of Voltage Distribution in Multibreak Breakers

By R. C. VAN SICKLE
MEMBER AIEE

## Summary

This paper discusses the need for good distribution of the voltage among the interrupters of a high-voltage multibreak circuit breaker and the results which have been obtained using capacitances.

## Introduction

THE DEVELOPMENT of high-speed circuit breakers capable of interrupting short circuits on 287-kv systems in not over 3 cycles, 0.05 second, has called attention to the importance of the distribution of voltage among a number of interrupters in series. To obtain such high speed of operation all parts must work promptly, quickly, and effectively. Obtaining adequate contact separation to interrupt the circuit and to withstand the restored voltages is accomplished by using a number of interrupters connected in series and operated simultaneously. This construction depends on a division of duty between the individual breaks, each interrupter being loaded with its share so that the interrupting capacity of the pole unit is approximately equal to the sum of the capacities of the units. Uniform distribution of duty is most desirable but it can only be approximated because short circuits of various kinds may occur on either side and the distorting forces cannot be neutralized for all conditions. This paper discusses the problem and capacitance shields which satisfactorily distribute the duty among the interrupters in multibreak circuit breakers.

## Factors Determining Voltage Distribution

The distribution of voltages should be suitable during the arcing period, during the extinction of the arc, and after the circuit is interrupted. During the first of these periods all circuit breakers have good voltage distribution. The similar conditions existing in the series gaps of a multibreaker should result in them having approximately equal arc voltages since arcs of equal length carrying equal currents in the same medium under the same conditions have equal voltages.

After the arcs are extinguished and normal voltage has appeared across the breaker, the voltage distribution is determined by the capacitance relationships of the various parts. If all capacitances except those across the gaps could be eliminated, there would be only a simple series circuit composed of equal capacitances. If a voltage were applied across them it would divide equally between the various gaps and this division would be unaffected by the relative potential of the ground. Unfortunately the conditions are not this simple and capacitances to ground and to other parts not at the same potential form a network of circuits so that the voltage distribution is distorted and may depart widely from uniformity. Moreover, different types of short circuits will produce different degrees of distortion. For convenience this distribution will be referred to hereafter in this paper as the static voltage distribution.

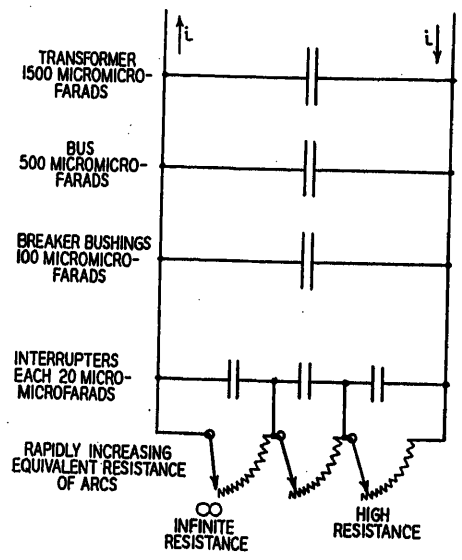

**Figure 1. A diagram representing a multibreak circuit breaker at the instant one arc is extinguished**

Between the 2 periods already discussed is an important transient period during which the arc space is changing rapidly from a good conductor to a good insulator and during which the voltage distribution is determined first by the arc resistance and later by the electrostatic capacitances of the parts and the relative potentials of the terminals.

When the breaker first starts to open, the current is carried by a continuous metallic path formed by the terminals, contacts, and connecting members. The separation of the contacts introduces arcs which conduct the current and which are acted upon by deionizing agents. As the current approaches zero at the end of a half-cycle, the deionization proceeds more rapidly than ionization

A paper recommended for publication by the AIEE committee on protective devices. Manuscript submitted March 29, 1937; released for publication June 18, 1937.

R. C. VAN SICKLE is circuit breaker engineer with the Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

and conductivity decreases. The conductivity becomes zero at about the time the current reaches zero and the arc does not restrike if the dielectric strength of the arc space is greater than the applied voltage.

The change of the arc space from a conductor to an insulator is not an instantaneous process but consumes an appreciable time interval, up to a few hundred microseconds. This time interval is a variable in an oil circuit breaker because of the conditions which exist between the arc terminals. The space is filled with a nonhomogeneous mixture of gases, oil vapor, and probably drops of oil, all of which are in rapid turbulent motion. A number of independent interrupters carrying currents of the same magnitude will not interrupt in exactly the same manner at exactly the same time. However, if the same current is passed through a series of interrupters operated simultaneously the operation of one unit may influence the operation of the others and effect a synchronization of their action.

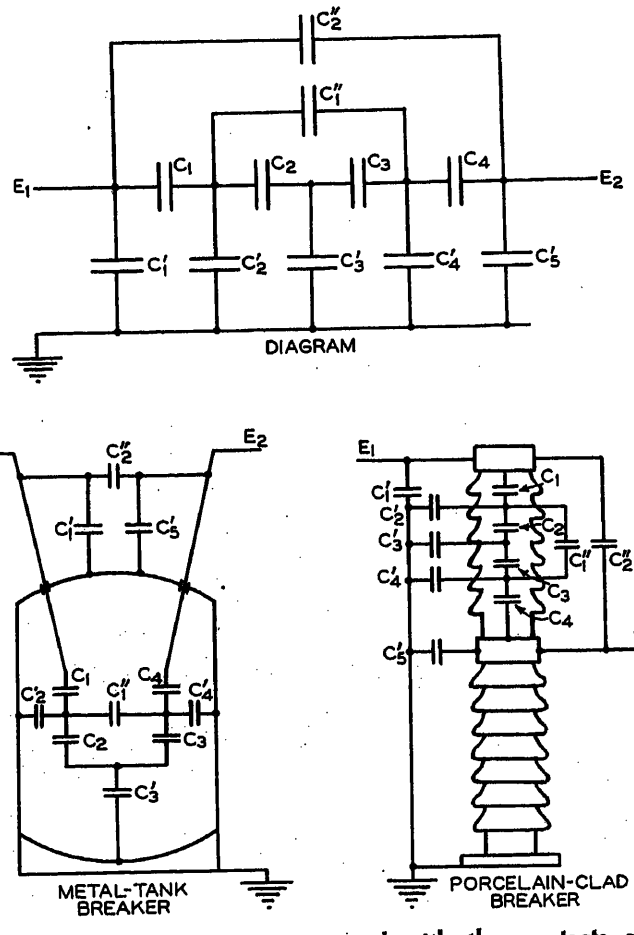

**Figure 2. Capacitances associated with the contacts and terminals of 4-break circuit breakers and typical of all multi-break breakers**

In a breaker without modern interrupting devices, the deionizing activity is relatively weak and the conductivity of the arc space changes relatively slowly. Consequently, the conductivity may be sufficiently high at the current zero to allow the restored voltage to reverse the current and build it up to a few amperes for a short interval before the interruption is finally completed. Since the rate of change of conductivity is relatively low, the differences between series interrupters is so small that this type of performance tends to divide the potential between interrupters equally even though the capacitances would produce a very uneven distribution.[1]

More effective interrupters have a higher rate of deionization and the change from a conducting arc to an insulating space is more rapid. Additional phenomena associated with the capacitances of the circuit assist in keeping the voltage divided between interrupters. These interrupters may deionize the space so rapidly that the dielectric strength required for interruption is obtained at current zero or even before the normal current zero. Oscillograms of circuit-breaker operations in which unstable arc conditions resulted in the arc being extinguished before the normal current zero have been discussed before the Institute.[2,3] This is the other extreme in breaker operation and in this case also the interrupters distribute the voltage among themselves. However, the resistances of the arc spaces will not do it since the resistances become infinite, but the capacitance currents and impedances become important and take over the function. The capacitances not only control the voltage distribution after the arcs are extinguished but also assist in sychronizing the deionization. Exact knowledge of this phenomena is lacking and the following is offered as a possible explanation.

The extreme in this type of operation is characterized by a very rapid increase in effective resistance of the arc as the current approaches zero. It is so great that the arc may become unstable and be suddenly extinguished from a current of about 10 amperes or less.[3] The conditions existing at such an instant may be represented by the diagram in figure 1. The small capacitances are chosen to represent a circuit having a high rate of voltage recovery.

When in the last few microseconds of a half-cycle of current one interrupter is able suddenly to produce infinite resistance between its contacts, the current flowing through the interrupter is diverted into the various ca-

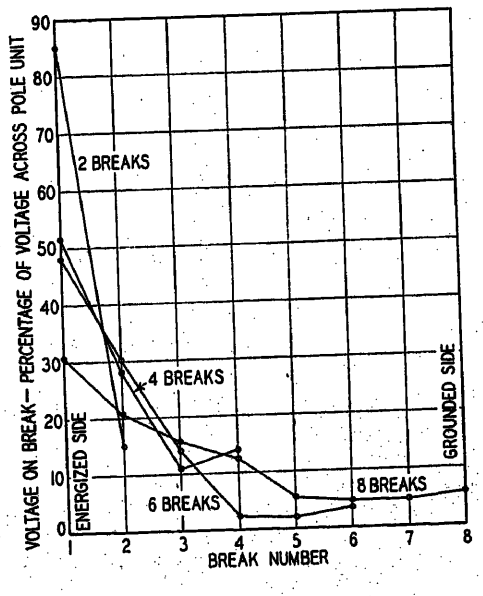

**Figure 3. Voltage distribution in multi-break oil circuit breakers having metal tanks and no shielding devices. The data are for 2, 4, 6, and 8 breaks with one terminal energized and the other grounded**

pacitances, $c$, in parallel with it. This current raises the voltage across the pole unit, starting at a maximum rate, $de/dt$, which depends on the magnitude, $i$, of the current flowing at the instant of arc rupture

$$\frac{de}{dt} = \frac{i}{c}$$

Because the capacitance of the interrupter is small compared to the other capacitances, the current flowing into it is almost negligible. In the case shown in figure 1 it would be only

$$i \times \frac{\text{20 micromicrofarads}}{\text{1,500 + 500 + 100 + 20 micromicrofarads}}$$

or about 0.01 $i$. Therefore the current through the other series interrupters would decrease rapidly from $i$ to 0.01 $i$ as their capacitances were discharged through the residual ionization in the arc spaces. However, all of these interrupters are similar and have about the same characteristics. Oscillograms show that at least one has been able to force its current to zero with more than its share of voltage across it. Therefore, it seems reasonable that the reduced energy input into the other interrupters would result in rapid increases in their effective resistances and that the voltages across them would not completely collapse. Since the change from finite to infinite resistance could hardly be instantaneous in the arc path of even the first interrupter, it appears probable that when one starts

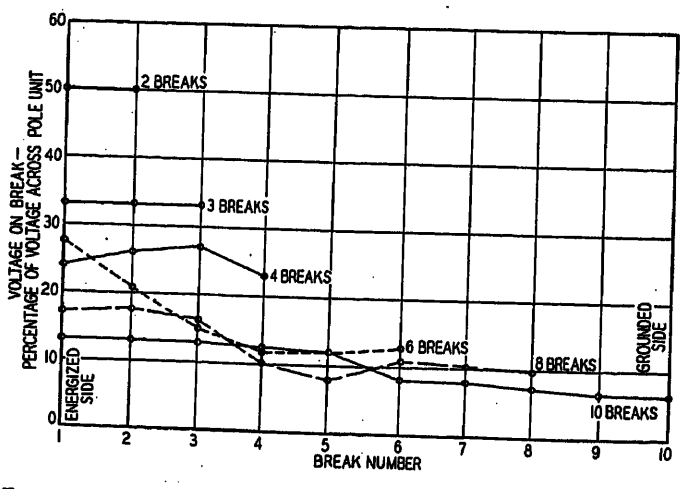

**Figure 4. Voltage distribution in multibreak oil circuit breakers having metal tanks and shielding devices. The data are for 2, 3, 4, 6, 8, and 10 breaks with one terminal energized and the other grounded and when compared with figure 3 show the improvement obtained by shielding**

to choke the current the others assist and the voltages across them are approximately equal.

The larger the capacitances across the interrupters or the more closely they are coupled to large capacitances such as shields, the less will be the voltage collapsing effect of small inequalities in the rates of deionization and the more uniform will be the voltage distribution at the time all units become nonconducting. After the arc spaces become deionized, the capacitances determine the

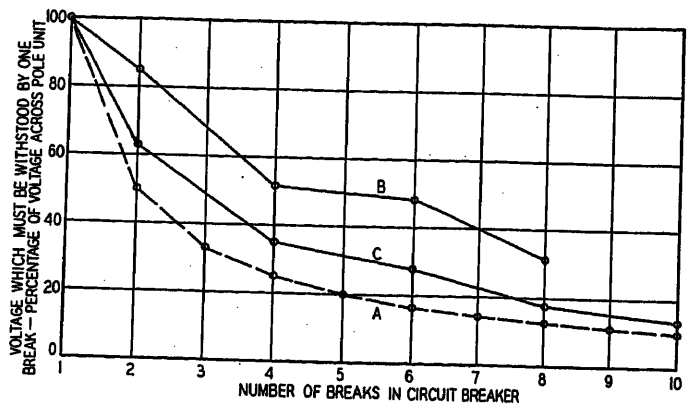

**Figure 5. Shielding reduces the maximum voltage which can appear across any one break**

Curve *A*—Minimum possible (assuming uniform distribution of voltage)

subsequent changes in the voltage across each interrupter.

Since the static voltage distribution is of importance in itself and is also a determining factor in the voltage distribution during interruption and since it is much more readily determined, it is taken as a criterion of the electrical stresses applied on the various breaks in a multibreak circuit breaker.

## Voltage Distribution in Breakers

The static voltage distribution depends upon the capacitances of the various parts of the breaker with respect to each other and with respect to ground and upon the voltages applied to the terminals of the breaker. A network representing a 4-break circuit breaker is shown in figure 2. Obviously still more capacitances are present and could be shown but generally they are relatively unimportant. This network shows that fundamentally the problem is the same in either a metal-tank breaker or in a porcelain breaker. The relative capacitances to ground are greater in a grounded metal-tank breaker but satisfactory distribution may be obtained in either case by adequate shielding means.

The relative potentials applied to the terminals of the breaker affect the distribution since some of the capacitances are to ground and their effect will depend on the potentials of the terminals. The distribution of the voltage between breaks is independent of the magnitude of the voltage between terminals, because none of the circuit constants change with voltage. Moreover, it is independent of frequency since all of the components of the circuit are capacitances and react in the same manner to changes in frequency. This is particularly important in connection with the voltage recovery transient. Grounding of the neutral of the system directly or through impedances and the location of the principal impedances determine the voltage applied across a pole unit but need not be discussed here since the voltage distribution in the breaker depends only on the relative potentials of the 2 terminals with respect to ground.

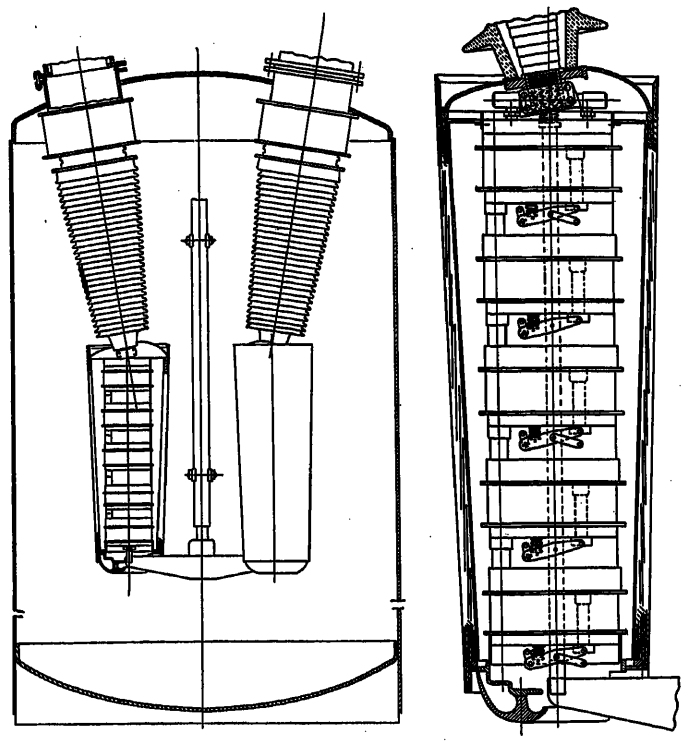

**Figure 6. Shields used in a 287-kv oil circuit breaker**

The best distribution is obtained usually with the connection corresponding to the opening of line-to-line voltage across a single pole because the recovery voltage after current zero impresses equal and opposite potentials on the terminals. The ground potential being midway between the terminal potentials results in a symmetrical distribution of voltage between interrupters and usually a minimum of distortion. A corresponding connection has been used in high-power laboratories for applying 264 kv across a pole unit. The testing transformers were insulated for only 132 kv to ground but by connecting the primaries of 2 of them to the same phase and the secondaries in series with the midpoint grounded 264 kv was obtained between terminals of the breaker.

A more usual condition is a line grounded on one side of the breaker. This is simulated by grounding one terminal of the breaker and energizing the other.

A 3-phase ungrounded short circuit would apply, to the first pole to interrupt, potentials of phase voltage on one terminal and minus half of phase voltage on the other. This is a condition which is between the 2 others with respect to the voltage distribution but it is important because of the magnitude of the voltage between terminals, 87 per cent of line-to-line voltage.

The magnitudes of the voltages impressed on the pole unit will be determined by the system and by the nature of the short circuit. The maximum voltage on any interrupter is determined for the various conditions by the impressed voltages on the pole unit and the corresponding voltage distributions.

The 3 important conditions for voltage distribution are given in table I in terms of the relative test potentials applied to the terminals of the pole unit. It should be noted that $E$ is the total test voltage between terminals and has no relation to the magnitude of the voltages impressed by the corresponding short circuits.

The poorest distribution is obtained with a grounded short circuit near the breaker terminal so this will be used as the basis of comparision to show the need for shielding and its effectiveness.

The voltage distribution in metal-tank breakers having various numbers of breaks and no special provisions to insure proper voltage distribution are given in figure 3. The data are taken from tests on 2-, 4-, 6-, and 8-break circuit breakers of experimental designs. The variations in the arrangements of contacts cause the curves to be of slightly different nature and account for the irregularities in the spacing of the curves at any particular break. The significant point is the inherent unequal distribution of voltage between interrupters in a multibreak circuit breaker having no special shielding provisions. The interrupter next to the bushing having potential is required to withstand more than twice the average voltage for the 4-, 6-, and 8-break circuit breakers. These data show that increasing the number of breaks without taking steps to insure proper voltage distribution does not result in reducing the voltage per gap approximately in proportion to the number of gaps. In fact, the most of the gaps take very little voltage and are actually a liability since they will produce just as much arc energy during the arcing period as the gap which has to withstand the most voltage at the interruption.

The voltage distribution can be modified and made to approach the ideal by the use of capacitances which reduce or eliminate the effect of those causing distortion. Improved distribution obtained with capacitance shields is shown in figure 4. The 2- and 3-break circuit breakers were single pole experimental types and were intended for operation with one side grounded. Consequently, the shielding was designed for this condition only and uniform distribution was obtained. The 6 - and 8-break breakers are the same ones that were tested unshielded and the data are directly comparable. They were designed for

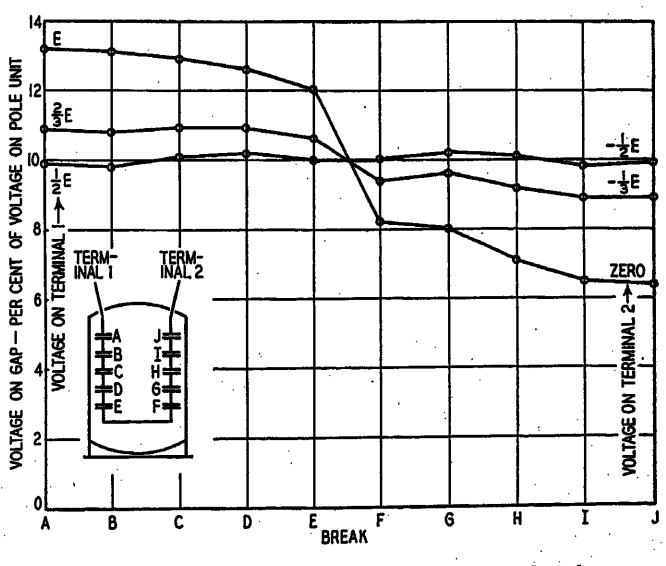

**Figure 7. Voltage distribution in a shielded 10-break circuit breaker under 3 conditions of applied voltage**

**Table I**

| Condition | Potential of the Terminals $E_1$ | $E_2$ |
|---|---|---|
| 1. A grounded short circuit near the breaker terminal | $E$ | Ground |
| 2. First phase to clear on an ungrounded 3-phase short circuit on a grounded system | $+\frac{1}{2}E$ | $-\frac{1}{2}E$ |
| 3. An ungrounded, line-to-line, single-phase short circuit through a single pole. (A test condition) | $+\frac{1}{2}E$ | $-\frac{1}{2}E$ |

Note: $E$ is the voltage across the pole unit and will not have the same value for each of the conditions given above.

grounding on either side so the shielding was symmetrical and the results approached but did not reach uniform distribution. The 6-break assembly is slightly under-shielded. In the 8-break assembly the fourth and fifth interrupters were slightly different from the others and not quite as effective. Consequently, the shielding was designed so that these 2 interrupters would get less voltage than the others. How well this was controlled is shown by the curves.

The advantages gained by shielding are clearly shown in figure 5. The ordinates are the maximum voltage on any one interrupter in percentage of the voltage applied across the pole unit.

Curve *A* indicates the percentage for uniform distribution in breakers, having from one to 10 interrupters. Curve *B* indicates the percentage as measured in some unshielded circuit breakers. Curve *C* indicates the percentage as measured in shielded breakers and shows a big improvement due to shielding. This figure shows that for a given service, about the same interrupting ability is required of the interrupters for the unshielded 8-break circuit breaker, as for the suitably shielded 4-break circuit breaker. The shielded breaker having half the number of interrupters, has half the total arc length and half the arc energy. The use of shielding in the 8-break circuit breaker permits the use of interrupters of about half the voltage interrupting ability and therefore, approximately half the arc length, half the arc duration, and an even smaller fraction of the arc energy.

## Devices Used for Controlling Voltage Distribution

The shielding devices which have produced the results already discussed are of new design. One recently developed for 287-kv breakers and described in a paper before the Institute[4] is shown in figure 6. It consists of a conical tube wound from treated paper and foil. Its construction is similar to that of a condenser bushing but differs in the location and length of the foil layers since the potential is applied between the ends of the shield instead of between the inside and the outside. The shield has an approximately uniform potential gradient from one end to the other on both the inside and outside surfaces. The interrupters located at uniform intervals inside it share the voltage equally among them. Each contact is shielded from ground and has a large capacitance to a layer of foil which has approximately the same potential as the contact. Two shields are used in a pole unit, each shield containing half of the interrupters. The large capacitances of the shields minimize the distorting effect of the capacitance to ground of the moving contact and connected metal parts. This divides the voltage between the 2 halves of the pole unit and the 2 shields divide these portions among the individual grids.

The results obtained with this shield are shown in figure 7 which gives the results of measurements under the 3 conditions of table I and shows the relations between them.

A similar shield was used during experimental work on 4 interrupters. The maximum voltage which could be interrupted was about 88 kv although individually the units could interrupt 30 kv. The electrical field inside the shield was then measured, figure 8, and found to give a voltage distribution of 24, 26, 33, and 17 per cent which indicated that one of the 4 units was being stressed to about 33 per cent of 88 kv or 29 kv. Subsequently an assembly of 4 35-kv interrupters having a voltage distribution of 24, 26, 27, and 23 per cent was tested and found to interrupt 132 kv successfully. The voltage on one unit should have been about 27 per cent of 132 kv or 35.6 kv.

**Table II. Voltage Limitations of Interrupter Assemblies Having Good Voltage Distribution**

| Number of Units in Series | Voltage Limitation (Kilovolts) | Voltage on One Interrupter Per Cent | Kilovolts |
|---|---|---|---|
| 1 | 35 to 40 | 100 | 35 to 40 |
| 2 | 65 to 75 | 50 | 32.5 to 37.5 |
| 3 | 100 to 115 | 33.3 | 33.3 to 38.3 |
| 4 | 132 or more | 27 | 35.6 or more |

The 35-kv interrupters were tested also in 2 and 3 unit assemblies with uniform distribution and the results substantiated the voltage distribution measurements as shown by the data in table II.

These series of tests demonstrated clearly the value of the static voltage distribution as a criterion of the voltage conditions existing during interruption.

## Methods of Measuring Voltage Distribution

The measurement of the voltage distribution in oil circuit breakers presents some interesting problems because of the presence of oil, the variation in the breakdown of gaps in oil, the difficulty or impossibility of locating shielded leads in equipotential surfaces, and the difficulty of making observations of phenomena below the oil surface or within the shields. A modification of the sphere gap method was selected. Gas discharge tubes replaced the sphere gaps and special viewing or detecting means were used in the determination of the breakdown. One assembly of 4 interrupters prepared for test but not yet covered by the shield, is shown in figure 9. Two small neon discharge tubes *A* having a breakdown voltage of about 60 volts are mounted adjacent to the metal assem-

blies between gaps. One lead from each tube is connected to the adjacent metal parts and the other, a flexible insulated lead is connected to a piece of metal fastened to a heavy cord. The cord passes vertically through metal guides along the assembly, the upper end goes directly to the manhole at the top of the breaker, and the lower end passes around the lower end of the shield and thence upward to the manhole. After the breaker is filled with oil, the lead can be pulled into contact with a guide, thereby connecting the tube across either the gap above the tube or the gap below the tube (as shown in the illustration). By stopping the cord midway between the end positions the flexible lead is held adjacent to the metal parts where it will exert practically no disturbing effect while measurements are being made with the other tube. This facilitates testing as it reduces the amount of oil handling.

The light from the small tube would be invisible through the oil, so a glass tube, which is sealed at the bottom and

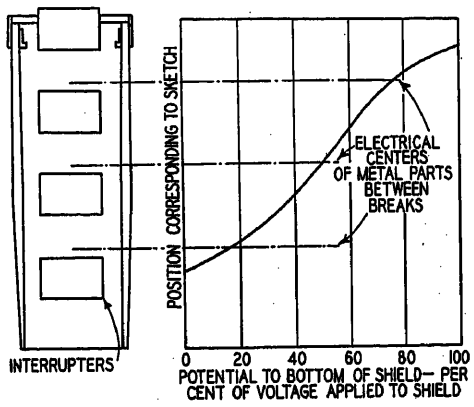

**Figure 8 (above). The electrical field inside a shield used in an experimental 4-break circuit breaker**

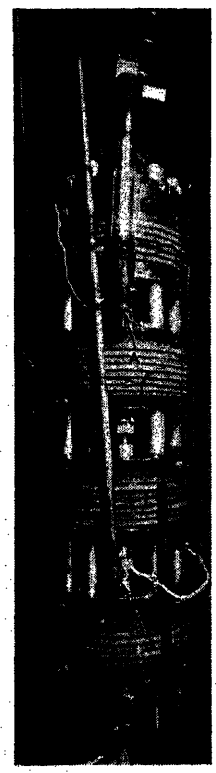

**Figure 9 (right). An assembly of interrupters with equipment for voltage distribution measurements mounted on it**

mounted directly above the discharge tube, is used to transmit the light upward to a point above the surface of the oil, where it is deflected by a prism to the manhole.

The test apparatus has little influence on the voltage distribution. The glass, Micarta, string, and air displace a small amount of oil and change slightly the dielectric, but the effect is negligible. The discharge tubes themselves have little capacitance and the leads are as short as possible and are located where they cause a minimum of error. Consequently the capacitance added to the capacitance of an interrupter by connecting the tube across it is relatively small and approximately constant, and a correction for it is easily made.

Voltage is applied by means of 2 variable-voltage potential test sets having a range of zero to 30 kv and connected to a common source of voltage, so that the secondary voltages are 180 degrees out of phase.

For tests with one terminal grounded, the procedure is as follows. By manipulation of the cords, a tube is connected across the gap under test. Potential is then applied to a terminal and increased until the voltage appearing across the gap under test is sufficient to cause the tube to break down and glow. The applied potential is recorded and 2 or 3 additional readings made as a check to be sure that the observer noticed the first breakdown. The percentage of the voltage appearing across the gap can then be obtained by dividing the breakdown voltage of the tube by the applied voltage and multiplying by 100 per cent. The leads to the terminals of the breaker are then reversed which in effect prepares for the test on the corresponding gap on the other side of the breaker. In this way only one assembly of interrupters needs to be fitted with tubes for test. After all the gaps have been tested, the percentages are added but, due to the increase in the capacitance across each gap when the tubes are connected for measurements, the sum is not 100 per cent. Since the effect of the apparatus has been about the same on each gap a constant multiplying factor is used in raising each percentage so the sum equals 100 per cent.

For tests with both terminals energized the procedure is similar but care must be taken that the potentials applied to the terminals are always in the correct ratio.

The consistency of the results and their agreement with

**Table III. Voltage Distribution on 10-Break Oil Circuit Breaker Equipped With Shields Around Contacts**

Data From Witness Test

| Grid | Voltage Applied (Volts) Term. I | Term. II | Average | Tube Breakdown Volts | Voltage on Gap (Per Cent) Reading | Corrected | Calculated |
|---|---|---|---|---|---|---|---|

calculations made before the shields were built are shown by the typical data presented in table III.

The results of tests made with tubes having breakdown voltages of 60 volts were checked by similar tests with tubes having a breakdown of about 30 kv. The tubes were larger and were inserted in the spaces between interrupters. This made viewing from above still more difficult so a choke coil was inserted in the lead to one terminal and one of the 60-volt discharge tubes was connected across it. This lead was grounded and the other connected to a high potential testing transformer. The voltage was raised until the 30-kv tube broke down. The discharge caused the 60-volt tube to glow. Data taken in this manner with one terminal energized and the other grounded gave the same voltage distribution as the data taken with the lower-voltage tubes. The other conditions were not tested with the high-voltage tube because of the greater difficulty in the manipulation of the higher potentials and the close agreement with the data more easily obtained at lower voltages.

## Conclusions

The efficiency of multibreak circuit breakers depends on the distribution of the voltage between the interrupters.

The presence of grounded parts near the interrupters and the capacitances between interrupters tend to distort the voltage distribution and to decrease the efficiency of the breaker.

Voltage distribution in multibreak circuit breakers can be controlled by capacitance shielding, so that each interrupter does its share under all short-circuit conditions.

Interrupting tests justify the use of static voltage distribution as a criterion of the voltage distribution during an interruption.

The distribution can be calculated and measured.

# Polyphase Rectifier Metering

IN PRESENTING a paper "The Metering of Mercury-Arc Rectifier Supplies and Outputs" at a recent meeting of The Institution of Electrical Engineers in London, England, C. Dannatt (A'29) research engineer for the Metropolitan-Vickers Electrical Company, Manchester, described in detail both the theoretical and practical problems involved in accurate metering of polyphase mercury-arc rectifier input and output quantities. In this 12-page paper, containing 11 illustrations and 8 tables, Mr. Dannatt stressed the essential that an accurate meter for rectifier inputs must be so constructed that its calibration is independent of frequency. The rigorousness of this requirement decreases, however, if the number of rectifier phases is increased, or if the wave form of the voltage applied to the rectifier transformer is improved. Table IV, which is reproduced from the paper, shows the variation in metering errors as the number of phases is changed.

A mathematical series describing the energy associated with current and voltage of distorted wave forms consists of a steady term and a series of pulsating terms, so that a meter used to measure energy must maintain its accuracy at frequencies as high as the component frequencies of the composite wave form. The proportion of pulsating energy to total energy decreases rapidly with an increase in the number of phases; consequently, serious difficulty in metering rectifier input is most likely to occur in rectifiers of low numbers of phases.

Except for known bad performance with respect to changes in frequency, the ordinary induction type of meter has so many advantages that its inherent errors were investigated very carefully to determine whether they were of sufficient importance to nullify the advantages of this type of meter for measuring rectifier input. The conclusion from the tests was that the error of a modern well-designed induction meter connected to rectifier supplies is not likely to exceed one per cent for a 3-phase connection, or 0.5 per cent for a 6-phase connection, provided that the meter is adjusted to register correctly with sinusoidal current and voltage.

The satisfactory performance of the induction meter encouraged the author to try other types of meters that may be used on either alternating current or direct current, and that consequently are less dependent on frequency than the induction meter in calibration. The Thomson motor type of meter is in this category, and was found to be sufficiently independent of frequency to make it an accurate instrument for rectifier power-input measurements, if no shunt is used across the field coils.

This type of meter is said to be satisfactory also for measuring the d-c output of polyphase rectifiers; satisfactory accuracy depends chiefly upon reducing the ripple component of the output, but appreciable inaccuracy of the meter may result from its use on 2- or 3-phase circuits with very little smoothing of the d-c output.

# Discussions

## Of AIEE Papers—as Recommended for Publication by Technical Committees

ON THIS and the following 16 pages appear discussions submitted for publication, and approved by the technical committees, on papers presented at the sessions on tensor analysis, synchronous machinery, and protective devices at the 1937 AIEE winter convention, New York, N. Y., January 25–29, and on one paper not presented at an AIEE meeting. Authors' closures, where they have been submitted, will be found at the end of the discussion of their respective papers.

Members anywhere are encouraged to submit written discussion of any paper published in ELECTRICAL ENGINEERING, which discussion will be reviewed by the proper technical committee and considered for possible publication in a subsequent issue. Discussions of papers scheduled for presentation at any AIEE meeting or convention will be closed 2 weeks after presentation. Discussions should be (1) concise; (2) restricted to the subject of the paper or papers under consideration; and (3) typewritten and submitted in triplicate to C. S. Rich, secretary, technical program committee, AIEE headquarters, 33 West 39th Street, New York, N. Y.

## A Single-Element Polyphase Directional Relay

**Discussion and author's closure of a paper by A. J. McConnell published in the January 1937 issue, pages 77–80, and presented for oral discussion at the protective devices session of the winter convention, New York, N. Y., January 27, 1937.**

**G. W. Gerell** (Union Electric Light and Power Company, St. Louis, Mo.): Mr. McConnell's paper brings to mind certain difficulties which our company has been experiencing with single-phase power directional relays. On rather too frequent occasions reverse power relays have operated during faults behind the relay. In most cases these incorrect operations occurred during single-phase ground faults. Invariably the relay operating falsely was not connected to the faulted phase. It should be noted that these operations have always taken place on systems grounded solidly at 2 or more points. A typical circuit arrangement would consist of 2 33-kv circuits supplying power to a substation. The circuits would be energized from the 13,800-volt power plant bus through 13.8/33 kv delta-wye grounded transformer. At the substation end the circuits would be bussed at 33 kv. The reverse power relays are located on the line oil switches at the substation end. No incorrect operations have been recorded on a number of other circuits, arranged in a similar manner, but bussed at the substation end through 33/4.5 kv transformer banks on the low-tension side.

Extremely low power factors, causing a reversal of torque in the relay may account for these operations, but I am more inclined to believe that they are caused by the relatively high currents flowing in the ungrounded conductors during a one-phase-to-ground fault. The *net* power flow at the point where the false operations occur, is of course, in such a direction to prevent incorrect operation, but in the ungrounded phases it is not necessarily so.

A polyphase relay, measuring net power in a 3-phase circuit, as Mr. McConnell has described, should effectively prevent operations so frequently experienced with the single-phase type of directional relays.

The phenomena reported here, occurs more generally on systems solidly grounded at several points, and such being the case, the question naturally arising is—why are the single-phase relays invariably applied to such systems. Polyphase directional relays were available, I believe, even before the advent of the single-phase type. Moderately high-speed polyphase relays have been available, at least during the last 6 or 7 years. For some reason or the other, they have been applied less frequently as time goes on.

Concerning a method of preventing incorrect operations on existing installations of the single-phase relays it is suggested that setting the over-current element of the directional relay for a pick-up in excess of the calculated value of current flowing in the ungrounded phases may constitute a solution, provided the setting is practical.

**J. H. Neher** (Philadelphia Electric Company, Philadelphia, Pa.): The increased use of pilot protective systems, of either the carrier current or metallic pilot-wire types, has brought about the need for a polyphase directional relay capable of high-speed and positive-contact operations. Mr. McConnell is to be congratulated on the development of such a relay which at the same time fulfills the demand for a rugged general purpose polyphase directional relay comparable in cost to, but occupying considerably less space than the present forms of such relays.

When voltage restraint is added to a directional element the resultant combination may be described as a directional distance fault detector, the range of which is a function of the angle of departure from the angle of maximum torque in the directional circuit and which is a maximum when this angle of departure is zero. In certain relay arrangements it is desirable to make use of this property such as for instance in the case of the starting unit of a reactance type distance relay.

Under such conditions it is desirable that the range of the relay be substantially the same for both 3-phase and phase-to-phase faults. The maximum range of a single-phase directional element with voltage restraint for a phase-to-phase fault is about 86 per cent of the range for a 3-phase fault, while in the case of a polyphase element with the quadrature connections, the range for a phase-to-phase fault is only 50 per cent of that for a 3-phase fault.

It appears that the connections shown in figure 2 will also have a maximum range of 50 per cent in the case of a phase-to-phase fault. As Mr. McConnell has pointed out, however, the construction of this new element is such that a number of other connections may be utilized, and possibly one can be found which will result in ranges for the 2 types of faults which are more nearly equal.

**E. W. Kimbark** (Massachusetts Institute of Technology, Cambridge): The correct working of practically every protective relay scheme, from simple overcurrent protection to carrier-current relaying, depends on directional relays, either of the single-phase type or of the polyphase type. Therefore it is important to know with accuracy what conditions limit the correct operation of such relays; and it would be desirable to have a complete mathematical analysis of their performance, like the analysis of distance relays which has been so ably achieved by Messrs. Lewis and Tippett. The paper by Mr. McConnell makes a good start at such an analysis for the polyphase type of directional relay, particularly by expressing the relay torque for each of 2 different connections in terms of the flow of positive- and negative-sequence power in the protected line, thereby enabling us to see that each of these 2 components of power contributes a suitable component of torque.

The directions of flow of vector power due to a short circuit on a 3-phase network are as follows in terms of symmetrical components: positive-sequence power flows toward the fault; while negative-sequence and zero-sequence power (if one or both are produced by the type of fault in question) flow away from the fault. The relative magnitudes of the positive-, negative-, and zero-sequence powers at a relay location depend on the type of fault, on the division of power of each sequence between the 2 ends of the faulted line, and on the distance between the fault and the relay.

(The relations derived in appendixes I *B* and II *B* of the paper for a dead phase-to-phase fault are exact only if the relay is close to the fault and only if the line is open at the far end, or if the positive- and negative-sequence powers divide between the two ends of the line in the same ratio.) Although the power at a relay location may consist of 1, 2, or 3 sequence components, mixed in various proportions, nevertheless the flow of each component is in the direction stated above; and any component which is present, or a combination of 2 or 3 of them, may be used to indicate the direction of the fault location. If all 3 components are used, the relay torque may be expressed by

$$\text{real part of } [k_1E_1\bar{I}_1\angle\theta_1 + k_2E_2\bar{I}_2\angle\theta_2 + k_0E_0\bar{I}_0\angle\theta_0] = k_1E_1I_1\cos(\phi_1+\theta_1) + k_2E_2I_2\cos(\phi_2+\theta_2) + k_0E_0I_0\cos(\phi_0+\theta_0) \quad (1)$$

(See end of discussion for notation used.) It is desirable that $\theta_2$ and $\theta_0$ should differ by approximately 180 degrees from $\theta_1$ so that the sign of each of the 3 terms of the expression will be the same when negative-sequence and zero-sequence power are flowing in the direction opposite to that of the positive-sequence power (that is, when $\phi_2$ and $\phi_0$ are approximately 180 degrees from $\phi_1$). This is on the assumption that the power factor is approximately the same for each sequence; it may differ somewhat for different sequences, and the positive-sequence power factor may vary with the type of fault. Since the positive- and negative-sequence torque terms are ordinarily obtained, not from a positive-sequence element and a negative-sequence element, but from several elements working on phase currents and voltages, $k_1$ and $k_2$ are necessarily equal, while $\theta_1$ and $\theta_2$ depend on $\theta$ (defined below) and on the relay connections.

The torque of each single-phase directional element is given by the

$$\text{real part of } k\,\bar{E}\,\bar{I}\angle\theta = kEI\cos(\phi+\theta) \quad (2)$$

and the combined torque of several single-phase elements of identical construction, or of an equivalent polyphase element, is given by

$$\text{real part of } k\angle\theta\sum\bar{E}\bar{I} \quad (3)$$

The factor

$$\sum\bar{E}\bar{I}$$

for various connections of 3 single-phase elements, using either *Y* (line-to-neutral) or Δ (line-to-line) voltages and either *Y* or Δ currents, may be expressed as follows:

$$\bar{E}_a\bar{I}_a + \bar{E}_b\bar{I}_b + \bar{E}_c\bar{I}_c = 3(\bar{E}_0\bar{I}_0 + \bar{E}_1\bar{I}_1 + \bar{E}_2\bar{I}_2) \quad (4)$$

$$\bar{E}_a\bar{I}_b + \bar{E}_b\bar{I}_c + \bar{E}_c\bar{I}_a = 3(\bar{E}_0\bar{I}_0 + \bar{E}_1\bar{I}_1\angle120 + \bar{E}_2\bar{I}_2\angle240) \quad (5)$$

$$\bar{E}_a\bar{I}_c + \bar{E}_b\bar{I}_a + \bar{E}_c\bar{I}_b = 3(\bar{E}_0\bar{I}_0 + \bar{E}_1\bar{I}_1\angle240 + \bar{E}_2\bar{I}_2\angle120) \quad (6)$$

$$\bar{E}_a\bar{I}_A + \bar{E}_b\bar{I}_B + \bar{E}_c\bar{I}_C = 3\sqrt{3}(\bar{E}_1\bar{I}_1\angle270 + \bar{E}_2\bar{I}_2\angle90) \quad (7)$$

$$\bar{E}_a\bar{I}_B + \bar{E}_b\bar{I}_C + \bar{E}_c\bar{I}_A = 3\sqrt{3}(\bar{E}_1\bar{I}_1\angle30 + \bar{E}_2\bar{I}_2\angle330) \quad (8)$$

$$\bar{E}_a\bar{I}_C + \bar{E}_b\bar{I}_A + \bar{E}_c\bar{I}_B = 3\sqrt{3}(\bar{E}_1\bar{I}_1\angle150 + \bar{E}_2\bar{I}_2\angle210) \quad (9)$$

$$\bar{E}_A\bar{I}_a + \bar{E}_B\bar{I}_b + \bar{E}_C\bar{I}_c = 3\sqrt{3}(\bar{E}_1\bar{I}_1\angle90 + \bar{E}_2\bar{I}_2\angle270) \quad (10)$$

$$\bar{E}_A\bar{I}_b + \bar{E}_B\bar{I}_c + \bar{E}_C\bar{I}_a = 3\sqrt{3}(\bar{E}_1\bar{I}_1\angle210 + \bar{E}_2\bar{I}_2\angle150) \quad (11)$$

$$\bar{E}_A\bar{I}_c + \bar{E}_B\bar{I}_a + \bar{E}_C\bar{I}_b = 3\sqrt{3}(\bar{E}_1\bar{I}_1\angle330 + \bar{E}_2\bar{I}_2\angle30) \quad (12)$$

$$\bar{E}_A\bar{I}_A + \bar{E}_B\bar{I}_B + \bar{E}_C\bar{I}_C = 9(\bar{E}_1\bar{I}_1 + \bar{E}_2\bar{I}_2) \quad (13)$$

$$\bar{E}_A\bar{I}_B + \bar{E}_B\bar{I}_C + \bar{E}_C\bar{I}_A = 9(\bar{E}_1\bar{I}_1\angle120 + \bar{E}_2\bar{I}_2\angle240) \quad (14)$$

$$\bar{E}_A\bar{I}_C + \bar{E}_B\bar{I}_A + \bar{E}_C\bar{I}_B = 9(\bar{E}_1\bar{I}_1\angle240 + \bar{E}_2\bar{I}_2\angle120) \quad (15)$$

The following 2-element combination is also of interest:

$$\bar{E}_A\bar{I}_C - \bar{E}_C\bar{I}_A = 3\sqrt{3}(\bar{E}_1\bar{I}_1\angle270 + \bar{E}_2\bar{I}_2\angle90) \quad (16)$$

Equations 7, 10, and 16 are for the 90-degree connection (equation 10 representing its usual form); equations 5 and 14 are for the 60-degree connection, which is equivalent to the one recommended in the paper for the new polyphase relay; and equations 9 and 12 are for the 30-degree connection (equation 12 the usual form.) A comparison of the expressions just mentioned, substituted in (3), with equation 1, yields the following values of $\theta_1$ and $\theta_2$:

| Connection | $\theta_1$ | $\theta_2$ |
|---|---|---|
| 90-degree | $\theta - 90$ | $\theta + 90$ |
| 60-degree | $\theta - 60$ | $\theta + 90$ |
| 30-degree | $\theta - 30$ | $\theta + 30$ |

By way of comparison, assume that for each connection the positive-sequence torque is made a maximum at 30 degrees lag ($\theta_1 = -30$). This assumption determines a different value of $\theta$ for each connection, and the value of $\theta$ determines the values of $\theta_2$ and of $\theta_2 - 180$:

| Connection | $\theta_1$ | $\theta$ | $\theta_2$ | $\theta_2-180$ |
|---|---|---|---|---|
| 90-degree | −30 | 60 | 150 | − 30 |
| 60-degree | −30 | 30 | 90 | − 60 |
| 30-degree | −30 | 0 | 30 | −150 |

The values of $(\theta_2 - 180)$ are the phase angles of the negative-sequence current with respect to the negative-sequence voltage for maximum torque, considering that the negative-sequence vector power is substantially opposite in direction to the positive-sequence; thus, the 90-degree connection gives maximum torque at 30-degree lag (equal to the lag at which the positive-sequence power gives maximum torque); the 60-degree connection at the greater lag of 90 degrees; and the 30-degree connection at the still greater lag of 150 degrees. Since so great a lag would never be obtained, the negative-sequence torque would be relatively low in the 30-degree connection, and possibly even reversed in direction. For this reason the 90-degree and 60-degree connections appear preferable to the 30-degree connection, even though the latter would probably operate correctly.

The connections just discussed give no zero-sequence torque, with the exception of the form of 60-degree connection represented by equation 5. For this case $k_0 = k_1$, and $\theta_0 = \theta + 180$. Assuming as before that $\theta_1 = -30$, there results $\theta_0 - 180 = 30$; maximum zero-sequence torque is obtained with current leading by 30 degrees. This is not the best relation that could be imagined, because the zero-sequence current will frequently lag by a considerable angle, giving a low or even reversed torque, though probably seldom strong enough to overweigh the positive- and negative-sequence torques. If desired, the zero-sequence torque can be eliminated by connecting the relay voltage windings in *Y* with no neutral connection. A more reliable and flexible way of introducing a zero-sequence torque is to use an electrically separate mechanically coupled zero-sequence element as described in the paper; by this means $k_0$ and $\theta_0$ can be given any desired values. It would be interesting to know the value of $k_0/k_1$ for the relay described as having a "strong ground-fault element."

The negative-sequence phase angle $(180+\phi_2)$ depends on the impedance from the relay to the generators, including lines, transformers, and generators, and will probably range from 60 to 90 degrees. The zero-sequence phase angle $(180+\phi_0)$ depends on the impedance from the relay to grounding points, including lines, transformers, and grounding impedance, and may range almost from 0 to 90 degrees. The positive-sequence phase angle depends on the negative- and zero-sequence phase angles at the fault, on the fault resistance, and on the line impedance from relay to fault. In the case of a 3-phase fault only the last 2 items come into play. A 3-phase fault near the relay, is, of course, a critical condition for the relay on account of the low voltage on all phases; hence the relay should be designed for maximum torque at a phase angle near the line impedance angle or somewhat more leading so that the arc resistance will have more effect.

Another critical condition for a polyphase directional relay is a single line-to-ground fault in which the fault current is limited by fault resistance or by system grounding impedance to a value comparable with normal load current; because the positive-sequence power flow during fault conditions is determined not only by the fault current but also by the normal load current; and for this reason it is possible for a directional relay actuated by positive-sequence power at the receiving end of a faulted line to give the wrong directional indication. This fact suggests the discarding of positive-sequence power for directional discrimination; however, it must be retained in order that the relay act during a 3-phase fault.

Having never seen a quantitative statement of the conditions under which load current may cause incorrect operation of a polyphase directional relay, I offer a criterion which is admittedly crude. It is

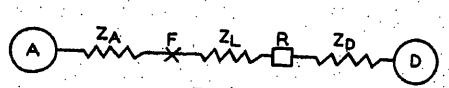

Figure 1

assumed that the power system beyond each end of the protected line may be represented by an equivalent electromotive force in series with an equivalent impedance. In figure 1, *F* represents the point of fault, *R* the relay location, *A* and *D* the equivalent electromotive forces, $Z_A$ and $Z_D$ the equivalent impedances, and $Z_L$ the line impedance. Figure 2 is an approximate vector diagram

of positive-sequence voltages. $AG$ and $DG$ are the equivalent electromotive forces at the sending and receiving ends, respectively, and are assumed to be unaltered by the presence of a fault. $F_1G$ is the voltage at the point of fault before occurrence of the fault and $R_1G$ is the voltage at the relay under the same conditions. $F_2G$ and $R_2G$ represent the voltages at the same points during a mild fault, and $F_3G$ and $R_3G$ the same during a more severe fault. $AF_1R_1D$ is a straight line on the assumption that

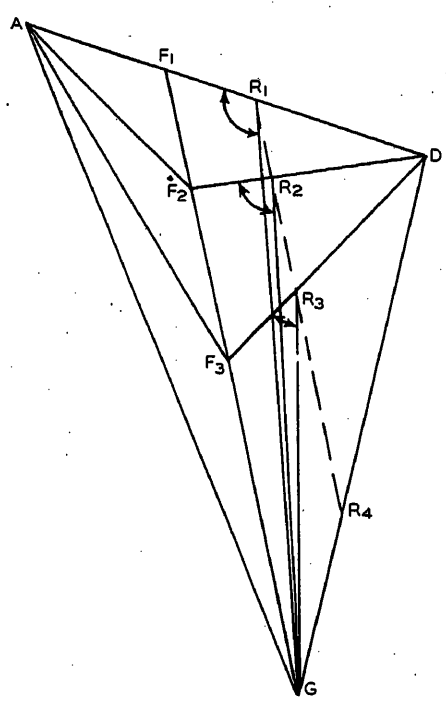

Figure 2

impedances $Z_A$, $Z_L$, and $Z_D$ have the same angle. $F_1F_2F_3G$ is a straight line on the assumption that the positive-, negative-, and zero-sequence impedances of the system have the same angle. $F_1R_1$, $F_2R_2$, and $F_3R_3$ are the respective positive-sequence line drops from the fault to the relay, and the positive-sequence line currents are proportional to them and lag behind them by angle $\lambda$. The positive-sequence torque on relay $R$ is proportional to $E_1I_1 \cos(\phi_1 + \theta_1) = R_1GXR_1FX \cos(\angle GRF + \lambda + \theta_1)$. If we assume for simplicity that the relay has maximum torque at an angle equal to the line impedance angle (i.e., $\theta_1 = -\lambda$), the torque is proportional to $R_1GXR_1FX \cos \angle GRF$. Angle $GRF$ has value $GR_1F_1$ with no fault present, $GR_2F_2$ or $GR_3F_3$ for faults of increasing severity, and finally $GR_4G$ or zero angle for a dead 3-phase fault. The relay torque changes sign when angle $GRF$ passes through 90 degrees. This occurs when the reduction $F_1F_2$ in positive-sequence voltage at the point of fault is about equal to the arithmetical voltage drop from $F$ to $D$ under normal load conditions. If the latter does not exceed 20 per cent, any fault except a line-to-ground fault would give sufficient reduction in voltage to give a relay torque in the correct direction; and a line-to-ground fault would probably do likewise unless the fault current were limited by fault resistance or system grounding impedance. Although several assumptions have been made that are not strictly correct, it appears reasonably certain that a line-to-line fault will always give correct operation. This conclusion has been reached on the basis of the positive-sequence torque alone. The negative-sequence power provides an additional torque acting in the right direction.

NOTATION

The notation used in this discussion is like that in the paper with the following additions:

$$I_A = I_c - I_b$$
$$I_B = I_a - I_c$$
$$I_C = I_b - I_a$$

$I_A$, $I_B$, $I_C$ will be called "delta currents," and may be obtained by a delta connection of the secondary windings of the current transformers.

$\phi$ = angle by which the current of a single relay element lags behind the voltage of same element.

$\phi_0$ = angle by which $I_0$ lags $E_0$.

$-\theta$ = value of $\phi$ at which relay has maximum torque.

$-\theta_0$, $-\theta_1$, $-\theta_2$ = values of $\phi_0$, $\phi_1$, $\phi_2$, respectively, at which relay has maximum torque.

$\lambda$ = angle of line impedance.

$k$, $k_0$, $k_1$, $k_2$ = constants in torque equations.

**W. R. Brownlee** (Tennessee Electric Power Company, Chattanooga): The author has chosen a very clear method of indicating the performance of the new polyphase relay in terms of fundamental system impedances. The low energy requirements and small inertia of moving parts are a most welcome contribution toward accurate high-speed relaying.

The difference of 30 degrees in phase angle between a 3-phase fault and a dead single phase-to-phase fault is indeed an advantage. In addition to the fact that a single-phase line-to-line short circuit causes a phase angle difference depending on the impedance back to and including the generator, this same system and generator impedance is available to produce voltage at the relay terminals considerably in excess of the voltage on the faulted phase at the relay. This method of securing positive directional action for single-phase short circuits has been used in the connections of various impedance relays, usually 3 single-phase units.

One of the chief uses for the new relay element should be the 3-phase directional element combined with a voltage restraint element to provide a directional fault detector. The need for such a device with greatly improved accuracy and speed has been felt for many years, particularly in connection with lines and systems where the short-circuit current under certain generating conditions may be actually less than load current under other conditions. In order to meet this requirement a fault detector should have a nonlinear characteristic so that the current required to operate the unit varies with the voltage at some power higher than the first. Such a fault detector was incorporated as early as 1930 in the Brown Boveri reactance type relay. Shortly thereafter the General Electric Company placed in service a single phase *directional* fault detector incorporated in their type $GAX$ reactance relay using voltage amplification by means of a circuit which was made resonant at low voltages only, by the application of a "thyrite" resistor. This equipment produced a characteristic curve of operating current versus voltage which was most highly useful in solving applications of high load current and low short circuit current.

It appears from the final equations that the new relay if provided with a voltage restraining element would have a straight line characteristic of operating current against voltage (for a balanced 3-phase condition) and even if the sensitivity has been increased it is disappointing that the nonlinear characteristic curve was not applied to the new relay. Perhaps further developments will make it possible to secure such a characteristic with the new relay without adding too much complication or expense.

This criticism is by no means intended to minimize the unquestionable achievement of the G. E. Company in developing the new cup type relay but to point out that the operating man is in urgent need of a much better directional fault detector relay than has been available in the past for taking care of 3-phase short circuits on transmission lines.

**A. J. McConnell:** Mr. Neher is correct in stating that with directional connections as in figure 2 and with a voltage restraining element connected to measure a value proportional to the area of the voltage triangle, the maximum range of the relay for a phase-to-phase fault is 50 per cent of that for a 3-phase fault. If the relay is designed to have the desired range for a phase-to-phase fault, it is sure to operate on a 3-phase fault at the same location. The limiting factor is that the greater reach on the 3-phase condition must not cause operation during normal load conditions.

The starting unit of the $GAX$ reactance relay mentioned by Mr. Brownlee had a nonlinear characteristic principally in order to increase the torque and speed at low voltage without overheating at normal voltage. The author believes that such expedients are seldom necessary with the induction cylinder relay because of the high torque level and low inertia.

The first system described by Mr. Gerell is definitely one in which single-phase directional relays are likely to operate incorrectly. Zero-phase-sequence currents may be present with no positive and negative, in which case the line currents will be equal and in phase, and consequently, the indicated direction of at least one of single-phase relays must be incorrect.

As Mr. Gerell pointed out, the polyphase relay would solve the problem. When supplied with delta voltages or currents, the polyphase relay is not influenced by zero-phase-sequence quantities. This suggests another solution, namely, eliminating the zero-phase-sequence currents from the single-phase relays by delta connection of current transformers. Since a ground directional relay would then be necessary, the delta currents would have to be obtained by means of auxiliary wye-delta current transformers. The polyphase relay would

also require a ground directional relay, but no auxiliary current transformers would be required.

The use of wye-delta current transformer is equivalent to the second system mentioned by Mr. Gerell. The probable reason why no incorrect operations have been recorded on this system is because the zero-phase-sequence currents are eliminated from the relays by the wye-delta power transformers.

Mr. Kimbark's extension of the analysis of polyphase directional relay torques to include other connections is a valuable addition to the paper.

Another interesting extension is to consider the relay torques when the currents, voltages, or both are obtained from the delta side of a wye-delta transformer bank, the fault being on the wye side.

Equation 16 is one of many interesting combinations which can be derived from equations 4 to 15 inclusive by substitution of one or more of the following equations:

$$I_A + I_B + I_C = 0$$
$$I_a + I_b + I_c + I_g = 0$$
$$E_A + E_B + E_C = 0$$
$$E_a + E_b + E_c + E_g = 0$$

where $E_g$ and $I_g$ are residual voltage and current, respectively.

Referring to the term "strong ground element" a value of 4 has been used for $k_0/k_1$. It should be noted here that when this ratio has not been sufficient for the ground element to overcome the polyphase element because of load, the latter has been de-energized by means of a simple instantaneous overcurrent relay operated by ground current.

Mr. Kimbark's analysis of fault conditions when load is present is interesting. It has been usual to consider the ground element torque under fault conditions in comparison with polyphase element torque before the fault. This is conservative because the load torque during the fault is always reduced. Actually, this may be too conservative because the polyphase element also has a component of torque in the correct direction. However, if the assumed load torque is comparable with the fault torque, it is advisable to give the ground element complete control either as described in the previous paragraph or by employing a separate ground relay.

## Operational Solution of A-C Machines

**Discussion of a paper by A. R. Miller and W. S. Weil, Jr., published in the November 1936 issue, pages 1191–1200, and presented for oral discussion at the winter convention, New York, N. Y., January 27, 1937.**

**S. B. Crary** (General Electric Company, Schenectady, N. Y.): The authors have shown quite conclusively that the operational methods of Park for analyzing the performance of synchronous machines, can be reasonably expected to check actual test results. Besides showing the nature of the phenomena such checks are valuable in creating confidence in this method.

The authors, in their equations, have used the per unit system presented in Park's paper "Synchronous Machines—An Extension of Blondel's Two Reaction Theory—I." When additional circuits besides the main field circuit are to be included, we have found that it is more convenient to express the equations with coefficients which are in terms of the armature circuit rather than their individual circuits. This makes possible the use of methods presented by T. M. Linville, "Starting Performance of Salient Pole Synchronous Motors," volume 49, AIEE JOURNAL, February 1930, pages 145–47. Furthermore, it reduces in half the number of mutual reactance coefficients required and makes it possible to draw simple equivalent circuits for the machine. This allows for a fair check of the calculations of the coefficients and, therefore, tends to reduce errors at this preliminary stage of the analysis.

## A Suggested Rotor Flux Locus Concept of Single-Phase Induction Motor Operation

**Discussion and author's closure of a paper by C. T. Button published in the March 1937 issue, pages 331–2.**

**Edward Bretch** (The Advance Electric Company, St. Louis, Mo.): The method used by Mr. Button in his paper on the single-phase motor, that of considering the rotor flux as substantially constant along a fixed diameter of the rotor, enables one to clearly visualize the actions taking place in the single-phase squirrel-cage motor.

In the single-phase squirrel-cage rotor at and near synchronism, the following conditions prevail:

1. It carries the main flux produced by the primary.
2. The alternating primary magnetizing impulses are rectified with respect to the rotor through its synchronous motion.
3. The rotor flux is completely enclosed by low resistance rotor short circuits tending to hold it constant.

After the rotor flux is once established, the induced currents in the short-circuited rotor exert a strong tendency to hold this rotor flux constant and in a fixed relation to the rotor conductors. Consequently the rotor then reacts on the primary the same as if it was magnetized by a fixed magnetizing force across a diameter and by its synchronous motion carries this sustained flux around with it, establishing mechanically a true rotary field and tending to keep in synchronism.

A squirrel cage in a stationary or d-c field is commonly used to illustrate the principle of the polyphase squirrel-cage motor, the torque being developed by induced currents in the short-circuited rotor conductors as they cut across the magnetic field, utilizing what is commonly called the "speed" action. This same method can be used to illustrate the principle of the single-phase motor if we substitute a rectified single-phase a-c excitation for the d-c so that the primary excitation consists of a series of unidirectional impulses instead of a uniform unidirectional force as when excited by direct current.

This pulsating magnetizing force is the condition that prevails in the single-phase squirrel-cage rotor at synchronous speed, as the magnetic impulses produced by the single-phase exciting current are rectified with respect to the rotor, through the synchronous motion of the rotor, so that the rotor magnetism is produced through a series of unidirectional impulses. Consequently if we hold the rotor stationary and rectify the single-phase primary exciting current we will reproduce in a stationary rotor the conditions existing in the single-phase squirrel-cage rotor at synchronism.

In order to visualize what takes place in a squirrel-cage rotor, when running at synchronism in a single-phase field, let us assume a bipolar field with a single-phase winding capable of setting up a flux along the line $y$—$y$. Also let us assume the rotor has 2 individual short-circuited coils $A$ at right angles to this flux and $B$ in line with it.

Noting the positions of the coils with reference to the primary we see that $A$ encloses the total flux, and is therefore in a transformer relation to the primary. Coil $B$, however, is in line with the flux and does not enclose it and consequently is not in the transformer relation to the primary. However, the conductors of coil $B$ lie in the area of maximum flux density and in such a position that any motion of the rotor will cause them to cut across the field, thereby inducing local currents by the speed action, opposing motion and producing torque.

When the primary is excited by direct current no current will be induced in either coil as long as the rotor is at rest. Any motion of the rotor will induce currents in

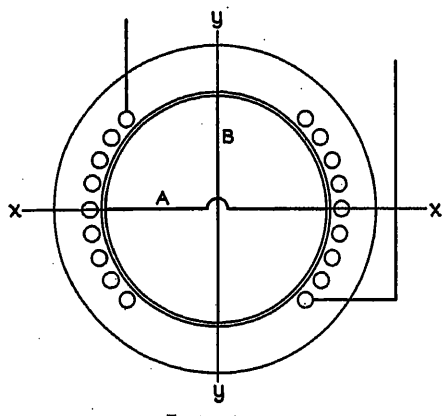

Figure 1

coil $B$ by the speed action, opposing the motion and thereby producing torque. Coil $A$ is in the neutral position with its conductors in the area of minimum or zero flux so that no current will be induced until the conductors move out of the neutral position and start cutting across the magnetic field. This is the polyphase condition.

If we now excite the primary with a rectified alternating current, to reproduce the single-phase rotor condition at synchronism, the magnetizing force will consist of a series of unidirectional impulses varying from

zero to a maximum. If it were not for coil $A$ the flux would coincide with the primary current and vary unidirectionally from zero to maximum. However, due to the transformer relation of coil $A$ any flux variation induces currents in the coil, opposing the flux change, so that when the primary magnetizing force decreases to zero, the flux does not, but is sustained between impulses by the induced currents in coil $A$. As the magnetizing impulses are unidirectional, the flux is unidirectional but varying in some degree with each impulse. The flux-sustaining currents induced in coil $A$ complete a cycle with each impulse, and there being 2 impulses for each cycle of the primary rectified exciting current, the frequency of these flux-sustaining currents is double that of the primary current. The amount of flux variation through coil $A$ between impulses depends upon its resistance. Theoretically with zero resistance the flux would be constant, and at the other limit, would coincide with the exciting current if the resistance was infinity. Both rotor resistance and magnetic leakage tend to decrease this sustained flux which is commonly called the cross flux.

With a substantially constant unidirectional flux established by the primary magnetizing impulses, stabilized by the double-frequency flux-sustaining currents in coil $A$, the opposition to the movement of coil $B$ across the field, due to speed action, produces the torque the same as with d-c excitation.

To illustrate the location and nature of the single-phase rotor reactions, a rotor with 2 individual short-circuited coils at right angles was assumed. However, in the ordinary squirrel-cage rotor, under slip conditions, the conductors are constantly shifting from the position where the speed action produces torque to the position at right angles where the transformer action produces the double-frequency flux-sustaining currents and vice versa. As the rotor slips the frequency of the flux-sustaining currents will decrease in the same manner that the frequency of the slip or torque currents increase. Thus in the single-phase squirrel-cage rotor there are superimposed 2 sets of induced currents at right angles. The one is the torque or slip currents, in the area of the maximum flux, produced by the speed action, with a frequency proportional to the slip, becoming zero at synchronism. The other is the flux-sustaining currents in the area of minimum flux density, produced by the transformer action, with a frequency of double the primary frequency less the slip and proportional to the primary exciting current.

This method of treatment indicates that the double-frequency flux-sustaining currents, proportional to the exciting current, flowing in the rotor at synchronism, although they incur an $I^2R$ loss, are produced through a transformer action at right angles to the torque currents, and thus do not act as a brake load and do not increase slip. It also indicates that the flux will not be as well maintained as slip increases due to the imperfect rectification of the primary magnetizing impulses as slip increases. The effectiveness of the rectification decreases with slip and when slip reaches 100 per cent, or with the rotor at standstill there is no rectification at all and consequently no torque producing condition.

In the polyphase motor, rotor resistance does not reduce the magnitude of the maximum, or breakdown torque, but merely lowers the speed at which it is developed.

In the single-phase motor we see that rotor resistance not only lowers the speed at which the maximum torque is developed, but through restriction of the double-frequency flux-sustaining currents and imperfect rectification of the magnetic impulses, the maximum torque is greatly reduced, as the speed at which it is developed is lowered. This explains the characteristic of single-phase motors that they must operate at less slip than polyphase motors for efficient operation.

It also indicates that high reluctance means high double-frequency rotor currents involving high rotor $I^2R$ losses, irrespective of load, and thus the desirability of both low magnetic reluctance and low rotor resistance for efficient operation under running conditions.

While the single-phase squirrel-cage motor is a rotary field motor, it is in reality not a special case of a polyphase motor since the rotary field is not produced in the primary by the combined action of polyphase currents, but is produced in the secondary from an intermittent or single-phase primary excitation, through the sustained rotor flux, mechanically rotated by the motion of the rotor. This direct method of analysis by assuming single-phase conditions as they really are, rather than the indirect method of assuming special polyphase conditions which are more or less a mathematical fiction, seems to afford a much clearer insight into the interrelations of the various factors involved in the single-phase squirrel-cage motor.

**C. T. Button:** The comments by Mr. Bretch on the "Rotor Flux Concept of Single-Phase Induction-Motor Operation" (March 1937 issue) are very interesting. I do not interpret these comments as indicating that Mr. Bretch cannot agree with any part of the original paper; but he is apparently merely advancing some thoughts prompted by reading the paper.

It is felt that one should be as precise as possible; and particularly premises should be accurately stated lest they lead to increasing divergence from actual conditions as conclusions are developed.

At the outset of the discussion, then, we would not say that the theory "considers the rotor flux as substantially constant along a fixed diameter." The statement just quoted evidently refers to the condition at synchronous speed only and should so indicate. Also, the statement neglects the pulsating component in the quadrature rotor axis (plane of coil $A$ in Mr. Bretch's figure). This is important—lack of completeness and precision leads to failure to obtain an explanation of such things as the pulsating torque component, negative torque existing at synchronous speed, etc.

The statement that "the primary magnetizing impulses are rectified with respect to the rotor through its synchronous motion" is an interesting way of expressing the situation, but is also lacking in the same way in conveying an accurate mental picture. Figure 2 of the paper is a picture that it is difficult to convey in a few words.

The paragraph by Mr. Bretch beginning with "after the rotor flux is once established" seems to be rather foggy and not to contribute anything omitted from the original paper. The concluding expression "and tending to keep in synchronism" is misleading. At synchronism the torque is negative and hence the tendency is to drop below synchronous speed.

Again, "if we hold the rotor stationary and rectify the single-phase primary exciting current," we will not "reproduce in a stationary rotor the conditions existing — at synchronism." There is a pulsating torque at synchronous speed, with a net or average negative value. The primary object of the paper was to lead to a concept of conditions as they are, rather than as they might be represented by something else, which in the case of the suggestion mentioned, would be inaccurate.

As soon as one attempts to investigate currents in rotor "coil $A$" and "coil $B$" he finds himself involved to such an extent that the only way out is to set up the mathematical expressions for voltages or currents, and proceed by the cross-field analysis as developed by H. R. West. The trouble is that "coil $A$" is only in a purely "transformer" relation to the primary for a passing instant, and "coil $B$" is only out of the transformer (or in a pure "speed") relation for a transient instant. Discussion as to which coil produces the cross field, and what the phase relations are, is not within the intended scope of the paper.

Take the statement by Mr. Bretch, "Coil $B$ by speed action induces local currents opposing motion and producing torque." True, negative torque is produced opposing motion. But this is not motor action. Well, then, coil $B$ is to set up the cross field. But if so, how can it produce a field in the $x$—$x$ axis in time quadrature with the main field, since coil $B$ itself would lie in the $x$—$x$ axis when the main flux is zero and the cross field is maximum?

The so-called "transformer" voltage and "speed" voltage are in reality fundamentally identical phenomena. A voltage may be said to be generated in coil $A$ because of change in magnitude of flux through it; and a voltage is correspondingly generated in coil $B$ because of change in direction of the primary flux with respect to it. If the primary flux is at one instant in the plane of coil $B$ and the next instant at an angle $\alpha$ with respect to coil $B$, then the next flux at the second instant has a sine $\alpha$ component which has developed in the plane of coil $A$. Thus change in direction of flux in the neighborhood of the plane of coil $B$ means a change in the component of this flux in the plane of coil $A$, or in other words a change in flux through coil $B$. This is also transformer action of course.

Thus both coil $A$ and coil $B$ as well as every conductor around the rotor periphery have voltages induced in them due to change of flux linking them, which is in turn due to change in both magnitude and direction of the total flux with respect to them. To select 2 sets of conductors one of which at a certain instant has zero voltage due to change in flux magnitude while the other set has zero voltage due to change in flux direction cannot in the opinion of the writer be used in a simple manner to arrive at a complete concept of the basic phenomena of the operation of the motor in question. The point is emphasized that, for the

purposes for which the paper was written, it seemed desirable to deal with total entities rather than any of their various possible components.

It is not necessary to proceed further through the comments submitted by Mr. Bretch with replies. The object of the paper was to present a simplified concept, and the comments do not seem to increase the clarity, accuracy, nor completeness of the theory; but rather seem to do the reverse.

Some of the remarks of Mr. Bretch, however, may inspire the derivation of further conclusions on the basis of the theory outlined in the paper—such as variation of torque with slip or with change in motor constants, and behavior of the cross field at various values of slip both below and above synchronous speed.

## Dyadic Algebra Applied to 3-Phase Circuits

August 1936 issue, pages 876–82

## Complex Vectors in 3-Phase Circuits

December 1936 issue, pages 1356–64

**Author's closure of 2 papers by A. Pen-Tung Sah published in the August 1936 and December 1936 issues, and presented for oral discussion at the tensor analysis session of the winter convention, New York, N. Y., January 26, 1937.**

**A. P.-T. Sah:** Before answering some of the specific points that have been raised regarding the author's 2 papers on dyadic algebra and complex vectors as applied to 3-phase circuits, a reiteration of the viewpoint of these papers is perhaps helpful. One of the chief objects of the papers is to apply the method of Gibbs to 3-phase circuit theory. Whether Gibbs's dyadics should be considered to be obsolescent or not is a matter of individual opinion. In fact, the appearance of such work as Lagally's "Vektor Rechnung" in 1928 and A. P. Wills's "Vector and Tensor Analysis" in 1931 and other more recent articles of a purely mathematical nature on the extension of Gibbs's ideas are probably sufficient to show that Gibbs's work is not going in the direction of the scrap pile.

All engineers will probably agree that new concepts and relations will be more easily understood and grasped by the practical men if they are given in concrete rather than abstract form. It is due to this fact that in the exposition of the set of equation 1 of the dyadic paper (page 876) the author has arbitrarily introduced the orthogonal unit vectors **i, j, k** in order to show that the triad numbers, $e_a$, $e_b$, $e_c$, and $i_a$, $i_b$, $i_c$ may be considered as the orthogonal projections of 2 vectors and that the 9 $z$'s a dyadic operator used to change one vector to another. It is true that if we choose, we can resort to matrix interpretation of this set of equations. Indeed, as pointed out by Gibbs-Wilson in their book, a dyadic may be considered as a square matrix with 9 coefficients and a row or column matrix as a vector. To give a geometrical interpretation to the set of equation 1 may appear to be "irrelevant" to a pure algebraist but certainly should not be without assistance to an applied mathematician. An analogy in this case will perhaps make the situation clearer to the electrical engineer.

In the days when complex numbers were first studied, they have been defined as a dual number with 2 components $a$ and $b$ and written as $(a, b)$. The addition of 2 such numbers is then defined as $(a, b) + (c, d) = (a + c, b + d)$ while their multiplication as $(a, b)\ (c, d) = (ac - bd,\ bc + ad)$. If this is compared with the present universal notation $a + jb$ for $(a, b)$ and the definition of the product through the relation $jj = -1$, so that $(a + jb)\ (c + jd) = (ac - bd) + j\ (bc + ad)$, it is evident that the introduction of the imaginary unit $j$ has not only clarified the algebraic work but also made a geometrical interpretation of complex numbers possible. If J. Slepian should think that $j$ is not irrelevant to the interpretation of complex numbers, probably he can also be persuaded to give proper value to the introduction of the unit vectors **i, j, k** in the present papers.

As an unbalanced 3-phase circuit is of necessity more complicated than a single-phase circuit, so are the computations and the representations. In view of the present difficulties encountered in the formulation of a satisfactory definition of power factor in an unbalanced 3-phase system, the fact that there is a definite though varying angle between the voltage and the current vectors even for an unbalanced system should be further studied to see if there is a way out of the present complications. Those who think that the elliptical representation of unbalanced 3-phase systems to be not so good may want to withhold their final pronouncement until such a study has been completed.

Slepian has also suggested that the definition of the scalar product between two complex vectors might be more attractively given as:

$$\mathbf{X}\cdot\mathbf{Y} = X_1{}^*Y_1 + X_2{}^*Y_2 + X_3{}^*Y_3$$

so that the 3 vectors **u, f, b** would become mutually perpendicular. The suggestion is interesting but has 2 defects. According to the suggestion the steady-state complex power in a 3-phase circuit would be **E·I** (or **I·E**) instead of **E·I*** (or **E*·I**) as given in the present paper. Since in single-phase circuits, complex power is either $E^*I$ or $I^*E$ and not $EI$, the unsuitability of such a suggestion when applied to electric circuit theory is at once apparent. The second drawback of such a definition lies in the fact that it invalidates the commutative law for scalar products. In other words **E·I** would not equal **I·E** unless both $E$ and $I$ be real. The attendant inconvenience to the failure of the commutative law for the scalar product lessens a large amount whatever attraction the suggestion may have in other respects.

Referring to the discussion by G. Calabrese on the formula of the force between 2 elements of current-carrying conductors, it should be emphasized that the currents therein given are currents in conductors oriented in a physically real space and should not be confused with the current vectors used by the author.

The author agrees with Irven Travis in that any simplification in actual calculation of networks will be due to symmetry of impedances. Hence, there will be a good deal of lost labor in the solution of completely unsymmetrical systems by the method of symmetrical components. The merit of the present scheme of solution lies in its systematized organization of the otherwise numerous equations. It is gratifying to note that Travis and his students have used matrices to represent Stokvis-Fortescue transformation. In this connection the author would like to call attention to the advantages of using the author's expressions 56, on page 1362, having a different scalar multiplier from Travis's expressions 3 and 4. These advantages have been pointed out in reference 5 of the paper on complex vectors.

C. E. Rose has correctly pointed out a typographical error in equation 28$d$, page 881. As given by Rose, the equation is still not right. This error together with 3 others, one of which had been mentioned by C. A. Havill in his letter to the editor (ELECTRICAL ENGINEERING, page 1287, November 1936), were all noted in the printed paper but escaped [the author's] notice on the galley proof. They were communicated on August 17, 1936, to the editor who promised to correct them later. [**Editor's Note:** Complete corrections as supplied by the author were printed on the "errata" fly leaf of the 1936 TRANSACTIONS in accordance with established practice.] In view of the fact that the correction has not yet appeared, they are here reported in order to save the readers some trouble. The corrections are as follows:

1. Page 877, equation 3: All the 9 dyads should be united by plus signs and the dyad $z_{ab}$**ik** should read $z_{ab}$**ij**.

2. Page 881, second column, line 10: The words "up" and "down" should read "down" and "up," respectively.

3. Page 881, equation 28$d$: All the double vertical lines should be single vertical lines to denote determinants and the $j$'s in front of each determinant should be $j^2$.

4. Page 882, equation 31: A dot should appear between each one of the impedance dyadics and the current vectors.

Rose's opinion regarding the covariancy and the contravariancy of the impedance and the admittance, though correct, does not apply to the first paper, because the unit vectors used therein are all orthogonal and there is no distinction between covariant and contravariant measure-numbers. Hence the indices used therein have been lower ones even in case of the admittance. Further, as shown in the author's second paper and concurred to by J. Slepian in his discussion there are covariant and contravariant measure-numbers of the same vector and measure-numbers of various degree of covariancy and contravariancy for the same dyadic. It would be better to say that both the impedance and the admittance dyadic can be expressed in one of the four forms as shown by equation 52, page 1362.

The author wants to thank K. L. Wildes for giving the new method such a fair trial in teaching it to his students. At present the author must admit that the technique

of solving actual problems by such a method has not yet reached its best possible stage. Undoubtedly if more professors can be induced to teach the method to their students, the required technique would be improved rapidly.

As regards the merits of the present method when compared with that of symmetrical components in solving actual problems, a good deal depends on the background of the user and the unbalancing condition of the system. The author has made a side-by-side calculation of several problems using both the present method and that of symmetrical components. The results speak very eloquently for the present method because it requires shorter and fewer equations besides less numerical and algebraic work. This does not mean that symmetrical components should be superseded by the present method. It simply shows that the present method is a general one, including the symmetrical components as a special transformation. In fact when machinery problems are studied from the present viewpoint, the Blondel 2-reaction theory will also come under the present scheme as a simple orthogonal transformation of co-ordinate system.

## A New Thermal Fuse for Network Protectors

**Discussion and author's closure of a paper by L. A. Nettleton published in the October 1936 issue, pages 1096–9, and presented for oral discussion at the protective devices session of the winter convention, New York, N. Y., January 27, 1937.**

**C. P. Xenis** (Consolidated Edison Company of New York, Inc., New York, N. Y.): The thermal fuse described by Mr. Nettleton incorporates an interesting principle in fuse design. The heat is generated at one point of the fuse assembly, and the circuit is interrupted at another. By properly selecting and proportioning the metals and alloys at these two points he has been able to obtain a very desirable current-time characteristic with minimum heat dissipation.

The author of the paper gives some data on 2 types of "all copper" network switch fuses, in comparison with corresponding data for the thermal fuse. In this connection it may be well to point out, that extensive investigations and tests on "all copper" fuses for use in network switches have resulted in designs which possess current-time characteristics far superior to those of "all copper" fuses used heretofore in connection with network switches. The small volume of copper fused when the circuit is interrupted makes it possible to successfully enclose such fuses in small individual fireproof enclosures which confine the arc and thus protect persons who may happen to be standing close to the fuse at the instant of blowing. This advantage, coupled with the relative simplicity and low cost of "all copper" fuses are points well worth considering in comparing with other types of construction.

Experience in the operation of distribution systems points definitely to the desirability of increased fuse protection wherever large amounts of equipment and cable insulation are liable to be in contact with the overheated conductors and arcs resulting from electrical failures. The thermal fuse, and other types of fuse designs which will adequately protect insulation from high copper temperatures and properly interrupt heavy short circuits constitute developments which will find several useful applications in energy distribution.

**F. E. Johnson, Jr.** (New Orleans Public Service, Inc., New Orleans, La.): I am glad to note that network protector fuses are now available which "follow through" the thermal-time curve of the transformer they are designed to protect. Attention was called to the need of such a fuse in connection with the discussion of a previous paper ("Developments in Network Systems," Brosnan and Kelly, AIEE TRANSACTIONS, July 1929, page 975) wherein the requirements of an ideal fuse were given. It was brought out at that time that the ideal fuse curve would lie just below, but parallel to, the safe thermal-time curve of the transformer. Figure 3 of the present paper indicates that the shape of the new fuse curve is practically ideal.

There are one or 2 points, however, which I believe warrant further discussion. The

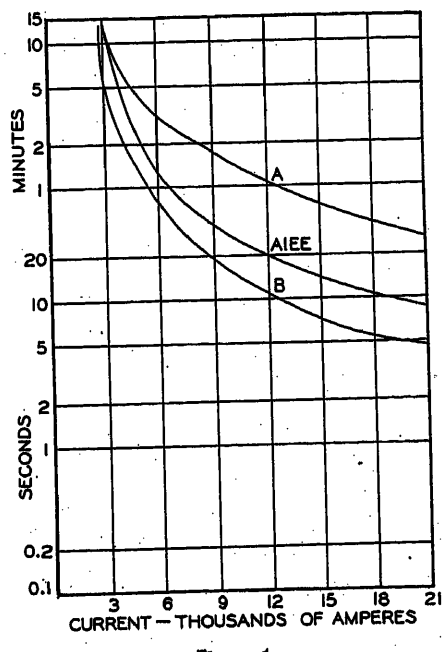

Figure 1

first of these concerns the permissible loading curve for a 500-kva network transformer, as shown in figure 3. Very little is definitely known about the life of transformers under short time overloads, and as a consequence the manufacturers have been somewhat hesitant about supplying curves which give allowable safe operating times for definite overloads. At the present time, however, the AIEE transformer subcommittee on electrical machinery has issued a proposed curve on short-time permissible overloads of network transformers 500 kva and smaller ("Proposed Transformer Standards," J. E. Clem, ELECTRICAL ENGINEERING, January 1937, page 32). This curve is to serve as a guide for intentional daily overloading (longer portion of curve) or emergency accidental short circuits (less than 5 minutes duration). For purposes of comparison, I have repeated curves *A* and *B* of figure 3 of the author's paper and have drawn in the proposed AIEE curve.

I have included the AIEE curve in order to draw attention to the need for standardization in applying the fuses to network transformer overload curves. In the present case, for instance, at 12,000 amperes the allowable overload time according to AIEE Standards is 20 seconds, while curve *A* gives a time of about 65 seconds, or over 3 times as long. Either the AIEE curve is very conservative or the operating company is willing to overload their transformers for higher final temperatures than was contemplated by the AIEE committee. Of course, in the present instance, the fuse would actually blow before the temperature set up by the AIEE curve was exceeded. In other applications, however, this might not be true. I would be interested in knowing what maximum copper temperatures were expected by Mr. Nettleton when curve *A* was drawn. If we apply the fuses on the basis of the AIEE curve in every instance, I believe that the transformer manufacturers would consider the action sufficiently conserative not to materially reduce the life of the transformer.

I would also like to ask Mr. Nettleton if fuses of this type have been developed for other sizes of network transformers.

**J. S. Parsons** (Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.): 1. The engineers of the Brooklyn Edison Company have, I feel, made a very important contribution to the art of fusing network protectors by developing the new low melting alloy fuse described by Mr. Nettleton. The Westinghouse company has been manufacturing fuses of this type for more than 2 years, first for the Brooklyn Edison Company and later for a considerable number of other companies operating low-votage a-c network systems.

2. The earlier fuses were built just as described by Mr. Nettleton and shown in figures 1 and 2 of his paper. Due primarily to manufacturing difficulties, however, some changes have since been made and others are now about to be made in this fuse.

3. As Mr. Nettleton has pointed out, the mounting ends of the fuse are bent at a slight angle from the mounting plane so as to prevent the possibility of the copper straps coming too close together or touching after the alloy has melted even though the mounting surfaces are poorly aligned. This construction puts the alloy slab under tension. To reduce this stress the copper strap portions of the fuse are now made of 2 or more copper laminations, depending upon the size of the fuse, instead of being made of a single heavy copper strap. The use of 4 laminations instead of a single copper strap reduces the stress on the alloy slab approximately 50 per cent. This reduces the possibility of the fuse opening mechanically due to the breaking of the bond between the copper and the alloy while in service. To guard against the possible mechanical opening of a fuse in service

because of the stress mentioned and those which may result from expansion and contraction of the protector, each fuse is given a tension test of 250 pounds. The failure rate under this test in production runs as high as 25 or 30 per cent failures due to the difficulty of getting a good bond between the copper and the cadmium-lead-tin eutectic alloy. Because of this we propose to change to the second alloy mentioned by Mr. Nettleton which is a eutectic mixture of lead and tin. It is very much easier to get a good bond between this alloy and the copper. A considerable number of these fuses have been built and tested at 1,000 pounds tension without a single case of failure. As a matter of interest, I might mention that one of these fuses, using the lead-tin eutectic alloy and having a minimum blowing current of about 2,800 amperes, was put under a continuous tensile stress of 500 pounds and tested for a week carrying 2,000 amperes for 8 hours and no current for 16 hours each day without being damaged. We are also considering the use of a $\frac{1}{16}$-inch diameter "nichrome" rivet through the alloy and copper to give an added factor of safety against mechanical failure.

4. The difficulties we have had with this low melting alloy fuse have all been mechanical and the changes mentioned should entirely eliminate them. The same current-time curve can be secured using the tin-lead eutectic alloy and the nichrome rivet as we have been getting with the cadmium-tin-lead eutectic alloy. The change in alloy will also have a negligible effect on the watts loss in the fuse. In this type of fuse only a small part of the total loss is in the alloy. For example, in the case of the fuse normally supplied on a 1,600-ampere protector only about 18 per cent of the loss is in the alloy. Mr. Nettleton has pointed out that the loss in this fuse is only about 25 per cent of that in the copper fuses the Brooklyn Edison Company previously used. The loss in the alloy fuse is also roughly only 50 per cent of the loss in the zinc fuse which we have supplied in the majority of our network protectors in the past. This fuse is also considerably shorter than the zinc fuse. Because of this, its improved current-time characteristics, and its decidedly lower loss we have used this low melting alloy fuse in our new type *CM*-22 heavy duty network protector. This fuse can also be used to replace the zinc or copper fuses supplied in most designs of our type *CM*-2 protector.

5. Since we adopted this fuse as standard on the type *CM*-22 protector I have been asked many times whether the gap which is left after the alloy melts is adequate to definitely open the circuit. We have naturally made a large number of interrupting tests on this type of fuse, and have successfully opened currents ranging in magnitude from the minimum blowing current of the fuse to 59,000 amperes root-mean-square with a recovery voltage across the blown fuse of approximately 208 volts. The normal gap between the outer end of the copper straps is $\frac{1}{8}$ inch, however, when the fuse blows on high values of current the magnetic forces bend the straps away from each other. After opening 59,000 amperes the gap between the outer end of the copper straps was about $\frac{3}{4}$ inch.

6. Mr. Nettleton mentions a critical current above which the fuse will blow in the bend of the copper strap. We found this critical point to be at 20,000 amperes root-mean-square on the fuse normally used on an 800-ampere protector, however, this critical point was not reached at 59,000 amperes root-mean-square on the fuse for a 1,600-ampere protector.

**J. A. Brooks** (Consolidated Edison Company of New York, Inc., New York, N. Y.): The last decade has seen a great increase in the extent of low-tension a-c networks. A great deal of time and effort has been expended in studying network requirements and in developing and improving network equipment. The automatic network protector has received a large share of this attention and has reached a high degree of perfection. In view of all this it is indeed surprising that so little has been accomplished toward improving the fuses used with network protectors.

As Mr. Nettleton stated in his paper, fuses were originally installed in series with network protectors to insure interrupting heavy back-feed currents from the network toward the primary feeder in cases where the network protector fails to trip. At that time the fuses were not regarded as essential for protecting the transformer against overloads and probably would not have been used at all if the network protector could have been trusted to operate correctly in every case of back-feed current.

The fuse originally used was the copper link fuse which was the only kind readily available. One disadvantage of this fuse is the high melting point which requires high losses in order to blow. At ordinary loads the losses are sufficiently high to reduce the rating of enclosed type network protectors. Another disadvantage is that the fuse operates too rapidly and often blows prematurely on short circuits in the network grid. On the other hand, it is possible to overheat and damage the transformer on currents that are not quite large enough to blow the fuse.

In recent years we are awakening to a realization of the dangerous overloading of equipment that may result from a partial shutdown of a network or that may occur when attempting to reenergize a dead network. Most improvements in network engineering are associated with actual operating experience. In the case of extremely rare but severe contingencies such as a partial or complete shutdown of a network area we cannot wait for experience to teach us the best procedure. Although we all hope to escape such a castastrophe as a network shutdown, it nevertheless is necessary to give careful consideration to plans for minimizing as far as possible the area affected, and for starting up the dead sections as promptly as possible. In view of the loss of capacity due to damage that may accompany a shutdown it is vitally important to be able to take advantage of available capacity up to the maximum permissible limit of loading.

The copper link fuse is a handicap to operation since its premature blowing on high currents may contribute toward shutting down networks and will hamper efforts to start up. At the same time the high minimum blowing current may permit the burning out of transformers and associated equipment. It would appear that "back up" protection is no longer the sole function of the fuse. The fuse is essential to provide overload protection and its characteristics should be such that it will only function as a last resort to prevent costly and embarrassing damage to equipment. When a satisfactory fuse is available to meet this requirement, a great advance will have been made. Such a fuse must be reasonably simple in construction, must have low losses, must be able to interrupt maximum currents, must be consistent in performance, must be stable under repeated heating and cooling, must be harmless to nearby workmen and must be available at a reasonable cost.

The use of a low melting point alloy in the fuse has inherent advantages in that the fuse operation becomes to a large extent dependent upon transformer and network-protector temperature. Starting cold at full load, for example, the fuse immediately takes a certain temperature rise above the network protector buses. The network-protector temperature rises more slowly, leveling off after 2 or 3 hours and after that increases at a very slow rate as the transformer and manhole warm up. A moderate overload that would blow the fuse in a few hours when the transformer and protector are already hot might require from one to 2 days when starting cold. On larger overloads the fuse blows without waiting for the other equipment to warm up but the time of operation will vary considerably according to the initial temperature of the equipment. In other words this type of fuse takes all possible advantage of any additional overload capacity that may be available.

The fuse described in Mr. Nettleton's paper meets most of the desirable requirements for a network protector fuse. Further development along this line may produce a fuse which comes even closer to meeting all the requirements.

**L. A. Nettleton:** The AIEE time-current curve for transformers, referred to by F. E. Johnson, Jr., shows the maximum duration of overloads that can be permitted without reducing the normal expected life. Curve *A* is based upon winding temperatures ranging from 125 degrees centigrade for 10 minutes up to 180 degrees centigrade for 25 seconds which will cause some deterioration and will probably shorten the life of the transformer to some extent.

The fuse must protect not only the transformer but also the network protector and connected cableleads. The network protector and leads have less thermal capacity than the transformer and may overheat first on overloads. The new fuse operates in sufficiently short time to be sure of protecting the network protector and leads in addition to the transformer.

Low losses are important for fuses used with enclosed network protectors, but where the protectors are not enclosed the losses are unimportant. Copper fuses require high losses to attain the necessary high fusing temperature. A design of copper fuse having a suitable time temperature characteristic, as mentioned by C. P. Xenis, should be satisfactory for use with non-enclosed protectors.

There is a wide variation in the permis-

sible overload that the transformer and associated equipment can withstand, depending upon the initial temperature. The fusible alloy used in the new fuse melts at such a low temperature (about 145 degrees centigrade) that the fuse operation is strongly influenced by the temperature of the network protector buses to which it is bolted. The fuse will, therefore, allow much greater overloading when the network protector is cold as compared to conditions where the protector is hot. Substitution of a metal or alloy having a higher melting temperature will reduce the ability of the fuse to distinguish between high and low initial temperatures of the equipment.

This fuse was developed for use with 500-kva network units which are used almost exclusively in Brooklyn. It can, however, be readily adapted to other ratings by changing the thickness of the copper straps.

This fuse meets most of the desired features enumerated by J. A. Brooks, the principal difficulty being the mechanical weakness discussed by J. S. Parsons, which results in an occasional fuse breaking open sometime after installation. However, it should be possible to correct this difficulty after further development.

## A New Service Restorer

**Discussion of a paper by E. F. Sixtus and W. R. Nodder published in the January 1937 issue, pages 180–2, and presented for oral discussion at the protective devices session of the winter convention, New York, N. Y., January 27, 1937.**

**D. C. Prince** (General Electric Company, Philadelphia, Pa.): The service restorer described by Messrs. Sixtus and Nodder should prove effective in improving service on lightly loaded lines to a considerable extent. It would appear that it gives somewhat the same performance as a repeater fuse but, of course, has the advantage of being totally enclosed and consequently better protected from the weather. It has in common with the fuse a property of operating a total of only 3 or 4 times before it must be serviced, although at such service intervals the only expense may be that entailed in sending a line man to its location.

Both the "service restorer" and the repeater fuse are open to the objection that they represent an unknown hazard to service. When they are first installed, or immediately after having been serviced, they can ordinarily be depended upon to open and reclose in the event of a temporary fault. However, after any storm there will immediately be a question as to the condition of all such devices; how many will have operated, how many will have operated more than once, which installations require immediate attention, and which require no attention at all. For these reasons, it seems as though the specifications outlined in the 7 points of the paper should be amplified somewhat, as:

8. The device after having reclosed any number of times short of the complete cycle to lock out should reset itself in a relatively short time to its original condition.

9. In the event of a persisting fault, the device should lock out after the complete cycle of trips and reclosures and then require manual reclosure after the fault has been removed.

10. The device should require no servicing until after lock out caused by a persisting fault and then it should require only manual reclosing after the cause of the fault has been removed; or in case of no lock out if should require servicing only at infrequent intervals, such as 6 months to a year.

On oil circuit breakers immediate reclosure serves a very useful purpose because from 75 per cent to 90 per cent of faults are of the nonpersisting type and are cleared after a single trip and reclosure. On the small service restorer, or oil circuit recloser, this feature is not so important, providing the reclosing time is relatively short, in fact a small time delay may often be beneficial.

Specification number 6 is not universally applicable. A very large fraction of all distribution lines serves single phase lighting and motor circuits. For such service, single-pole devices in the single-phase branches afford adequate protection. A triple-pole device in the 3-phase line would, in case of a persisting fault, unnecessarily interrupt service on some of the single-phase branches not in trouble.

In designing the *FP*-19 recloser, the possibilities of spring and weight operation as well as local battery were considered. As pointed out, the use of short circuit current is obviously the most attractive, but was discarded by the authors because they saw no way of securing a low enough trip current. The recloser, however, does operate at a sufficiently low tripping current without either the complication or cost of the alternative arrangements. There are doubtless applications for which a 3-pole device is essential and in which the limitation of 3 or 4 operations only between servicing will not be a prohibitive objection, for which applications the "service restorer" should prove of value.

## Ultrahigh-Speed Reclosing of High-Voltage Transmission Lines

**Discussion and authors' closure of a paper by Philip Sporn and D. C. Prince published in the January 1937 issue, pages 81–90, and presented for oral discussion at the protective devices session of the winter convention, New York, N. Y., January 27, 1937.**

**I. W. Gross:** See discussion, page 1038.

**T. G. LeClair** (Commonwealth Edison Company, Chicago, Ill.): The paper by Messrs. Sporn and Prince is very timely, because it describes a new and important step in the art of furnishing greater reliability of service for transmission systems. The practical development of 6-cycle circuit breakers and one-cycle relays has made possible this forward step, the prevention of service interruptions on a single-circuit, high-voltage transmission line. The laboratory and field tests indicate that the reclosing mechanism is satisfactory and that the new device can be expected to have a number of applications.

It is not possible, and the authors have not attempted to make a general statement that reclosing circuit breakers could be used to prevent service interruptions on all single-circuit transmission lines. It is indicated that, with reasonable development, commercial circuit breakers can be made which will reclose within the minimum time allowable to prevent undue risk of restriking an arc on the transmission line. The question of whether or not this time will be short enough to prevent service interruption is a function of the system conditions rather than a function of the characteristics of the relays and circuit breakers. To know whether this principle can be applied, the important question is whether or not during the momentary interruption of the circuit the rate of acceleration of equipment at the sending end of the line and the rate of deceleration at the receiving end of the line will be too rapid to avoid instability.

On a system such as the one where the tests were made, the interconnection is between 2 large generating systems, each with a capacity of over 1,000,000 kva. In this case the inertia in each of the 2 systems is such that the frequency of neither system will drift rapidly at the moment the interconnection is broken. Therefore, the chances of successful reclosure are appreciably greater than they would be if the 2 systems were only $^1/_{10}$ as large with the same power flow through the circuit under test.

An interesting example of the possibility of reclosing circuit breakers is the 132-kv interconnection from Powerton station to Waukegan station in Illinois. One circuit of this interconnection is supplied by a single, 50,000-kw generator and carries a load of 50,000 kw distributed over more than 200 miles of circuit. A set of reclosing circuit breakers between the Powerton generator and the next adjacent load would be useless to prevent service interruptions, because the Powerton genertor would accelerate too rapidly when its full load was suddenly interrupted. However, a reclosing circuit breaker near the Waukegan end of the long transmission system could be used very effectively to prevent service interruption, because the load on the circuit between Powerton and Waukegon is great enough to prevent the Powerton and Waukegan systems from drifting apart rapidly.

This reclosing scheme could also be used very effectively to improve service to relatively small important loads carried from a high-voltage interconnected system. By the use of reclosing circuit breakers on a branch line with a single circuit, it should be possible to maintain a standard of service very nearly equal to that to be obtained on the orthodox double-circuit tower line.

**A. C. Schwager** (Pacific Electric Mfg. Corporation, San Francisco, Calif.): The authors are to be commended for contributing valuable information on a subject which promises to become of major importance in the improvement of continuity to service on transmission lines. The field as well as laboratory tests reported show that a large percentage of arc-overs on lines can be cleared by means of an extremely short service interruption.

It is interesting to note that the special reclosing mechanism is of the spring actu-

ated type, the authors apparently realizing that the conventional solenoid control is not feasible for application to such high speeds.

The restriction of the opening stroke to 8 inches appears to be a serious limitation to the general application of this mechanism.

Although the arc length during all the tests was of 7 inches or less cases will have to be anticipated where longer arc lengths must be expected. Reference is made to an AIEE paper by Messrs. Spurck and Skeet, "Circuit Breaker Field Tests on Standard and Oil-Blast Explosion-Chamber Oil Circuit Breakers," figure 9 of which shows that on a different 132-kv system arc lengths of 14.5 inches were recorded. It would be interesting to know if reclosing in this case could be accomplished without a radical change in mechanism design and without increase in the reclosing time.

The company with which the writer is associated has also designed and built a motor-operated spring-actuated mechanism suitable for ultrahigh-speed reclosing. This mechanism gives full initial opening stroke to the blades with a de-energized interval of 17 cycles. A 69-kv breaker equipped with this mechanism is in service since February 1936, a 115-kv installation having been recently completed. A paper is being prepared by the writer giving detail information on construction and field experience.

**R. D. Evans** (Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.): 1. The authors are to be commended for their work in obtaining operating experience on high-speed reclosing breakers. Of particular value is the data on the time necessary to avoid fault re-establishment upon circuit re-energization.

2. The problem of maintaining service continuity on systems with synchronous machines (or the stability problem) has been

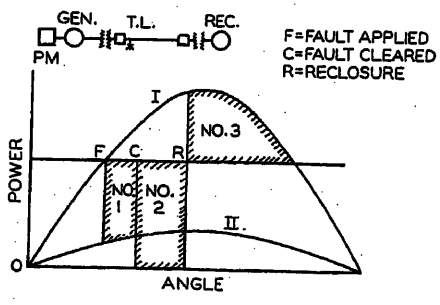

**Figure 1. Power-angle diagram for reclosure, single-circuit case**

I—Curve for normal circuit
II—Curve for fault condition (2L-G)
For stability, areas (1 plus 2) < area 3

one of particular interest to me. A number of years ago some of my associates and I proposed the high-speed clearing of faults as a means of improving system stability. This proposal was followed almost immediately by one to use high-speed reclosure to improve stability. U.S. Patent 1,899,613, filed in 1929, employed high-speed reclosure at high voltage and a superposed frequency relay scheme to obtain high-speed simultaneously opening of circuit breakers. Considerable development has been required to bring these schemes to commercial use, and the high-speed fault clearing scheme being simpler came into use first. As a part of the general investigation of high-speed reclosure, work was carried out by Messrs. Griscom and Torok, as mentioned by the authors, in order to determine the de-energizing time necessary to prevent re-establishing the arc.

3. The paper does not discuss the stability features of the problem, that is, the

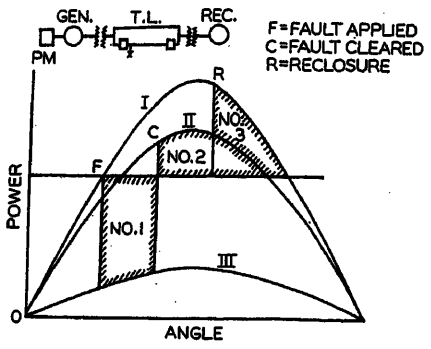

**Figure 2. Power-angle diagram for reclosure, 2-circuit case**

I—Curve for 2 lines (normal)
II—Curve for one line (normal)
III—Curve for fault (2L-G)
For stability, area 1 < (areas 2 plus 3)

relation between the fault clearing and reclosure time to the amount of load that can be carried with stability. For this reason 2 illustrations have been prepared to discuss this phase of the problem in general terms. Figure 1 assumes a simple system in which power is transmitted from a generator over a single-circuit transmission line. The line is assumed to be subjected to a fault requiring isolation to suppress the arc. This is followed by reclosure to improve stability. The power-angle diagrams for the different conditions from the application of the fault to the subsequent reclosure are shown in the figure. Stability will be secured if the sum of areas number 1 and number 2 is less than area number 3. It is of some interest to point out that for 2 breakers with equal reclosing time without arc re-establishment, the one with the slower fault clearing time will be more favorable from the stability standpoint.

4. High-speed reclosure is also applicable to improve the stability of two-circuit transmission systems illustrated in figure 2. The power-angle diagrams for this case are somewhat different than for the single-circuit case of figure 1. In this case stability will be secured if area number 1 is less than the sum of areas number 2 and number 3. The size of area number 3 is a measure of the advantage secured by high-speed reclosure.

5. In connection with the application of reclosing breakers to either single-circuit or double-circuit systems, considerable improvement in stability will be secured if the sending-end machines are not greatly unloaded during the fault condition. Hence, artificial means for loading the sending end may prove valuable in combination with reclosing circuit breakers. Such artificial loading may be obtained by the "stabilizing" resistors, the use of neutral resistors, and other measures. Such a combination may avoid the necessity for unduly high speed in reclosing breakers and make possible the use of simpler tripping mechanism than would be feasible otherwise, thus reducing first cost and maintenance expense which are obviously desirable.

**V. M. Marquis** (American Gas and Electric Company, New York, N. Y.): Ultrahigh-speed reclosing of high-voltage transmission lines places the transmission system, and especially important tie lines between systems or sections of systems, in an entirely new light. It is only necessary to consider that ultrahigh-speed reclosing allows a line to trip out and reclose without losing synchronism between systems in order to realize the field which is opened up by the development of this equipment.

Many important developments have been made for combating lightning on transmission lines but all cases of trouble do not result from lightning, so that even if the lightning problem were solved, there would still be cases where transmission line faults would cause interruptions. Ultrahigh-speed reclosing, however, offers a definite possibility for insuring substantially continuous service of lines on which it is applied.

After the successful results with the ultrahigh-speed reclosing on the Fort Wayne-Marion line, described in the paper, studies were made with reference to the application of ultrahigh-speed reclosing to the Twin Branch-Fort Wayne line. Figure 3 shows this line which is part of the Ohio-Indiana high-voltage transmission system of the American Gas and Electric Company. This line between Howard and Twin Branch forms a very important tie and it is essential that its continuity of service be maintained. The large interconnected system, of which the section shown is a part, normally has some 7,000,000 kilowatts of capacity in service; of this, approximately 2,000,000 kw of capacity is west of Fort Wayne and 5,000,000 east of Fort Wayne.

At the time this study was started, this double-circuit line had only one circuit installed, and calculations were made to determine the speed of reclosing required for various amounts of load transmitted over this tie line. With the present single circuit, it is possible to carry about 100,000 kilowatts over this line and maintain proper voltage. The calculations indicated that it would be possible to deliver this amount of power if the total time of separation was kept to about 30 cycles. The calculated curve showed that this amount of power could be increased to approximately 140,000 kw for a 12-cycle total time of separation and to approximately 160,000 kw for a 6-cycle total time of separation.

In general it can be stated that for single-circuit operation, the amount of power that can be carried through a disturbance with rapid reclosure of the faulted circuit increases appreciably as the time of separation between the systems is decreased. This, of course, indicates the desirability of keeping the fault and reclosing time to a minimum even though the systems are large.

Since these first studies were made, it has

been decided to double-circuit this line and further checks were made to determine the advisability of ultrahigh-speed reclosing for both circuits. This showed that, with double-circuit operation, rapid reclosing for faults on one of the circuits would make it possible to transmit appreciably more power by reclosing the faulted circuit than if this circuit were not reclosed. In general, it can be said that the gain to be realized by successful reclosing of the faulted circuit increases with the increase in the distances between high-tension bussing stations and also with the increase in size of the 2 systems to be interconnected. In this case, however, it is obvious that the speed of reclosing of the second circuit is not critical. For double-circuit faults, rapid reclosing on both circuits is particularly advantageous and in general to obtain full benefits in connection with a double-circuit line, both circuits should have ultrahigh-speed reclosing.

There still remains one unknown in connection with reclosing a faulted transmission circuit and that is the question whether the arc would be sufficiently deionized that it will not restrike when the circuit is reclosed. This has to be considered in connection with reclosing the faulted circuit of a double-circuit line, for if the faulted circuit is reclosed and the arc restrikes when reclosed, then the system would be disturbed more than if this circuit had not been reclosed.

In the case cited, the systems on either side of the tie line in question are very large and have correspondingly high inertias. Cases involving a single hydro plant connected to a large steam system or even a small steam plant or system connected to a larger system will require much faster reclosing. However, even in this case there is a possibility that upon reclosing, the smaller plant or system will pull into step. Each case should, of course, be carefully analyzed to definitely determine the gain to be realized in using ultrahigh-speed reclosing. This analysis should not only determine if the systems will lose synchronism but also determine, if synchronism is lost, whether synchronism can be quickly regained without undue disturbance to the systems if reclosed—that is, there may be some cases where there is a definite advantage in reclosing even though synchronism is momentarily lost.

Ultrahigh-speed reclosing seems to offer such large gains that its application should be seriously considered on all high-tension lines where their continuity of service is a major factor in the operation of the system. There are obviously still some unknown quantities in connection with the application of ultrahigh-speed reclosing. It is hoped that others will help in thoroughly investigating their unknowns to make this new tool in the art of transmission a thoroughly reliable one.

**J. B. MacNeill** (Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.): High-speed reclosing is a natural corollary to high-speed circuit interruption. The reduced arc energy and depreciation of contacts and oil associated with modern interrupters makes it feasible to restore service without waiting for the circuit breaker to vent gases and establish dielectric strength.

To illustrate the growth of reclosing service, reference is made to data presented to the electrical equipment committee of the Edison Electric Institute for the year 1935

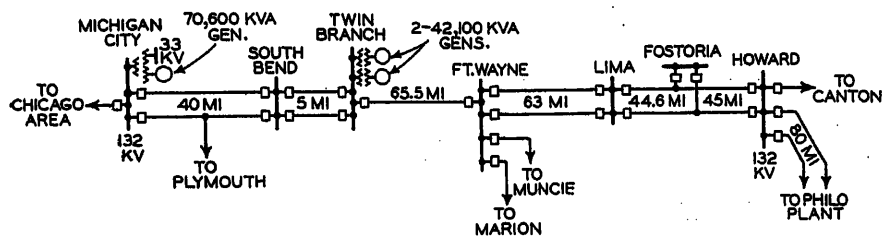

Figure 3

covering 3,680 reclosing operations on all voltage classes from 2.3 kv to 110 kv. First reclosure was successful in 78 per cent of these cases, subsequent reclosure was successful in 10 per cent, and there remained 12 per cent of lockouts.

The paper by Griscom and Torok in the *Electric Journal* for May 1933 gave at this relatively early date a good approximation of the limitations imposed by deionization of the arc stream upon the possible speed of reclosure. Other contributions have since been made, and there appeared in ELECTRICAL ENGINEERING for October 1936 an interesting paper by Pearce, Powers, Stewart, and Heberlein covering the application of carrier relaying and rapid reclosing of a 110-kv line which acted both as a trunk interconnection and a load feeder. The paper now under discussion by Messrs. Sporn and Prince adds considerably to our knowledge of the subject.

The method and apparatus used for securing high-speed reclosure by the authors is novel. By means of a very powerful duplex operating mechanism they were able to get reclosure in 16 cycles from the time the tripping impulse was given; but to secure this time the breaker was permitted to open only 8 inches. This is only a fraction of the normal travel of a circuit breaker for 138-kv service, and it would seem encroaches definitely on factors of safety for circuit interruption. There is no assurance that all types of short circuit can be ruptured at this voltage and under all operating conditions with an 8-inch stroke.

The writers summarize by stating:

"If reclosing is to be at a long enough interval to give little probability of a restrike, voltage must not be applied to the line for about 12 cycles after the arc has been interrupted. With an 8-cycle breaker this gives 20 cycles for the over-all reclosure time. At the other extreme, reclosure after 2½ cycles will be successful sometimes. If a flashover is caused by multiple lightning strokes, some reclosures longer than 20 cycles over-all may well be followed by restriking. For that reason the final limits will not have been determined until after a considerable period of experience under actual service conditions."

Since this appears to be the case, then we should investigate carefully to see if the necessary reclosing functions cannot be obtained at moderate expense and with relatively simple mechanisms. Admittedly the mechanism used by the authors is very expensive and complicated and will possibly be difficult to maintain in satisfactory operating condition.

As an illustration of what can be accomplished by relatively simple means, figure 4 shows the operating mechanism on a 3-pole 115-kv circuit breaker of large capacity normally operated from a battery, but on a recent job furnished with a "rectox" built into the mechanism for operation from an a-c source. This mechanism is practically a standard solenoid of simple and sturdy construction arranged with some features to adapt it to high-speed reclosure, such as improved relationships between the power requirements of the breaker and the physical efforts of the solenoid at different points of its stroke.

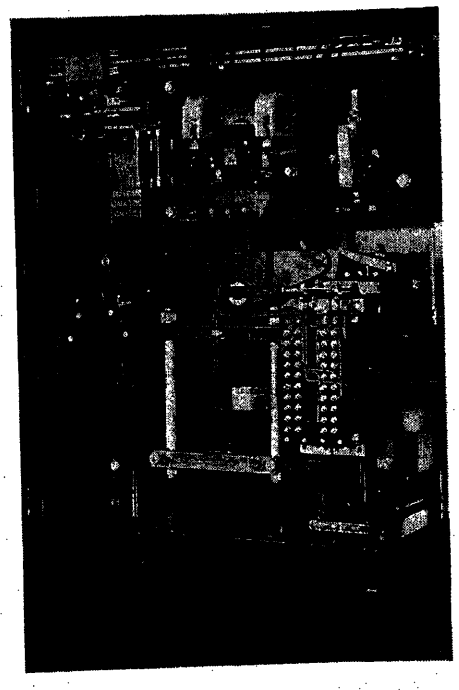

Figure 4

Figure 5 shows an oscillogram of the operation of this breaker consisting of tripping followed by reclosure, in which the breaker is permitted to reach a travel of 21 inches, or 75 per cent of its total stroke before reversing the downward movement of the contacts. This length of stroke obviously gives a large factor of safety for circuit interruption, and had this distance been encroached on to speed up the reclosing action, the time for opening and reclosing could have been materially reduced.

Of course, the high-voltage apparatus presents a more difficult problem than low

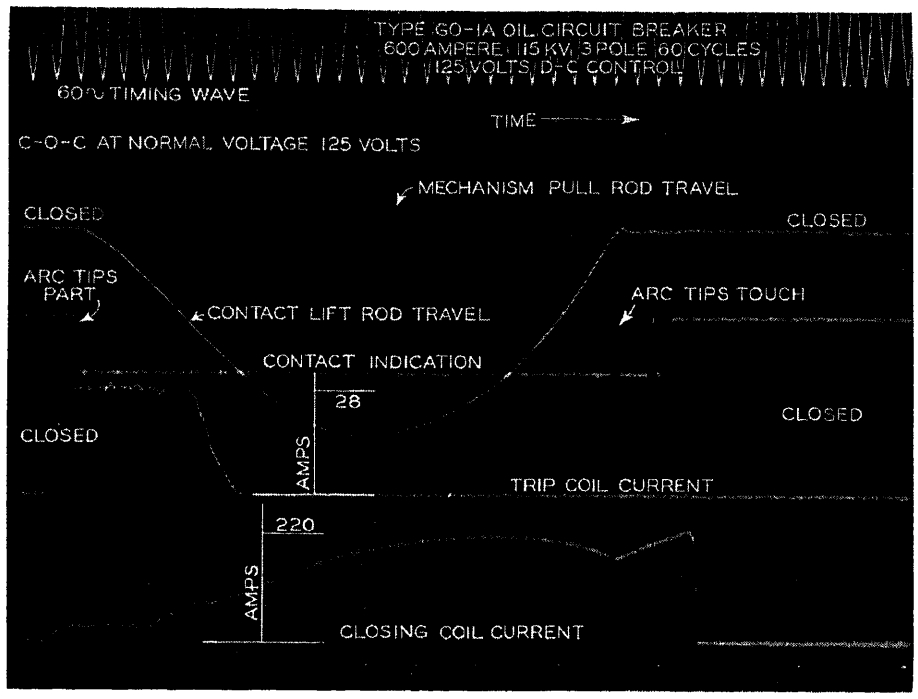

**Figure 5**

voltage, and the elapsed time for such voltages as 230 kv will be greater than on smaller devices. Considering, however, the nature of the elements involved and the necessity for having assurance of original fault deionization before reclosure is made, it seems wise to conclude that practically all reclosing requirements—at least at moderate voltages—can be taken care of with relatively simple and inexpensive mechanisms.

In discussing this subject it is well to remember that a reclosing time consists of two parts: first, the time to open the short circuit; and, second, the time to reclose the breaker. For a given total time consumed by the reclosing cycle, it is very desirable that a minimum amount be taken up by circuit rupture, leaving as large a share as possible available for reclosure. This division of the time will insure better circuit breaker action, less depreciation of line material and circuit breaker parts, and increased assurance that the original short will have been deionized at the time reclosure is complete.

**E. E. George** (Tennessee Electric Power Company, Chattanooga): From the standpoint of transmission companies, Sporn and Prince and their associates have apparently made one of the most important developments presented to the Institute in several years. Rapid reclosing of tie lines does not necessarily mean that one line will do all of the work of 2 lines heretofore, but it should mean that one line will do most of the work most of the time. The authors have actually accomplished and put in practice what some of us have only talked about. Differences of opinion about details should not detract from the luster of an outstanding accomplishment, so it may perhaps be pardonable to discuss the term "ultrahigh-speed" as applied to reclosing. The following definitions have been taken from the dictionary. "Ultra" means beyond familiar limits and indicates ordinarily something of microscopic or astronomical dimensions.

"Immediate" means consecutive, "instantaneous" means as fast as possible—with no intentional delay. This is why some of us have always preferred the name "instantaneous reclosing." Regardless of what name is used the principle will still be readily accepted by operating men.

In conclusion, it would seem that the authors have perhaps been too modest and too conservative in describing the utility and general application of this new development.

**Philip Sporn** and **D. C. Prince:** The authors are highly gratified by the reception this paper has received. All the discussion has been of such constructive character as to add materially to the value of the paper.

Mr. LeClair points out that longer reclosing time is available between large systems because of their high inertia, while smaller systems would generally lose synchronism.

Mr. Marquis develops this point further, showing actual case studies and indicating possible advantages of ultrahigh-speed reclosure even with double circuits and even in some cases though synchronism is lost momentarily. Mr. Evans has contributed stability diagrams indicating an advantage in stability from slower fault clearing while Mr. MacNeill indicates the desirability of minimum time in circuit interruption. This difference of opinion is only superficial, since the minimum time between circuit interruption and reclosure is fixed by nature rather than the over-all time of Mr. Evans's hypothesis.

Both Messrs. MacNeill and Schwager comment on the breaker contact travel and the size and complexity of the reclosing mechanism. The contact travel required is a function of the arc-extinction device. In this case 8 inches proved quite adequate for 138 kv. Had the breaker failed to clear in 8 inches the second mechanism would have opened it full stroke. Since mechanical stresses go up as the square of velocity, the minimum stroke was preferred for mechanical reasons.

The complexity of the mechanism was due to its many features of adjustability. Now that the ultimate requirements are known, much smaller departures from standard mechanisms are required.

Mr. Gross points out the possibilities of simplification of line construction by the use of ultrahigh-speed reclosure. The extent to which such simplifications will prove practical must be determined by field experience which everyone will watch with great interest.

Mr. George very modestly refrained from mentioning the important part which he and Mr. Logan have played in the development of "instantaneous" reclosure. They have shown what it is possible to do with standard mechanisms. It was the purpose of the authors in undertaking the development covered by the present paper to study and find out how much more is possible if mechanism and circuit limitations are removed, leaving only physical phenomena limitations to indicate what may or may not be done. The results, I believe, have indicated that speeds of reclosing much faster than any heretofore contemplated are possible. From this point the economics of reclosing must be developed by further system study and particularly by field experience, the final proving ground of all developments.

## The Control Gap for Lightning Protection

**Discussion and authors' closure of a paper by Ralph Higgins and H. L. Rorden published in the September 1936 issue, pages 1029–34, and presented for oral discussion at the protective devices session of the winter convention, New York, N. Y., January 27, 1937.**

**K. B. McEachron** (General Electric Company, Pittsfield, Mass.): As pointed out by the authors, the sphere gap (if used within proper limitations of spacing) gives a substantially uniform field and therefore has a relatively flat volt-time spark-over curve, while the rod gap, because of its nonuniform field has a volt-time curve which rises rapidly as the time to spark-over is decreased. As a protective device the sphere gap has excellent impulse characteristics and might have been widely used if it did not have 3 inherent disadvantages which are rather serious:

1. The wet 60-cycle spark-over is from 1/2 to 1/3 of the dry value which means that if a level of 3.5 (Lewis and Foust have shown that 13 per cent of switching surges exceed 3.5 times normal voltages: see "Lightning Investigation on Transmission Lines—II," W. W. Lewis and C. M. Foust. AIEE TRANSACTIONS, volume 50, December 1931, page 1139) times normal is established as the lowest permissible spark-over value for switching surges the sphere gap could not be expected to hold the impulse voltages to less than from 7 to 10.5 times normal, which would not be suitable since the present impulse test gap for transformers rated above 25 kv is between 6 and 7 times normal.

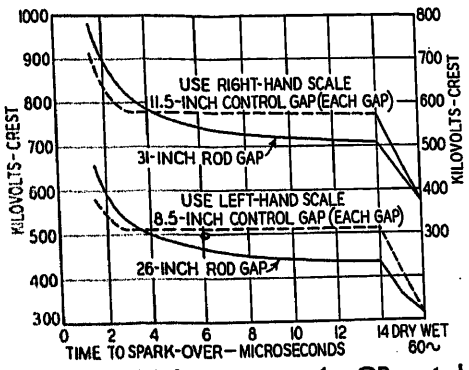

**Figure 1. Volt-time curves for OB control gaps (data from figure 5), also rod gaps spaced 26 and 31 inches (positive values plotted)**

2. The sphere gap on account of its uniform field is sensitive to any nearby conducting objects, and this limitation combined with the size of the sphere, especially for high-voltage systems, introduces a serious problem in the space required for the gap.

3. The sphere gap is not self quenching, i.e., will not stop power follow, resulting in the possibility of damage to the spheres and the probability of an outage.

The rod gap, on the other hand has much poorer impulse characteristics, but is much less affected by rain. The wet power-frequency spark potential of rod gaps is in general only 10 to 15 per cent lower than the dry value. Thus, for a spark-over time of 2 microseconds the rod gap will have a wet 60-cycle-to-impulse ratio of a little less than 2. For a 31-inch gap the ratio is 1.86, which means that if the rod gap is set so as to have a wet spark-over of 3.5 times normal line-to-ground potential, the voltage at 2 microseconds spark-over time would be 6.6 times normal which is still much too high for safe operation—leaving no margin or factor of safety between the demonstrated strength of the transformer and the potential allowed by the gap. For still higher rates of rise the situation would be still worse, since the potential allowed by the gap would be correspondingly increased.

Following the work of Austin, the authors have attempted to incorporate in the control gaps the impulse characteristics of the sphere gap and the lack of sensitiveness of the rod gap to rain conditions. It seems quite obvious that any scheme which secures the impulse advantages of the sphere gap through control of flux, which is the means the sphere gap itself uses, will be subject to the same wet and dry spark-over values if the same impulse characteristics are secured.

Comparing the wet 60-cycle and 2-microsecond flashover values of the 8.5-inch, and 11.5-inch control gaps as given in figure 5 of the paper a ratio of 1.73 and 1.70 is obtained which is only slightly less than a rod gap having the same 60-cycle spark-over value. These control gap settings apparently correspond to gaps rated 110 kv and 132 kv. I have reproduced the corresponding volt-time curves as figure 1 of this discussion. For times greater than about 4 microseconds the rod gap offers better protection. For times between 1 1/2 microseconds and 4 microseconds the data shows the control gap a maximum of 9 per cent below the rod gap. For times shorter than one microsecond more data are needed, since the shape of the curves as drawn do not indicate whether the curves might cross again or not.

Lightning arresters whose spark potentials are not affected by the weather, can be designed for much closer protection than gaps because their spark potential need not be above switching transient levels. They can in general be expected to hold potentials to values ranging from 2.5 to 5 times normal depending upon rating and whether for grounded or ungrounded neutral operation.

When reading the paper I was somewhat puzzled by the statement appearing in the second paragraph in the right hand column of page 1030 relative to the term "flat volt-time characteristic being a misnomer." It seems to me the authors' statement would be true if volt-time curves were only taken through the use of overvoltage. However, volt-time curves may be taken on sphere gaps on the front of the wave in which case flat volt-time characteristic does have a definite meaning.

On page 1031 when concluding the discussion of the "principle of control gaps" the authors state that capacities large enough to control voltage distribution in all kinds of weather must be used. This is usually a rather difficult matter when all kinds of weather are included, and I am curious to know how the authors have accomplished their objective. I know of cases where melting ice has caused unbalance under conditions which appear to be somewhat similar to that used by the authors.

A question arises concerning figure 9 *A*, *B*, and *C* where full-wave spark-over times are given ranging from 20 to 28 microseconds. This time is about twice as long as we have experienced under average laboratory conditions, and the authors' comment on this point would be helpful to those working in this field, I am sure.

On page 1034, at the end of the second paragraph under figure 10, the statement that where "insulation levels are higher than that shown, and where lightning arresters are used in combination with the control gap, higher gap spacings may be used," seems to require some further clarification.

**V. M. Montsinger** (General Electric Company, Pittsfield, Mass.): I wish to discuss this paper partly from the standpoint of protecting transformers in service against lightning with a gap having a flat volt-time curve characteristic, and partly from the standpoint of testing transformers with both long and short waves whose voltage values are controlled by flashing over a gap having a volt-time characteristic similar to that for transformer windings.

We used to consider that a sphere gap had no time lag but we now know that for short time to flashover in the order of one microsecond or less, sphere gaps have time lag.

It is, of course, possible to construct a gap that has no time lag, i.e., the volt-time curve is flat all the way from 60 cycles back to approximately zero time. Such a gap for 132-kv line has been constructed of small metal disks mounted on a rod making use of known resistances and capacitances between disks to control the flux. As pointed out by Mr. McEachron in his discussion, it was found that unless the gap was kept dry, the low 60-cycle wet flashover

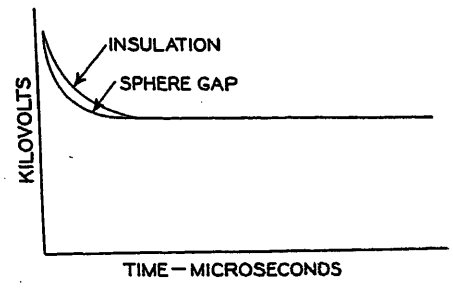

**Figure 2. Volt-time curves of sphere gaps and transformer insulation**

value required too great a spacing to properly protect against impulse voltages, although it gave considerably better protection for steep wave fronts than the control gap gives. This illustrates the point that when flux control is made use of, the low 60-cycle wet flashover makes it necessary to raise its impulse protective level up close to that of a plain rod gap. The difficulty in this particular case was overcome by enclosing the gap in the top porcelain of a 115-kv bushing to make it weatherproof: but, unfortunately, the gap was not self quenching which means that it probably would not protect the transformer if there were several strokes in rapid succession, since the gap would, no doubt, be destroyed on the first stroke if power current followed through.

If front-of-wave testing of transformers is ever standardized, it might be possible to construct a gap that has the same shape of volt-time curve as transformer insulation. Either such a gap must be developed or a general agreement must be reached on the correct kilovolt values to be applied for short times to flashover of whatever kind of gap is used to chop the wave off.

In fact a gap that is almost (but not quite) good enough for the purpose is already available. I mean the sphere gap.

Tests made on various thicknesses of barriers and with 25-, 50-, and 100-centimeter sphere gaps connected in parallel to control the kilovolts of long and steep-front waves show in all 3 cases that starting with the sphere gap to give the same kilovolts as the breakdown of the barrier on a full wave, then as the voltage is increased the sphere-gap spacing has to be slightly lengthened to keep it balanced with the breakdown of the insulation barrier. The lengthening of the gap continues and then as the time to flashover gets quite short the gap must be shortened. For very short times to flashover the gap length has to be decreased to, or even slightly less than, the spacing that corresponded to the full wave strength of the insulation.

Plotted on a volt-time curve basis the shapes of the 2 curves are as shown in figure 2. These curves mean, of course, that if a sphere gap were used with a constant spacing equal to the full-wave test kilovolts to control the voltage of both long- and short-impulse waves for testing transformers, the factor of safety (i.e., the difference between the breakdown strength and the tested value) would slightly increase as the time to flashover decreased, until the time got quite short and then it would again become the same as for the full wave test. In other words, there would be a band in which the spheres would provide an extra

safety factor during the test. It appears, therefore, that for front-of-wave testing at the present time sphere gaps could be used as a suitable test gap for transformers.

**J. R. North** (The Commonwealth & Southern Corporation, Jackson, Mich.): The control gap described in the paper by Messrs. Higgins and Rorden offers possibilities as a back-up protective device for use in the higher voltage classifications. However, some of its characteristics approximate a sphere gap and it does not have the ability to clear itself once arc-over occurs. These must be given consideration in its application.

The principal factors in the selection and application of a protective device such as a gap are:

1. The *maximum dynamic voltage* which may occur during fault conditions between the sound phases and ground.

2. The *ability of the protective device* to maintain an adequate protected level on a volt-time basis for both short time and long time intervals.

Considering the dynamic voltage limitations (item 1), studies of actual overvoltages occurring on transmission systems by the joint subcommittee on development and research—EEI and Bell system, as published in Engineering Report No. 30, have shown that the overvoltages arising from system operation are normally of the order of 2 to 5 times the normal voltage to neutral $E_n$. Therefore, it is generally conceded that a protective device should have a 60-cycle flashover or breakdown voltage under any weather conditions of at least $3^1/_2$ times normal and preferably higher.

An analysis of the performance of the control gap, based upon the characteristics as given in the paper, indicates that with gap settings as would probably be used, the 60-cycle *dry* flashover voltages are above the normal maximum dynamic voltages which may be expected. However, the 60-cycle wet flashover voltages are rather low.

For example, consider the control gap on the basis of giving protection comparable to that of a modern full-voltage arrester and assume 2 systems, one using 46-kv equipment and the other using 161-kv equipment. Figures 3 and 4, of this discussion show the volt-time characteristics of the lightning arrester and the control gap for these conditions. The table I summarizes some of the values shown on these sketches.

**Table 1**

| Apparent Voltage (Kv) | Short Time: Lightning Arrester Breakdown (Crest Kv) | Short Time: Control Gap Setting (Inches) | Short Time: Control Gap Dry FO | Short Time: Control Gap Wet FO | Short Time: Control Gap Wet FO | Long Time: Lightning Arrester IZ at 5,000 (Crest Kv) | Long Time: Control Gap Setting (Inches) | Long Time: Control Gap Dry FO | Long Time: Control Gap Wet FO | Long Time: Control Gap Wet FO |
|---|---|---|---|---|---|---|---|---|---|---|
| 46 | 170 | *4 | 145 | 85 | $2.3E_n$ | 200 | $5^1/_2$ | 175 | 110 | $2.9E_n$ |
| 161 | 570 | *8 | 440 | 355 | $2.7E_n$ | 705 | 12 | 570 | 470 | $3.6E_n$ |

* Lowest possible setting with this gap

It will be noted that in the 46-kv classification, the control gap would be given a setting of $5^1/_2$ inches to be equivalent to the voltage across the arrester during discharge and that with this setting the wet flashover voltage of the gap would be approximately 2.9 times the normal voltage to neutral $E_n$. With the control gap set at 4 inches to give performance equivalent to the breakdown of the arrester gap, the wet flashover voltage would be only 2.3 times $E_n$. Similar values are obtained for the 161-kv classification. There is a possibility that these low values of wet flashover voltage might result in undesirable outages due to flashover of the gap caused by dynamic overvoltages. It may, therefore, be concluded that the control gap must be set above the protected level afforded by a modern full-voltage-rated arrester in order to eliminate any possibility of flashover due to dynamic overvoltages. The control gap thus acts chiefly as a back-up protective device.

We would like to inquire of the authors as to the effect on the control gap structure of high values of power follow current.

**A. C. Monteith** (Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.): Considerable work has been done to get the results of the different manufacturers' laboratories into agreement on the minimum impulse test on line insulators and rod gaps. Apparently there is still considerable disagreement for the shorter time lags as rod-gap data for a 138-kv installation at 860-kv give, from the author's data a time lag of 3.3 microseconds and for the Westinghouse data 1.8 microseconds. This difference is significant because it is largely in this zone that the authors can claim superiority of the control gap over the rod gap. It is true that the authors have done considerable work on a direct comparison of rod gaps with the control gap at the minimum impulse flashover and some at $1^1/_2$ microseconds but it is going to be necessary to have the data from the several laboratories on a common basis to be able to co-ordinate the complete substation apparatus.

To those who consider the lightning arrester as the best form of protection (the modern arrester giving protection to from 50,000 to 100,000 amperes without causing an outage) the control gap still offers the same limitations as the rod gap for the protection of transformers.

On solidly grounded systems in the higher-voltage classes the De-ion Protector offers a device that gives protection with the same limitations as the rod gap or control gap but will prevent an outage when it is called upon to operate. Although only test results with positive waves are shown it has very favorable characteristics with negative waves. A band is shown to give some indication of the variation in protection due to variation in particular designs.

These several points are illustrated in the attached figure. The maximum impulse test level on modern transformers is taken from actual tests made by Vogel and Bellaschi.

**I. W. Gross** (American Gas and Electric Company, New York, N. Y.): These 2 papers center around the problem of protection. The gap paper considers protection to apparatus; the ultrahigh-speed breaker the more comprehensive problem—protection of service. This latter objective requires, first, that interruption of power flow in a circuit should not exceed $^1/_4$ to $^1/_2$ second, as pointed out by Messrs. Sporn and Prince, and second, that the supply equipment such as generators, transformers, etc., be protected against failure. A most economical solution to this entire problem in many cases may be a protective gap of some form in combination with the ultra-high-speed breaker described by Messrs. Sporn and Prince.

The protective gap, that is, the so-called standard rod gap, has in the past had 2 weaknesses. First, at spacings generally proposed on the basis of impulse tests recommended for transformers, it was recognized the gap would not limit the volt-

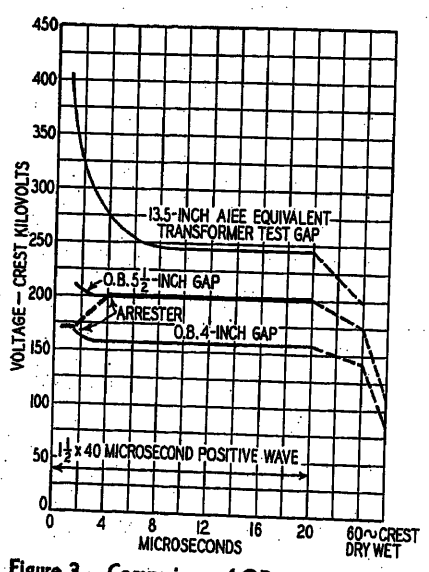

**Figure 3. Comparison of OB control gap and lightning arrester, 46-kv class**

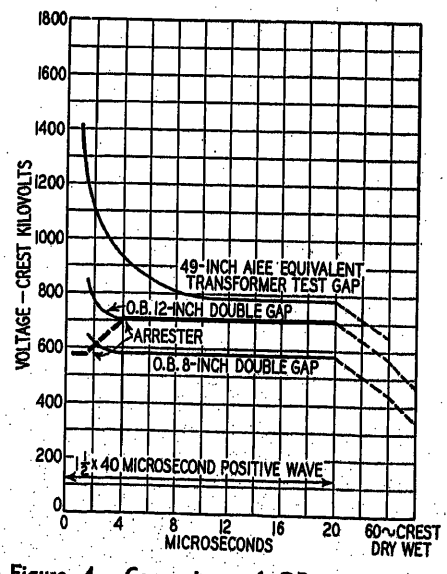

**Figure 4. Comparison of OB control gap and lightning arrester, 161-kv class**

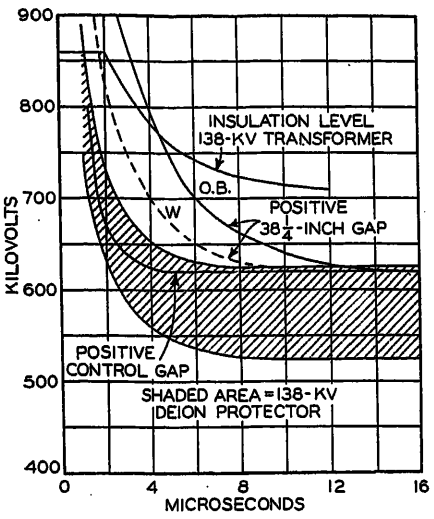

**Figure 5**

age to a value below the safe impulse strength of standard insulation, on steep wave fronts. On the other hand, if the spacing of the protective gap was reduced to supply protection for steep front waves, an increase in line outages might occur as a result of normal switching surges. In any event, if the protective gap flashed over, whatever its setting, a circuit outage was sure to follow. With the ultrahigh-speed reclosing breaker, however, it should be possible to greatly reduce, if not entirely eliminate line outages due to gap operation.

The control gap described by Messrs. Higgins and Rorden, appears from the data to have considerably better protective characteristics against steep wave front surges than the standard rod gaps, although it still has the undesirable rising characteristics at short time lags.

Based on the data given in the paper a trial design for 132-kv application with standard 132-kv transformer insulation showed that the control gap allows some 20 per cent higher magnitude of switching surge voltage without flashover as compared with a standard rod gap set for the same protective voltage level at $^1/_2$ microsecond. This is a margin that may well be considered when attempting to supply better protection against steep wave fronts, and at the same time reduce line outages due to switching surges to a minimum.

With this set-up of an inexpensive protective gap and ultrahigh-speed reclosing breaker, a reasonable frequency of line flashovers due to switching surges could be tolerated in many cases, as the circuit would be re-energized immediately without objectionable energy interruption. The frequency of breaker operation allowable would depend largely on breaker maintenance, and the degree of risk taken as regards the gap protecting the apparatus on steep wave fronts.

Should such a protective scheme as outlined above prove effective, it would entirely change the present requirements for lightning protection of transmission lines, the continuous ground wire, low tower-footing resistances, and counterpoises not being necessary. While the degree of lightning protection to apparatus with any present known gap appears to be inferior to the protection afforded by modern lightning arresters properly installed, it is well known that our knowledge of the performance of both gaps and lightning arresters under conditions of steep rates of rise of impulses is all too meager. Then too, we have little actual data on the frequency and severity of these steep-front lightning impulses in actual practice. If it is found, by continued field research, that the maximum severity of lightning is less than we are now generally considering, even the present available gaps may prove effective protection to the apparatus, and the high-speed breaker will preserve the continuity of service.

There is one question I wish to ask Messrs. Higgins and Rorden, and that is what is the relative 60-cycle wet and dry flashover of the control gap with and without the porcelain control insulators? The point I have in mind is, if the gap functions, and the power arc disrupts one or more of the control insulators the projecting supports formerly supporting the insulators may be so closely spaced that the gap may have difficulty withstanding normal line voltage, to say nothing of switching surges in the order of 3 to 5 times normal.

**Ralph Higgins** and **H. L. Rorden:** The control gap is intended to provide protection for the severe lightning surges—those that do the real damage. Existing forms of protection are capable of relieving the less severe transients, such as induced strokes and traveling waves. But failures still seem to occur, and this is evidence that existing protection does not relieve the most severe surges. It is questionable whether failures would occur from the majority of surges which cause present protective devices to function. Indications are that most failures occur at some one severe surge. The control gap is not expected to function for the majority of low-voltage and low-energy surges, since operation of the gap is accompanied by an outage. Its purpose is to maintain a voltage limit at a reasonable margin below the level of station equipment, so that it will operate only when potentials approach dangerous proportions. When direct strokes occur, an outage is almost inevitable, but whether such outage occurs over a directed protective path or breaks through expensive equipment, is a vital question.

The AIEE Standards of Lightning Arresters No. 28 (March 1936) state "Present types of lightning arresters are not in general designed to protect against direct strokes to electric circuits. ....." The control gap is intended for direct-stroke protection. On this basis, their fields of application do not conflict. We do not contend that control-gap characteristics equal that of arresters for low-energy surges. The control gap has a volt-time characteristic independent of energy (current). Arrester characteristics involve volts, current, and time, since the arrester contains resistance material.

Mr. North illustrates an outstanding point in the comparison of the control gap and lightning arresters. In his table of short-time breakdowns, he lists the kilovolts at which the series gap breaks down for 2 rated circuit voltages. In the table of long times, secondary rise or the recovery voltages across the arrester resistance material is given for the same kilovolt ratings. These crest voltages are the potentials to to which the equipment is subjected if the surge is limited to 5,000 amperes. The voltages are about $3^1/_2$ times line-to-neutral (crest). This is of interest because it is mainly above this range ($3^1/_2$ times line-to-neutral) that the control gap is intended to function. It might be said therefore, that arresters can maintain a safe potential for currents below 5,000 amperes, but that the secondary potential rise above that current limit is indefinite. Recent publications have shown that a fair percentage of the more severe surges approach 40,000 amperes.

It would be interesting to know the voltage rise under the 50,000 to 100,000 amperes mentioned by Mr. Monteith, for a high-voltage system. Since arresters in general apparently are not intended for protection against direct strokes (AIEE Standards No. 28) it would be interesting to know if the arresters Mr. Monteith suggests are for other than the lower voltage or distribution systems.

We do not agree with Mr. Monteith's rod-gap figure of 860 kv at 1.8 microseconds for $38^1/_4$-inch spacing, nor can we find any Westinghouse data to substantiate his value. In the figure of Mr. McEachron's discussion, a 31-inch rod gap reaches 860 kv at 2.4 microseconds and is in close agreement with our data. Although our rod-gap curve referred to is from a specific test and is not intended to represent an average, it is in fair agreement with Westinghouse published data also. In ELECTRICAL ENGINEERING, December 1934, Bellaschi and Teague have given very complete curves on rod-gap flashovers, in their paper "Impulse and 60-Cycle Strength of Air." These authors mention that they have measured time on their oscillograms from the point on the wave front corresponding to the 60-cycle flashover voltage. To bring their curves to the basis of measuring time from the origin of the wave, as we have done, would require adding about one microsecond or more to their figures. We are inclined to the opinion that Mr. Monteith has overlooked this correction in offering his suggestion of laboratory disagreement. We appreciate his statement that it is going to be necessary to have the data from the

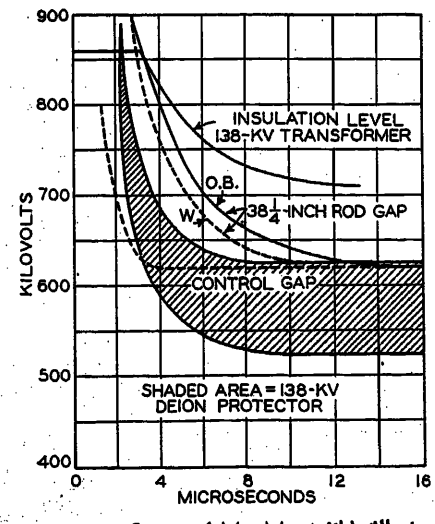

**Figure 6. Curves of Mr. Monteith's illustration shifted to time scale measured from origin of wave**

several laboratories on a common basis for co-ordination purposes. In the past, it has been the practice of most laboratories to measure voltage from the origin of the wave. We also appreciate his statement that it is largely in this (overvoltage) zone that we can claim superiority of the control gap over the rod gap. On the basis of the suggested correction to his figures, Mr. Monteith should undoubtedly understand the superiority of the control gap. In figure 6 we have replotted his curves corrected approximately to our time scale. The margin between the control gap and the several other curves for the short-time lags is apparent. We observe that the control-gap curve closely parallels the insulation throughout its range, excepting at the short time where an unusual and abrupt change in the insulation curve occurs. An explanation of this "flat" interval, indicating no increase in voltage on front of wave tests would be interesting. Mr. Montsinger (*Electrical World*, February 13, 1937, page 537) apparently does not agree that this interval should be flat.

We are interested in Mr. Monteith's comparison of De-ion tubes with gaps for station protection. Published data suggest these tubes for transmission line service and do not indicate that they are proposed for station protection. It is regrettable that the complete characteristics of the De-ion tube have not been included, since the shaded area tells only part of the story. This area indicates that in the short time intervals, the De-ion tube is equivalent to the control gap, although the complete characteristic is plotted as a band. The upper limit of the tube flashover is shown approximately equivalent to that of the various gaps at minimum flashover, while in the overvoltage range, the control gap curve is approximately an average of the band. At minimum flashover, a spread of 100 kv is apparent. What would this mean under power-frequency wet conditions?

Mr. Gross has discussed a combination which seems to be ideal, particularly for the severe surges. As previously mentioned, an outage is almost inevitable with direct strokes. The high voltage and energy must form a path to ground in any event, and the combination of the control gap with high-speed breakers affords the advantage of protection irrespective of energy and restores the system to service without the usual interruption. Under these conditions, the danger of destroying control insulators is greatly reduced. The switching time, perhaps more than the magnitude of the follow current, would seem to be the major item relative to the ability of the gap to withstand follow current. If a control insulator should be damaged, the result would be loss of advantage of the surge characteristic. The power frequency flashover would be reduced less than 20 per cent. This should not interfere with normal operation until repairs could be effected at later convenience.

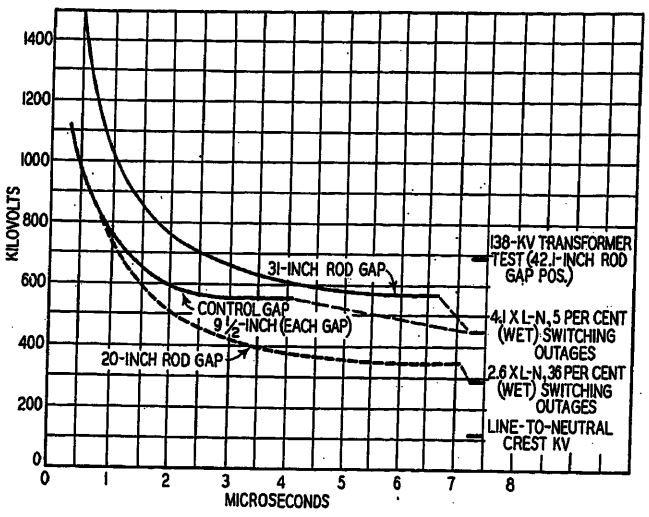

**Figure 7. Control gap versus rod gap for 138-kv transformer protection**

Negative impulse and switching surges both under rain spray

In commenting on Mr. McEachron's discussion, we wish to emphasize some characteristics of controlling flux in a dielectric field in air. For the same minimum impulse flashover the spacing of a rod gap is $3\frac{1}{2}$ or more times that of a sphere gap (spaced within its operating range). A sphere gap has a "flat" volt-time characteristic, while the rod gap has a sloping characteristic (figure 9 *A* and *E* of the control-gap paper). If smaller spheres are used for the same voltage, the spacing is greater and the curve is more sloping. At high overvoltages the rod-gap spacing must be reduced to nearly that of the sphere gap for a balance. The sphere gap and the rod gap are opposite extremes, and partial control of the field results in a spacing and volt-time characteristic proportionately between the two. Thus the general form of a volt-time characteristic may be predicted by the spacing of electrodes at the minimum flashover. For dissimilar electrodes, the same general law holds true for a given polarity.

Mr. McEachron states it is obvious that any scheme that secures the impulse advantages of the sphere gap through control of flux will be subject to the same wet and dry spark-over. We concur in this opinion and this point illustrates the advantage of the control gap. From figure 9 *A*, *D*, and *E* of the paper the control-gap curve is adjusted to be between that of the sphere gap and the rod gap. It follows that its electrode spacing and its power-frequency wet performance are also between the 2 extremes. From the previous explanation and from Mr. McEachron's statements, the control gap has a considerable advantage over the rod gap for impulse characteristics, and is considerably better than the sphere gap for wet flashovers. The control gap is designed to have the best impulse characteristic obtainable with tolerable wet flashover voltages. When so adjusted, the volt-time characteristic of the control gap closely parallels that which has been published (Montsinger, *Electrical World*, November 21, 1936; Bellaschi and Teague, ELECTRICAL ENGINEERING, January 1937) to represent transformer insulation. It is therefore only necessary to provide a reasonable margin between the breakdown strength of insulation and control gap flashover to have the protection properly co-ordinated.

Mr. McEachron's figure 1 illustrates the positive impulse comparison between a rod gap and a control gap when adjusted to the same 60-cycle wet flashover. It has been commonly accepted that 60-cycle wet flashovers are equivalent to switching surges. This must be inferred since 60-cycle wet tests are frequently cited and obviously operating voltages, particularly on grounded-neutral systems, do not rise to several times their normal value. Since publication of the paper, we have endeavored to learn if this assumption is justified. On tests with the control gap, we find that it is not. The wave used in our switching-surge tests was obtained by saturating a high-voltage testing transformer with a d-c current and then breaking the circuit abruptly by switching under oil. The wave obtained prior to flashover was very similar to that reported by Bellaschi and Teague in the January 1937 ELECTRICAL ENGINEERING ("Dielectric Strength of Transformer Insulation") though somewhat more irregular. Using these switching surges as the criterion of operating tolerance, we have attempted to show the complete performance which Mr. McEachron's figure 1 is intended to illustrate, in figure 7. The tests were made with negative polarity since direct strokes are predominantly negative (Lewis and Foust show 95 per cent, *G. E. Review*, November 1936). We have selected a 31-inch rod gap so these results will compare with Mr. McEachron's illustration for a 132-kv system. These test results are obtained by direct comparison of the 2 gaps and with oscillographic records. The analysis is based on the assumption that the limits of a gap as a protective device are its ability to relieve high overvoltages, and its performance for switching surges in rain. With switching surges applied, the 31-inch rod gap was found to balance with a control gap spaced with each gap $9\frac{1}{2}$ inches. The flashover measured 445 kv, which according to Lewis and Foust, should result in 5 per cent switching outages. When dry, the control-gap outages will be less but the rod gap will not change greatly. With high overvoltage negative surges applied to the same gaps, it was found that the rod gap had to be reduced to 20 inches to balance with the control gap having the same spacing as in the switching-surge tests. If a rod gap of 20-inch spacing were installed on a 132-kv system, its switching surge flashover would be 2.6 times line-to-neutral and would cause 36 per cent switching outages—over 7 times that of the control gap having the same short time impulse protection.

We are not quite sure what Mr. McEachron means by a rod gap offering greater
